8 **Résumé** We assess the differences of future climate changes over Europe in  
9 summer as projected by state-of-the-art regional climate models (RCM, from  
10 the EURO-Coordinated Regional Downscaling Experiment) and by their for-  
11 cing global climate models (GCM, from the Coupled Model Intercomparison  
12 Project Phase 5) and study the associated physical mechanisms. We show  
13 that important discrepancies at large-scales exist between global and regional  
14 projections. The RCMs project at the end of the 21st century over a large  
15 area of Europe a summer warming 1.5-2 K colder, and a much smaller de-  
16 crease of precipitation of 5%, versus 20% in their driving GCMs. The RCMs  
17 generally simulate a much smaller increase in shortwave radiation at surface,  
18 which directly impacts surface temperature. In addition to differences in cloud  
19 cover changes, the absence of time-varying anthropogenic aerosols in most  
20 regional simulations plays a major role in the differences of solar radiation  
21 changes. We confirm this result with twin regional simulations with and wi-  
22 thout time-varying anthropogenic aerosols. Additionally, the RCMs simulate  
23 larger increases in evapotranspiration over the Mediterranean sea and larger  
24 increases / smaller decreases over land, which contribute to smaller changes  
25 in relative humidity, with likely impacts on clouds and precipitation changes.  
26 Several potential causes of these differences in evapotranspiration changes are  
27 discussed. Overall, this work suggests that the current EURO-CORDEX RCM  
28 ensemble does not capture the upper part of the climate change uncertainty

## 1 Introduction

The resolution of global climate models (GCMs) is generally too coarse to capture the fine-scale features of the regional climate and key physical processes. This may be problematic to study regional climate phenomena, small regions (islands, mountains) or for the precise assessment of the impacts of climate change. Regional Climate Models (RCMs) are therefore frequently used to downscale low-resolution GCMs in order to obtain the necessary high resolution climate information.

The added value of RCMs compared to GCMs is clear for some aspects of the simulated climate. Variables that strongly depend on orography or that are impacted by land sea contrast benefit of a finer representation of the relief or of the coastline. For example, several studies have highlighted the added value of RCMs for climatological precipitation in mountain regions (e.g. Prein et al. 2016), for extreme precipitation (Déqué et Somot, 2008; Fantini et al., 2018) and for extreme winds (Herrmann et al. 2010).

The added value of RCMs may not be limited to the scales not resolved by GCMs and to the regions of strong physiographic features. Sorland et al. (2018) show a reduction of climatological temperature biases over Europe in two RCMs compared to the multiple GCMs used to force them, not limited to the regions with steep orography or near the coast. They also show important differences in the response to climate change, with a substantially smaller warming in the RCMs, especially over eastern Europe.

While it is in general easy to assess whether RCMs provide a more or a less realistic representation of the present-day climate compared to GCMs, it is obviously much more complicated in the climate change context, as no observational reference then exists. The added value of RCMs for climate change signals is therefore more elusive. Fernandez et al. (2018) based on a very large meta-ensemble of regional and global climate projections have concluded that the projected changes by RCMs and GCMs are essentially similar over Spain. Little added value of RCMs therefore exists in this case, which is not necessarily surprising as we do not necessarily expect an added value at large scales. Conversely, there are also some evidences that physically meaningful differences between RCMs and GCMs may exist in the climate change context, with an added value of RCMs, for example regarding changes in convective rainfall in the Alps in summer (Giorgi et al. 2016).

When differences between projected changes from RCMs and GCMs arise, it should not be automatically concluded that it demonstrates an "added value" of RCMs. The realism of climate projections is much more than a simple

71 question of resolution. The physics of the model, the quality of the paramete-  
72 rizations are crucial. It is all the more so true since the same classes of process  
73 have to be parameterized in GCMs and RCMs at current standard resolutions.  
74 Additionally, some specific methodological issues may exist for RCMs. Some  
75 methodological choices such as the use or not of spectral nudging (Colin et al.  
76 2010), the placement of the domain (Leduc et al. 2009) may impact the results  
77 in a non negligible way (Giorgi and Gutowski 2015). The lack of coupling with  
78 the ocean in most regional climate simulations (Somot et al. 2008; Gaertner  
79 et al. 2018, Akhtar et al. 2018) or the potential inconsistencies between the  
80 physical parameterizations of the RCMs and its forcing GCMs (Saini et al.  
81 2015, Pinto et al. 2018) may also have some impacts.

82 Additionally, some climate forcings may be missing in current RCMs. Je-  
83 rez et al. (2018) mention that some RCMs do not include time-varying  $CO_2$   
84 concentrations within the regional domain, affecting the regional change in  
85 radiative forcing. They show that, not surprisingly, it impacts temperature  
86 changes. Given the importance of the direct and local impact of  $CO_2$  on pre-  
87 cipitation changes, including over the Mediterranean and Europe (He and  
88 Soden 2017) it could also lead to an underestimation of summer drying. It  
89 is also deducible from Table 2 in Bartok et al. (2017) and from the table in  
90 Annex in Gutierrez-Escribano (in revision) that time-varying concentrations  
91 of anthropogenic aerosols are not taken into account by most of the EURO-  
92 Coordinated Regional Climate Downscaling Experiment (EURO CORDEX,  
93 Jacob et al. 2014) RCMs. It could be problematic : Nabat et al. (2014) show  
94 with a regional climate model that anthropogenic aerosols explain roughly  
95 81% of the brightening and 23% on the surface warming over Europe for the  
96 1980-2012 period. Nabat et al. (2015) also demonstrate the climate impacts  
97 of forgetting aerosol mean forcing on radiation, temperature and the water  
98 cycle. The inter-model differences in the sensitivity to anthropogenic aerosols  
99 also have important impacts in terms of past and future hydrological changes  
100 over western Europe (Boé 2016).

101 It is crucial to assess whether the results of ensembles of regional and glo-  
102 bal climate projections are consistent, especially at the larger scales resolved  
103 by both systems. Should some differences arise, understanding the mecha-  
104 nisms at play is necessary. Only a fine understanding of these mechanisms  
105 may allow to conclude whether the RCM or GCM results are more credible,  
106 by judging how structural differences between GCMs and RCMs may impact  
107 these mechanisms. e.g. Is there a reason to think that the representation of  
108 these mechanisms benefits from a higher resolution? Is there any specificity  
109 in the regional modelling framework (e.g. lack of ocean-atmosphere coupling)  
110 that could be problematic in that context? Are there forcings not taken into  
111 account by the RCMs that could be important?

112 Over most of Europe except Scandinavia, the most preoccupying impacts  
113 of climate change are arguably expected to occur during summer, with a de-  
114 crease in precipitation, very strong over the south of Europe, and an amplified  
115 warming (Terray and Boé 2013, Collins et al. 2013, Kröner et al. 2017, Brogli  
116 et al. 2019), with associated increases in droughts (e.g. Orłowsky and Sene-

viratne 2013, Ruosteenoja et al. 2018) and heatwaves frequency and severity (e.g. Fischer and Schär 2010, Schoetter et al. 2015). Additionally, the model uncertainties are also very large in summer over western and central Europe (e.g. Terray and Boé 2013). The first objective of this study is to characterize precisely the differences in projected summer climate changes over Europe between current GCMs and RCMs, from the Coupled Model Intercomparison Project phase 5 (CMIP5, Taylor et al., 2012) and EURO-CORDEX respectively. The second objective is to understand the causes of the differences, in order to better judge of the relative realism of regional and global projections.

In section 2, the data used in this study is described. In the third section, the differences between RCMs and GCMs for precipitation and temperature changes are characterized. In section 4, the role of anthropogenic aerosols in these differences is studied. We analyse the role of the differences in evapotranspiration changes over land in section 5 and over the Mediterranean sea in section 6. The main conclusions of this study are finally drawn in the last section.

## 2 Data and methods

### 2.1 Global and regional climate projections

In this paper, we study the 12 km EURO-CORDEX climate projections (Jacob et al. 2014) with most of the variables necessary for our analyses available on the Earth System Grid Foundation (ESGF) at the time of this study. We focus on the highest resolution EURO-CORDEX projections (12 km) because if the resolution matters, its impact is likely to be greater at 12 km than at 50 km. A resolution of 12 km is moreover closer to the needs of most impact studies. We focus on historical and RCP8.5 simulations. The summer changes between the 2070-2099 and 1970-1999 periods are studied. Seven RCMs (some of them in multiple versions) forced by six GCMs from the CMIP5 project, for a total of 24 projections, are analyzed (Table 1). One member per RCMs is studied, as most of the RCMs have a single member.

Some studies have rejected a priori the results of IPSL-WRF331F model after sanity checks, e.g Giorgi et al. (2016) or Rajczak and Schär (2017). We still study this model as it has been used in many previous studies, but we are careful that none of our conclusions depends on whether it is included or not.

An issue has been detected for some regional historical regional simulations forced by CNRM-CM5 (CNRM ALADIN53, CLMcom CCLM4-8-17, SMHI RA4). The historical member of CNRM-CM5 used to provide the lateral boundary conditions is not the same as the one used for the surface forcing. At climatological time scales, which we are interested in, as the two members come from the exact same GCM, this issue is not expected to have important impacts. We therefore use these three RCMs forced by CNRM-CM5 in this study. For the other regional simulations forced by CNRM-CM5 (CNRM ALADIN63, KNMI RACMO22E, DMI HIRHAM5), this issue

159 has been corrected. Some other issues have been noted for EURO-CORDEX  
160 RCMs. They are listed in the EURO-CORDEX errata table at [https://euro-](https://euro-cordex.net/078730/index.php.en)  
161 [cordex.net/078730/index.php.en](https://euro-cordex.net/078730/index.php.en).

162 The results of the RCMs are compared to the ones of their driving GCMs  
163 (Table 1), from the Coupled Model Intercomparison Project Phase 5 (CMIP5,  
164 Taylor et al. 2012). In general, the GCM member used to force the RCM is  
165 considered. Aside from the issue mentioned above regarding some simulations  
166 forced by CNRM-CM5, the only exception concerns the DMI-HIRHAM5 run  
167 forced by EC-EARTH. The third members of EC-EARTH was used to provide  
168 the boundary forcing to HIRHAM5, but we have not been able to find the  
169 output of this member on ESGF. The member 12 of EC-EARTH is used in  
170 our analyses as a replacement.

171 We also characterize the change in precipitation and temperature in a  
172 larger ensemble of 37 CMIP5 GCMs (Table 2) to assess whether the smaller  
173 ensemble used to drive the EURO-CORDEX RCMs is representative of the  
174 full one. To study the role of anthropogenic aerosols, we use 16 CMIP5 GCMs  
175 that provide both the aerosols optical depth (AOD) at 550 nm and clear sky  
176 shortwave radiation at surface (Table 2).

177 Among the RCMs studied, only ALADIN and RACMO use time-varying  
178 anthropogenic aerosol forcing. ALADIN uses the same aerosol forcing data-  
179 set as its driving GCMs and RACMO uses the aerosol forcing of EC-EARTH  
180 independently of its driving GCMs (see the annex of Gutierrez-Escribano et  
181 al., in review, for a detailed description of how aerosols aerosols are dealt with  
182 in the EURO-CORDEX RCMs). All the forcing GCMs (and more generally  
183 all the CMIP5 GCMs) use time-varying anthropogenic aerosol forcing, follo-  
184 wing the historical and RCP8.5 scenario. The concentrations are prescribed  
185 in CNRM-CM5, IPSL-CM5A-MR, EC-EARTH, MPI-ESM-LR and calculated  
186 interactively given the concentrations of forcing agents in HadGEM2-ES and  
187 NorESM1-M (Table 12.1 in Collins et al. 2013). With respect to the indirect  
188 effects of aerosols, HadGEM2-ES and NorESM1-M simulate both the cloud  
189 albedo and cloud lifetime effects, CNRM-CM5 and IPSL-CM5A-MR simulate  
190 the cloud albedo effect, EC-EARTH and MPI-ESM-LR simulate none of the  
191 indirect effects (Table 12.1 in Collins et al. 2013).

192 WRF331F and HIRHAM5 also do not take into account the time variations  
193 of  $CO_2$ , which, not surprisingly, impacts their results (Jerez et al., 2018).

194 Among the driving GCMs, EC-EARTH, IPSL-CM5A-MR, HADGEM2-  
195 ES, MPI-ESM-MR take into account the physiological impact of  $CO_2$  on eva-  
196 potranspiration through the modification of the stomatal resistance (Table  
197 12.1 in Collins et al. 2013). To the best of our knowledge, no RCM studied  
198 here simulates this effect. Some other forcings may differ between RCMs and  
199 GCMs. Most notably, to the best of our knowledge, the RCMs used in this  
200 study do not consider land use / land cover changes. Conversely, all the forcing  
201 GCMs except CNRM-CM5 consider changes in land use / land cover (Table  
202 12.1 in Collins et al. 2013).

**TABLE 1** Regional climate models and forcing global climate models used in this study. The tag of the forcing member is given. The symbols used in some figures for the different RCMs are given after the RCM name.

## 203 2.2 Methods to compare GCMs and RCMs

204 The GCMs are first conservatively interpolated on a common grid at a  
 205  $1.5^\circ \times 1.5^\circ$  resolution. For the maps, all the grids points are interpolated. For  
 206 the spatial averages over land, which are computed after interpolation on the  
 207 common grid, only the points with a fraction of land greater than 0.75 are  
 208 interpolated. The average evaporation over the Mediterranean sea is computed  
 209 after the interpolation of the grid points with a fraction of land less than 0.25.  
 210 The Mediterranean sea is defined as the sea points between  $30^\circ$  N,  $45^\circ$  N,  $-5^\circ$   
 211 E,  $35^\circ$  E. Spatial averages over continental Europe are computed for the land  
 212 points between  $42^\circ$  N,  $52^\circ$  N,  $-5^\circ$  E,  $30^\circ$  E (red box in Figure 1e). The same  
 213 definitions of land and sea points are used for the RCMs.

214 The box in the box-and-whiskers plots shown in this paper are delimited  
 215 by the 25th and 75th percentiles with the median in between. The whiskers  
 216 extend to the minimum and maximum of the sample.

217 Some driving GCMs are more represented in the EURO-CORDEX en-  
 218 semble (Table 1). For example, IPSL-CM5A-MR only drives two RCMs, while  
 219 CNRM-CM5 forces six RCMs. In order to compare fairly the results of RCMs  
 220 to their driving GCMs, the driving GCMs are weighted according to the num-  
 221 ber of RCMs they force. A GCM that forces  $n$  RCMs receives a weight of  $n$  in

222 the ensemble mean (unless otherwise specified). Following the same approach,  
 223 for the boxplots depicting the inter-model distribution of the driving GCMs,  
 224 the change projected by a GCM used to forced  $n$  RCMs is repeated  $n$  times  
 225 before computing the distribution. As a result, multiple identical values exist  
 226 in the forcing GCM distribution, which explains why the median of the box-  
 227 plots can be equal to the 25th or 75th centile, or the minimum equal to the  
 228 25th percentile.

### 229 2.3 Changes in solar radiation inferred from changes in cloud cover

230 Clear sky downwelling shortwave radiation at surface (RSDS) is unfortuna-  
 231 tely not available for the RCMs and some forcing GCMs. In order to approxi-  
 232 mately assess to what extent the differences in cloud cover changes impact  
 233 the differences in RSDS changes, the following approach is followed. For each  
 234 RCM and GCM separately and at each point, JJA cloud cover and RSDS on

the 1960-2004 period are linearly detrended. RSDS is then linearly regressed on cloud cover. At each point, the regression coefficient obtained is finally multiplied by the future changes in cloud cover in order to assess the change in RSDS inferred from the simple change in cloud cover, assuming no change in the relationship between cloud cover and RSDS, i.e. no change in cloud properties (except for cloud cover). The subtraction of RSDS changes inferred from cloud cover from total RSDS changes gives an estimate of the impact of aerosols, water vapor and cloud properties unrelated to cloud cover on changes in RSDS. This value is not exactly comparable to the change in clear sky RSDS as cloud cover is indeed not the only cloud property that plays in the cloud / solar radiation relationship. For example, the nature and altitude of the clouds are also important and may change in the future climate. A part of the indirect effects of aerosols on solar radiation through changes in cloud properties simulated by some models (Section 2.1) is therefore also likely included in the Total minus Inferred RSDS estimates.

## 2.4 Sensitivity experiments

In section 4.2, we analyse the results of a sensitivity experiment with the latest version of the ALADIN regional climate model (CNRM-ALADIN63, Table 1). The standard historical and RCP8.5 simulations on the 1951-2100 period forced by CNRM-CM5 (Table 1) are used as a reference. As previously said, the same time-varying aerosol forcing as in CNRM-CM5 is used for these simulations. Following a protocol defined in the dedicated CORDEX Flagship Pilot Study (FPS), the so-called FPS-aerosol, a twin simulation on the 2021-2050 period with a constant anthropogenic aerosol forcing has also been run with CNRM-ALADIN63. The aerosol optical depth of CNRM-CM5 from the historical simulation averaged on the 1971-2000 period is used. The lateral boundary conditions are the same as in the standard run. This simulation therefore allows to quantify the impact of not considering the time-variations of anthropogenic aerosols on the simulated changes on the 2021-2050 period. Note that this period, set by the FPS-aerosol protocol, is not the same as the one generally used in the rest of the study.

## 3 Differences of projected temperature and precipitation

The general pattern of future temperature and precipitation changes in summer over Europe is now well known (e.g. Collins et al. 2013, Terray and Boé 2013), with an amplification of surface warming over southern Europe associated with a large decrease in precipitation, and an increase in precipitation over Scandinavia. Both the RCMs and their driving GCMs exhibit such a pattern (Figure 1). Some important differences between them are however noted, especially regarding the intensity of the changes.

A smaller warming of at least 1 K is indeed simulated by the RCMs compared to their driving GCMs over most of Europe, and differences as large as

**FIGURE 1** Ensemble mean changes in summer temperature (K) over Europe between 2070-2099 and 1970-1999 as (a) projected by the RCMs, as (c) projected by their driving GCMs, and (e) differences ((a)-(c)). The GCMs are weighted according to the number of RCMs they force. b,d,f : same as a,c,e for relative summer precipitation changes (no unit). The red box in (e) shows the domain used for the calculation of the spatial averages over Europe in the paper (note that only land points are used; see also section 2).

**FIGURE 2** Intermodel distribution of (a) changes in summer temperature (K) and (b) relative changes in summer precipitation (no unit), averaged over Europe (land points within the red box in Figure 1e), in the complete ensemble of CMIP5 models ("GCMs all"), in the CMIP5 models used to drive the 12 km EURO-CORDEX RCMs ("GCMs") and in the RCMs ("RCMs"). The differences between 2070-2099 and 1970-1999 are calculated. See the description of the boxplots in Section 2. Circles : ensemble means. For the forcing GCMs, the empty circle shows the unweighted ensemble mean. The filled circles show the weighted ensemble mean, according to the number of RCMs forced by each GCM.

276 2 K are noted over the south of eastern Europe (Figure 1e). The smaller dif-  
 277 ferences are seen over Spain, Great Britain and Scandinavia, with differences  
 278 close or inferior to 1 K. Large differences in precipitation changes, between  
 279 10% and 20%, are also seen over a large part of Europe, the main exception  
 280 being Spain (Figure 1f). The sign of precipitation anomalies is even different  
 281 in the RCMs and in their driving GCMs over the north of central Europe.

282 The larger differences of temperature and precipitation changes over land  
 283 are generally seen in a band approximately between 42°N and 52°N, and -5°E  
 284 and 30°E (red box in Figure 1e), which we use throughout the paper for the

285 calculation and analysis of spatial averages. This area is named “Europe” for  
286 the sake of simplicity.

287 Six GCMs among the nearly 40 CMIP5 models have been used to drive  
288 the 12 km-resolution RCMs in the EURO-CORDEX project (Table 1). The  
289 selection of these six models has been mainly ad-hoc and not based on the  
290 type of methodologies proposed by McSweeney et al. (2015) or Monerie et al.  
291 (2017) to ensure the representativeness of the sub-sample. The driving GCMs  
292 may therefore not be representative of the full CMIP5 ensemble, which would  
293 have important consequences for the results of the EURO-CORDEX ensemble.  
294 As shown by Déqué et al. (2012) based on previous RCMs, the forcing GCMs  
295 indeed explain an important part of the dispersion of regional projections, for  
296 example roughly 1/3 of the variance for summer precipitation changes over  
297 Europe and 2/3 for summer temperature changes.

298 The multi-model averages of future summer temperature and precipitation  
299 changes over Europe are very similar between the driving GCMs (unweighted  
300 or weighted according to the number of RCMs forced) and the full ensemble  
301 of CMIP5 GCMs (Figure 2a). With regard to the ensemble mean changes, the  
302 sub-sample of GCMs used to force the RCMs is therefore adequate. However,  
303 some differences of distributions are seen. No CMIP5 model with a small warm-  
304 ing (less than 4.5 K) has been used to force the RCMs. This type of large scale  
305 temperature change is therefore not regionalized within the EURO-CORDEX  
306 ensemble. Regional simulations forced by GFDL-ESM2G, GISS-E2-R, MRI-  
307 CGCM3, or inmcm4, which show a small warming over Europe in summer (not  
308 shown), would be interesting to complete the EURO-CORDEX ensemble.

309 As we are firstly interested in understanding the physical mechanisms res-  
310 ponsible for the differences between RCMs and GCMs, we focus on the differ-  
311 ences between the RCMs and their driving GCMs only. The spatial averages  
312 confirm that summer warming is much greater in the driving GCMs than in  
313 the RCMs, with a clear shift of the RCM distribution towards lesser warming  
314 (Figure 2a). The ensemble mean change is close to 6 K for the GCMs and close  
315 to 4 K for the RCMs, i.e. 50% larger in the GCMs. While some GCMs simulate  
316 warmings close to 9 K, surface warming never reaches 7 K in the RCMs. The  
317 smaller warming of the RCMs compared to their forcing GCMs noted here is  
318 consistent with the results of Sorland et al. (2018), who also found a smaller  
319 warming projected by two EURO-CORDEX RCMs forced by several GCMs.  
320 Note that in the distribution of temperature changes in the forcing GCMs, the  
321 minimum is equal to the 25th percentile because of the replication of values  
322 necessary to give to each GCM a weight proportional to the number of RCMs  
323 forced, as explained in Section 2.3.

324 The ensemble mean decrease of precipitation is also almost 4 times greater  
325 in the driving GCMs than in the RCMs over western Europe (-20% versus  
326 -5%, Figure 2b). More than 25% of RCM projections show an increase in  
327 precipitation, as large as 30% in WRF331F. Only 8% of the GCMs (full CMIP5  
328 ensemble) show an increase in precipitation and this increase never exceeds 5%.

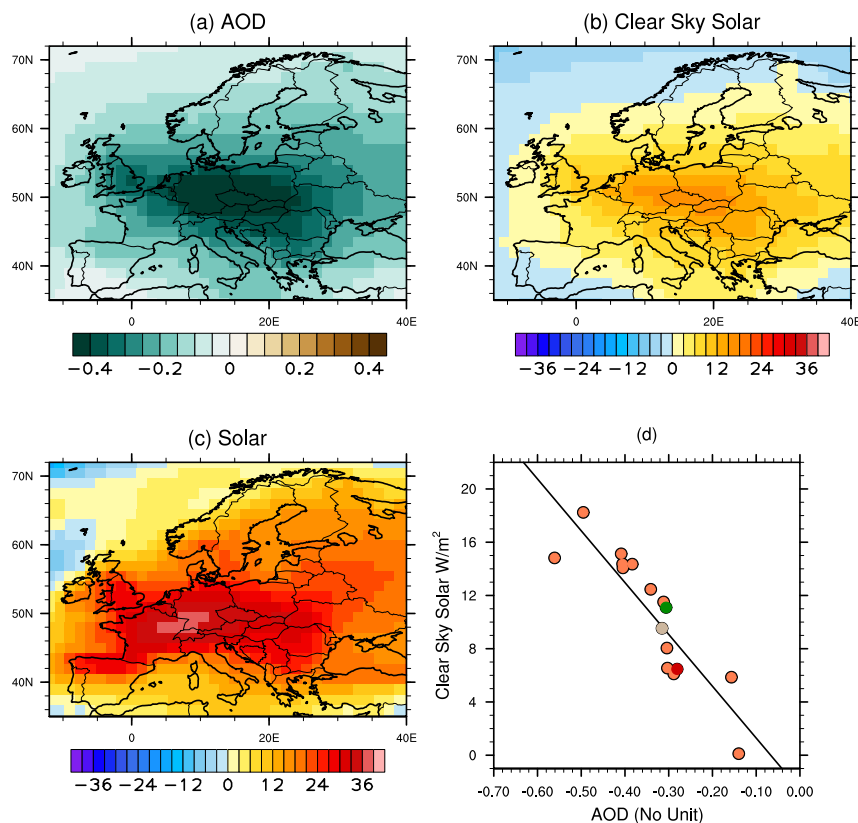

## 4 Role of shortwave radiation and anthropogenic aerosols

### 4.1 Analysis of EURO-CORDEX and CMIP5 projections

As noted in Section 2, most EURO-CORDEX projections do not account for the time-evolution of anthropogenic aerosols contrary to the CMIP5 models. It could be problematic because large future changes in AOD are expected over most of Europe (Myhre et al. (2013) and Figure 3). The concentration of anthropogenic aerosols, dominated by sulfate aerosols, indeed peaked over Europe at the end of the 1970s and has decreased since then, as a result of anti-pollution measures (Wild 2009). Nabat et al. (2014), with a coupled ocean-atmosphere regional model based on ALADIN53, have shown that this decrease of AOD had a strong impact on the European climate past trends, and explains roughly 80% (25%) of the trends in shortwave radiation at surface (temperature, respectively) on the 1980-2012 period. The direct effect of aerosols, namely the scattering on incident solar radiation, is indeed responsible on this period of a brightening phenomenon, causing an extra warming at surface. The decrease of AOD is expected to continue through the 21st century, at a much smaller rate after 2030-2040 (e.g. see Supplementary Figure 3 in Boé 2016). In any case, the AOD is generally much smaller in the CMIP5 GCMs at the end of the 21st century than at the end of the 20th century (Figure 3a). The larger decrease of AOD (-0.4, which roughly corresponds to -80%) is seen over central Europe. The evolution of AOD described here lies in the RCP emission scenarios, which have important uncertainties and make strong assumptions regarding the future emissions of aerosols (e.g. see discussion in Bellucci et al. (2015)). These scenarios do not cover the full range of potential future evolutions of aerosols. For example, air quality policies are supposed to become more stringent over time as a result of rising income levels (van Vuuren et al. 2011), which may not be the case in practice.

Not surprisingly, as aerosols are the dominant driver of changes in RSDS in clear sky conditions, clear sky RSDS increases over most of Europe in the CMIP5 GCMs (Figure 3b). This increase is maximal over eastern Europe (Czech Republic, Slovakia and Poland) where it reaches 10-15  $W.m^{-2}$ . Shortwave radiation at surface in clear sky conditions is also impacted by water vapor. However, AOD changes explain most of the inter-model spread in clear sky RSDS changes over Europe (Figure 3d,  $r=-0.88$ ), and water vapor therefore plays a much lesser role in that context. Additionally, the value of clear sky RSDS changes that corresponds to no change in AOD based on the regression line in Figure 3d, and is therefore an estimation of the role of water vapor, is roughly  $-2.5 W.m^{-2}$ . The small decrease in clear sky RSDS over sea away from the continent, where AOD does not evolve much, still can be attributed to the increase in atmospheric water vapor (e.g. Figure 12). Because of water vapor, the direct impact of anthropogenic aerosols on clear sky RSDS over land is actually greater than the anomalies shown in Figure 3b.

Note that the forcing GCMs for which the AOD is available have intermediary values of AOD changes (Figure 3d, see also legend) and therefore of

**FIGURE 3** (a) Ensemble mean changes in the aerosols optical depth at 550 nm for ambient aerosols (no unit) in an ensemble of 16 CMIP5 models for which this variable is available (see Section 2). (b) same as (a) for clear sky RSDS ( $W.m^{-2}$ ). (c) same as (a) for RSDS ( $W.m^{-2}$ ). (d) scatter plot of the changes in clear sky RSDS versus changes in AOD at 550 nm averaged over Europe (land points within the red box in Figure 1e). Each point is a CMIP5 model. Models used to drive the RCMs and for which AOD is available are highlighted : the green point corresponds to HadGEM2-ES, the light brown point to NorESM1-M and the red point to IPSL-CM5A-MR. The change of AOD in CNRM-CM5 is -0.34 and in EC-EARTH is -0.28. These two models are not on the scatter plot as clear sky RSDS is not available. The differences between 2070-2099 and 1970-1999 are calculated.

373 clear sky RSDS changes (between 7 and 11  $W.m^{-2}$ ). The EURO-CORDEX  
 374 RCMs do not provide clear sky RSDS and therefore they cannot be compa-  
 375 red to their driving GCMs. As all EURO-CORDEX RCMs except ALADIN  
 376 and RACMO do not take into account the time evolution of anthropogenic  
 377 aerosols, we don't expected large changes in clear sky RSDS for most regional  
 378 projections, except for a small decrease due to water vapor.

379 Total sky RSDS also strongly increases over Europe in the CMIP5 models  
 380 (Figure 3c). Over eastern Europe, clear sky RSDS changes represent up to

roughly half of the change in total RSDS, which is especially large there (greater than  $30 \text{ W.m}^{-2}$ , Figure 3c). The relative importance of clear sky changes compared to total sky changes is smaller over western Europe, especially over France, suggesting an important decrease of cloud cover there. For the 16 CMIP5 GCMs that provide both AOD and clear sky RSDS (see Table 3) used in Figure 3, the decrease of RSDS in clear sky conditions explains 1/3 of the change in all sky conditions over our domain of interest ( $10 \text{ W.m}^{-2}$  versus  $30 \text{ W.m}^{-2}$ ).

Very large differences in RSDS changes between the RCMs and their driving GCMs are noted (Figure 4a), consistently with Bartok et al. (2017) and Gutierrez-Escribano et al. (in review) who have noted a large difference in RSDS changes between EURO-CORDEX RCMs and their driving GCMs for annual means. The driving GCMs simulate an increase of RSDS of  $25 \text{ W.m}^{-2}$  over Europe, while in average the RCMs simulate an increase of RSDS as small as  $5 \text{ W.m}^{-2}$  over the same area (Figure 4a). Also consistently with Bartok et al. (2017), important differences in cloud cover changes exist between the RCMs and their driving GCMs. While the decrease is close to 6% over Europe in the GCMs, it is close to 4% in the RCMs (Figure 4b; Figure 5a,c).

Inferred changes in RSDS from the changes in cloud cover (see Section 2.3 for a description of the methodology) are now studied. Important changes in inferred RSDS are projected over western Europe, France in particular, where the decrease of cloud cover is large, especially in the GCMs (e.g.  $20 \text{ W.m}^{-2}$  over France in the GCMs and  $10 \text{ W.m}^{-2}$  in the RCMs, Figure 5). The inferred changes in RSDS are generally larger in the GCMs, because the decrease of cloud cover is also larger (Figure 5a,c). Note that in Figure 5f, only the forcing GCMs are considered, which explains why the results in Figure 5f and Figure 3, which uses a larger sample of GCMs, are different, with smaller RSDS changes in the sub-sample of GCMs used to force the RCMs.

The total changes of RSDS in the RCMs (full ensemble) are generally smaller than the ones inferred from changes in cloud cover alone, although the difference is generally small except over the north of the domain (Figure 5j). The behaviour of the driving GCMs is generally very different. Except over southern Spain and northern Scandinavia, the total changes of RSDS are indeed greater, and sometimes much greater as over eastern Europe (differences as large as  $15 \text{ W.m}^{-2}$ ), than the changes inferred from changes in cloud cover alone.

The changes in cloud cover and inferred RSDS are similar in RACMO and ALADIN compared to the full RCM ensemble (Figure 5a,b and g,h). However, a much stronger increase in total RSDS is noted in RACMO and ALADIN (Figure 5d,e), with strong positive differences between total and inferred RSDS changes over most of Europe, much more similar to what is seen in the GCMs than in the full RCMs ensemble. An exception concerns a few points in the Alps. It is probably due to the fact the orography is higher in the RCMs than in the GCMs, with therefore a much smaller impact of aerosols at surface.

**FIGURE 4** Intermodel distribution of changes in (a) summer downwelling shortwave radiation at surface ( $W.m^{-2}$ ) and (b) summer cloud cover (%), averaged over Europe (land points within the red box in Figure 1e) in the CMIP5 models used to drive the RCMs and in the RCMs, See section 2 for the details on the boxplots. Circles : ensemble means. For the forcing GCMs, the empty circle shows the unweighted ensemble mean. The filled circle shows the weighted ensemble mean, according to the number of RCMs forced by each GCM. The differences between 2070-2099 and 1970-1999 are calculated.

426 The much larger increase in solar radiation at surface noted in ALADIN  
 427 and RACMO compared to the other RCMs (Figure 5d,e) is therefore not  
 428 mainly explained by cloud cover : anthropogenic aerosols play an important  
 429 role, as concluded by Gutierrez-Escribano (in review).

430 Consistently with the large direct impact of anthropogenic aerosols on  
 431 RSDS in the GCMs noted previously (Figure 3), this analysis shows that  
 432 cloud cover changes alone don't explain the totality of the differences in RSDS  
 433 changes between RCMs (without time-varying aerosol concentrations) and  
 434 GCMs, as large differences remain after controlling for the impact of cloud  
 435 cover changes.

**FIGURE 5** Future ensemble mean changes in summer between 2070-2099 and 1970-1999 of cloud cover (%) in (a) the full ensemble of RCMs, (b) in RACMO and ALADIN, and (c) the driving GCMs. (d) to (f) same as (a) to (c) for downwelling shortwave radiation at surface ( $W.m^{-2}$ ). Inferred changes between 2099-2070 and 1999-1970 in downwelling shortwave radiation at surface ( $W.m^{-2}$ ) according to the simple change in cloud cover in (g) the full ensemble of RCMs, (h) in RACMO and ALADIN, and (i) the driving GCMs. See Section 2 for details. Differences between changes in downwelling shortwave radiation at surface and inferred changes ( $W.m^{-2}$ ) in (j) the full ensemble of RCMs, (k) in RACMO and ALADIN, and (l) the driving GCMs. Note that IPSL WRF3.11 is not used in the RCMs because cloud cover is not available for this model.

**TABLE 3** Future ensemble mean changes in summer between 2070-2099 and 1970-1999 averaged over Europe of total downwelling shortwave radiation at surface (Total), inferred from cloud cover changes in downwelling shortwave radiation at surface (Inferred), difference between the two (Inferred-Total) and ratio ((Total-Inferred)/Total). The multi-model average and standard deviation (between brackets) are given. The domain used for the spatial average is the red box in Figure 1e. "Forcing GCMs" corresponds to the forcing GCMs weighted by the number of RCMs forced, "Forcing GCMs of ALADIN and RACMO" corresponds to the forcing GCMs of ALADIN and RACMO weighted by the number of RCMs forced, "ALADIN and RACMO" corresponds to the seven regional climate simulations with either ALADIN or RACMO (see Table 1), "Other RCMs" corresponds to the regional simulations with the other RCMs. "All RCMs" corresponds to all RCMs. Note that the results of IPSL WRF3.11 and of its forcing GCM are not included in these results because cloud cover is not available in IPSL WRF3.11.

	Forcing GCMs	Forcing GCMs of ALADIN and RACMO	ALADIN and RACMO	Other RCMs	All RCMs
Total ( $W.m^{-2}$ )	25.6 (6.0)	26.9 (6.4)	18.6 (7.3)	3.5 (3.8)	8.1 (8.7)
Inferred ( $W.m^{-2}$ )	13.9 (10.8)	10.6 (10.5)	5.1 (3.8)	8.6 (3.3)	7.5 (3.8)
Total-Inferred ( $W.m^{-2}$ )	11.7 (9.8)	16.3 (6.2)	13.5 (7.6)	-5.0 (2.7)	0.6 (9.9)
(Total-Inferred)/Total (No Unit)	0.46 (0.41)	0.64 (0.30)	0.73 (0.25)	-0.75 (7.7)	-0.29 (6.4)

436 Table 3 synthesises the main results of Figure 5 for our domain of inter-  
437 est. Considering the difference between total and inferred from clouds RSDS  
438 changes as an approximate estimate of the impact of anthropogenic aerosols  
439 (within the limitation discussed in Section 2.3; i.e. the inclusion of the impact  
440 of water vapor and changes in cloud properties unrelated to cloud cover), ae-  
441 rosols would explain in ensemble mean 45% of the change in total RSDS in  
442 the forcing GCMs and 73% in the RCMs with time-varying aerosol concen-  
443 trations (81% for ALADIN simulations and 68% for RACMO, not shown).  
444 This difference is not explained by a much greater direct impact of aerosols  
445 (as approximated by "Total-Inferred") but by smaller changes in cloud cover  
446 in these two RCMs (Figure 4) and therefore in total RSDS changes compared  
447 to many GCMs. Note also that the forcing GCMs of ALADIN and RACMO  
448 themselves generally show a smaller increase in inferred solar radiation com-  
449 pared to other forcing GCMs (because of a smaller decrease in cloud cover, not  
450 shown). Aerosols explain approximately 64% of the change in total RSDS in  
451 the forcing GCMs of ALADIN and RACMO, a value closer to the one of ALA-  
452 DIN and RACMO (73%). The difference between total and inferred RSDS in  
453 the RCMs with constant aerosols is negative (Table 3), consistently with the  
454 dimming effect of increased water vapour content in the atmosphere.

455 Our conclusions differ from the one of Bartok et al. (2017) who attribute  
456 the difference between RSDS in RCMs and GCMs mainly to cloud cover. The  
457 absence of time-varying aerosols in most EURO-CORDEX RCMs is also very

458 important in this context. Not coincidentally, the two RCMs with time-varying  
459 aerosols behave much more similarly to the forcing GCMs.

460 Note that aerosols might play an even greater role. They indeed may impact  
461 the differences in cloud cover changes between RCMs and their forcing GCMs  
462 through the indirect aerosol effects on clouds included in some GCMs (Section  
463 2.1). They may also impact cloud cover through induced climate changes. For  
464 example, they impact the surface energy balance, and potentially the surface  
465 water balance through evapotranspiration. The associated potential changes  
466 in the vertical temperature and humidity profiles could alter the cloud cover.

467 The analyses in this section show that anthropogenic aerosols have a strong  
468 impact on shortwave radiation at surface in the CMIP5 models. This impact  
469 is greater than  $10 W.m^{-2}$  from the analysis of clear sky RSDS in a larger  
470 ensemble of GCMs or  $11 W.m^{-2}$  for the forcing GCMs based on the analysis  
471 of inferred from cloud cover changes in RSDS (Table 3), as these figures also  
472 include the dimming effect of water vapor. This clearly represents a strong  
473 perturbation of the surface energy budget. Most of the regional climate pro-  
474 jections (17 out of 24) cannot capture this impact because they do not take  
475 into account the time variations of anthropogenic aerosols. The only two RCMs  
476 that use time-varying aerosols have an impact of aerosols of about  $13.5 W.m^{-2}$ ,  
477 close to the forcing GCMs.

478 Anthropogenic aerosols are therefore very likely partly responsible for the  
479 smaller warming in the RCMs than in their driving GCMs in ensemble mean,  
480 based on simple surface energy budget considerations. Not surprisingly, a  
481 strong inter-model relationship between differences in RSDS and temperature  
482 changes is noted. The greater the difference in changes in incoming shortwave  
483 radiation at surface between a RCM and its driving GCM is, the larger the  
484 difference of surface warming is (Figure 6,  $r=0.74$ ). As shown in Figure 6b,  
485 and consistently with previous results, the inter-model differences in RSDS  
486 changes between the RCMs and their driving GCMs are weakly explained  
487 by the differences in cloud cover changes, pointing to an important role for  
488 aerosols.

489 Note that the ALADIN53 and ALADIN63 simulations almost do not show  
490 differences in RSDS changes with their forcing GCM (CNRM-CM5), consistent  
491 with the fact that the time-varying aerosol forcing of CNRM-CM5 is also  
492 used in the ALADIN simulations. The differences of RSDS changes between  
493 RACMO and EC-EARTH are also small, consistent with the fact that the time-  
494 varying aerosol forcing of EC-EARTH is used in the RACMO simulations.  
495 The other RACMO simulations (forced by CNRM-CM5, NorESM1-M and  
496 HadGEM2-ES, Table 1), which all use the EC-EARTH aerosol forcing, show  
497 differences in RSDS changes with their forcing GCMs, probably because of  
498 these differences in aerosols forcing to some extent.

**FIGURE 6** (a) Differences of surface temperature changes (K) between the RCMs and their forcing GCMs (RCMs-GCMs) versus differences of changes in shortwave radiation at surface ( $W.m^{-2}$ ) averaged over Europe in summer (land points within the red box in Figure 1e).  $r=0.74$ . Each symbol corresponds to a particular RCM (see Table 1) and each color to a particular forcing GCM (see legend on the graph). (b) same as (a) for differences of changes in shortwave radiation at surface ( $W.m^{-2}$ ) versus differences of changes in cloud cover (%).  $r=-0.27$

#### 499 4.2 Evaluation of past trends

500 Important uncertainties exist in the future evolution of aerosol concentra-  
 501 tions and the response of solar radiation to this evolution (e.g. Figure 3d).  
 502 Obviously, it is not possible to assess the realism of future changes in solar  
 503 radiation, but the evaluation of the past evolution may be very valuable, es-  
 504 pecially since strong changes have already occurred. Since the 1980s, a strong  
 505 reduction of anthropogenic aerosol concentrations over Europe has indeed oc-  
 506 curred with a consequent increase in solar radiation at surface (e.g. Wild 2009).  
 507 The trends in the same observed series from the Global Energy Balance Ar-  
 508 chive (GEBA, Gilgen et al. (1998), Wild et al. (2017)) used in Nabat et al.  
 509 (2014) but for summer and the stations within our domain of interest are  
 510 calculated on the 1980-2005 period, and then the spatial mean is calculated  
 511 (Figure 7). A strong trend in summer solar radiation at surface, greater than  
 512  $7 W.m^{-2}/10yrs$  has been observed. For the RCMs, a very large inter-model  
 513 spread in the trends exists (Figure 7). The trends are small or even negative  
 514 in many RCM simulations. The trends of ALADIN53 and ALADIN63 forced  
 515 by CNRM-CM5 however come very close to the observed one, closer than any  
 516 other regional simulation. It gives confidence in this configuration to study  
 517 shortwave radiation processes.

**FIGURE 7** Trends in downwelling shortwave radiation at surface over Europe in summer on the 1980-2005 period in the RCMs and in the observations (GEBA dataset), adapting the analysis from Nabat et al. (2014) to summer and to our domain of interest. The GEBA stations within our domain of interest (red box in Figure 1e) and, for the RCMs, the grid points the closest to these stations are considered. The color code for the forcing GCM and the symbol for the RCMs are the same as in the other figures (e.g. see Figure 6 for the colors and Table 1 for the symbols).

#### 518 4.3 Results of the sensitivity experiment

519 In order to further assess the impact of the absence of time-varying anthropo-  
 520 genic aerosol forcing, the sensitivity experiment with ALADIN63 described  
 521 in Section 2.4 is analysed. This experiment follows the CORDEX FPS-aerosol  
 522 protocol, which focuses on the 2021-2050 period. The standard ALADIN63  
 523 projection, with time varying aerosol forcing, is compared to the sensitivity  
 524 experiment in which aerosol forcing is constant on the 2021-2050 period and  
 525 equal to the 1971-2000 average.

526 It is clear from Section 4.1 that large model uncertainties exist regarding  
 527 solar radiation processes. The aerosols-driven changes in RSDS are large in  
 528 ALADIN. This RCM is at the higher end of the spectrum of values obtained  
 529 for Total minus Inferred changes in RSDS :  $20 W.m^{-2}$  in average (not  
 530 shown), more than the  $11.7 W.m^{-2}$  of the forcing GCMs (Table 3). However,  
 531 ALADIN63 forced by CNRM-CM5 simulates realistic past trends in RSDS,  
 532 more realistic indeed than in any other regional simulation (Figure 7). This  
 533 gives good confidence in the skill of ALADIN regarding solar radiation pro-  
 534 cesses and in the aerosol forcing used in both ALADIN and CNRM-CM5, from  
 535 Szopa et al. (2013). It reinforces our confidence in the results of the sensitivity  
 536 experiments described in this section.

537 Variations of anthropogenic aerosol forcings lead to major differences of  
 538 changes in shortwave radiation at surface in summer, as large as  $30 W.m^{-2}$   
 539 over Germany (Figure 8c). In average over Europe, aerosols explain most of  
 540 the changes in solar radiation at surface in the ALADIN63 regional projection.

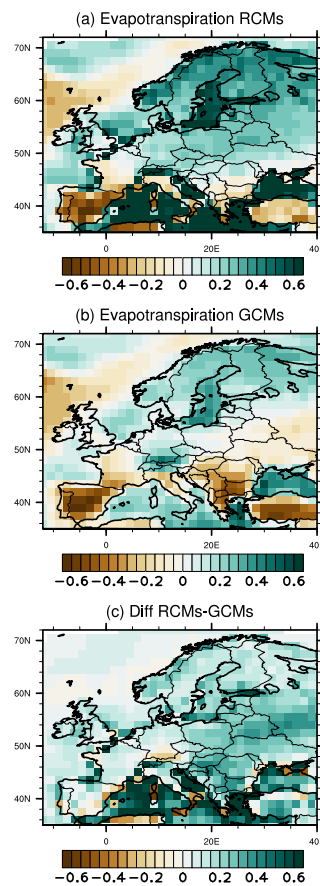

**FIGURE 8** (a) Future summer changes (2021-2050 minus 1971-2000) in downwelling shortwave radiation at surface ( $W.m^{-2}$ ) in ALADIN63. (b) Same as (a) with constant aerosol forcing. (c) Differences of future summer changes in downwelling shortwave radiation at surface ( $W.m^{-2}$ ) between the reference ALADIN63 projection and the ALADIN63 simulation with a constant aerosol forcing (i.e. (a)-(b)). See section 2. (d)-(f) same as (a)-(c) for 2m air temperature (K). (g)-(i) same as (a)-(c) for evapotranspiration (no unit, relative changes are shown). (j)-(l) same as (a)-(c) for precipitation (no unit, relative changes are shown).

541 Such large differences of energy available at surface lead to large differences  
542 of temperature changes, close to 1 K over central and eastern Europe (Figure  
543 8f). These differences are all the more notable because on the early period stud-  
544 ded here (2021-2050) the warming in the reference simulation is only between  
545 1 and 3 K over Europe (Figure 8d). In average over our domain of interest,  
546 aerosols explain roughly 0.5 K of the 1.8 K warming (i.e. roughly 30% of the  
547 warming) on 2021-2050. Note that uncertainties due to internal variability  
548 exist as these estimates are based on single members.

549 With time-varying aerosol forcing, a larger increase in evapotranspiration  
550 over the northern half of Europe is noted, in particular over Germany and  
551 the Benelux (Figure 8g-i). It is likely the result of the much larger increase  
552 in solar radiation at surface noted previously in the reference simulation with  
553 time-varying aerosol forcing. In the RCM used here, there is no strong limita-  
554 tion of evapotranspiration over Europe by soil-moisture (not shown) and  
555 therefore a larger increase of solar radiation at surface is expected to lead to a  
556 larger increase of evapotranspiration. It is all the more true since an increase of  
557 precipitation is generally simulated by this RCM over the northern half of Eu-  
558 rope (Figure 8j). This increase in precipitation is smaller in the simulation with  
559 constant aerosol forcing (Figure 8k). This difference in precipitation changes  
560 might be due to the larger increase in evapotranspiration in the simulation  
561 with evolving aerosols, through an associated larger increase in atmospheric  
562 moisture. The differences of precipitation changes due to anthropogenic aero-  
563 sols are however not straightforward to interpret. On the early period studied  
564 here, internal variability plays a major role in precipitation changes (e.g. Ter-  
565 ray and Boé 2013), and a single member, as used for the sensitivity experiment,  
566 may not be sufficient to extract a robust signal.

567 The sensitivity experiment described in this section clearly shows that  
568 time-varying aerosol forcing plays an important role on temperature changes  
569 through the modulation of solar radiation. It is consistent with the idea that  
570 the absence of time-varying anthropogenic aerosol forcing in most EURO-  
571 CORDEX simulations explains a part of their smaller warming at surface  
572 compared to their forcing GCMs.

573 For precipitation, the conclusions are less clear. In the model analysed here,  
574 time-varying anthropogenic aerosol forcing tends to lead to a larger increase  
575 of precipitation rather than to a smaller one. This result is however likely  
576 dependent on the dominant control of evapotranspiration in the RCM. In a  
577 model (or on a period) in which evapotranspiration is limited by soil moisture  
578 rather by energy, the larger increase in solar radiation at surface due to time-  
579 varying aerosol forcing is expected to lead to an increase in sensible heat flux  
580 and therefore to an additional warming rather than to an increase in evapo-  
581 transpiration (e.g. Boé 2016). This would tend to reduce relative humidity and  
582 precipitation. The same type of experiments with other RCMs would be ne-  
583 cessary to test this hypothesis, and also to assess whether the strong response  
584 in shortwave radiation in the RCM studied here is a robust feature.

**FIGURE 9** Ensemble mean change in evapotranspiration (mm/day) in summer over Europe between 2099-2070 and 1999-1970 as (a) projected by the RCMs, as (b) projected by their driving GCMs, and (c) difference. The GCMs are weighted according to the number of RCMs they force.

## 585 5 Role of land evapotranspiration

586 As discussed in the previous section, changes in shortwave radiation may  
 587 have different impacts on the surface climate depending on whether the evapo-  
 588 transpiration is primarily energy or water limited (e.g. Boé and Terray 2008,  
 589 Boé 2016). In energy-limited regimes, changes in shortwave radiation tend to  
 590 lead to an increase of evapotranspiration while in water-limited regimes an in-  
 591 crease in sensible heat flux and surface temperature is favoured, with potential  
 592 feedbacks leading to a drying of the soil and a reduction of evapotranspiration  
 593 (e.g. Boé and Terray 2014).

594 Both the RCMs and their forcing GCMs generally simulate an increase in  
 595 land evapotranspiration over the north of Europe and a decrease over sou-  
 596 thern Europe (Figure 9). Despite the much larger increase of solar radiation

**FIGURE 10** Difference between the RCMs and their forcing GCMs (RCMs-GCMs) in summer temperature changes (K) versus the differences in summer evapotranspiration changes ( $r=-0.89$ ), averaged over Europe (land points within the red box in Figure 1e). Each symbol corresponds to a particular RCM (see Table 1) and each color to a particular forcing GCM (see legend in Figure 6).

597 at surface in the GCMs than in the RCMs (Figure 5), the GCMs generally  
 598 simulate more negative (over southern Europe) or less positive (over Scandi-  
 599 navia) changes in evapotranspiration than the RCMs. This is likely the sign  
 600 that soil-moisture is a stronger limiting factor of evapotranspiration changes  
 601 in the GCMs, likely because of the more severe precipitation changes noted  
 602 previously (Figure 1), and is consistent with a larger surface warming due  
 603 to less evaporative cooling. The greater differences in land evapotranspiration  
 604 changes are seen over eastern Europe (Ukraine, Belarus), where the average  
 605 projected change is close to  $-0.2$  mm/day for the forcing GCMs and close to  
 606  $0.2$  mm/day for the RCMs.

607 Unsurprisingly, a very large inter-model anti-correlation between differ-  
 608 ences in temperature changes between GCMs and RCMs and differences in  
 609 evapotranspiration changes over land is noted (Figure 10,  $r=-0.89$ ).

610 The ultimate causes of the difference of evapotranspiration changes bet-  
 611 ween GCMs and RCMs are not clear. Differences in precipitation changes  
 612 are clearly involved, but the causes of the differences in precipitation changes  
 613 remain to be understood. A first hypothesis is that the differences in preci-  
 614 pitation changes may be related to some extent to the differences in aerosol  
 615 forcing discussed previously. Indeed, the smaller warming over land due to the  
 616 lack of anthropogenic aerosols variations in most RCMs could lead to smaller  
 617 relative humidity changes and therefore less severe precipitation and finally  
 618 evapotranspiration changes over land.

619 Other causes may be envisaged. Boé and Terray (2008, 2014) showed that  
 620 in both GCMs and RCMs of previous generations, future changes in evapo-  
 621 transpiration over continental Europe are very dependent on the present-day

**FIGURE 11** Intermodel distribution of present-day interannual correlations averaged over Europe (land points within the red box in Figure 1e) in summer between detrended evapotranspiration and total downwelling radiative flux at surface on the 1960-2004 period in the RCMs and their driving GCMs. See the description of the boxplots in Section 2. The symbols have the same signification than in Figure 2.

622 controls of evapotranspiration. Over Scandinavia, the models tend to agree on  
 623 a control of evapotranspiration by the energy available at surface, and over  
 624 southern Europe they tend to agree on a control of evapotranspiration by soil  
 625 moisture. Over an intermediate area, the simulated controls of evapotranspira-  
 626 tion are very uncertain. The models in which evapotranspiration is controlled  
 627 by soil moisture in the present climate tend to simulate much larger decrease  
 628 in evapotranspiration in the future climate (Boé and Terray 2008 ; 2014).

629 The present-day inter-annual correlations between evapotranspiration and  
 630 total downwelling radiative fluxes at surface, a metric of the climatological  
 631 controls of evapotranspiration (Boé and Terray 2008), is computed for the  
 632 RCMs and their driving GCMs. As for the previous generation of climate  
 633 models (Boé and Terray 2008, 2014), large inter-model uncertainties exist in  
 634 the controls of evapotranspiration, especially in the RCMs (Figure 11). In  
 635 average, the value of this metric in the RCMs and their driving GCMs is  
 636 however quite similar. The present-day controls of evapotranspiration therefore  
 637 cannot explain the systematic differences in evapotranspiration changes over  
 638 continental Europe.

639 Sorland et al. (2018) have shown smaller biases for climatological temper-  
 640 ature over land in two EURO-CORDEX RCMs compared to their multiple  
 641 forcing GCMs. They make the hypothesis that it is the sign of more realis-  
 642 tic land-atmosphere interactions in the RCMs, which could then lead to more  
 643 realistic future temperature changes. It is not the case regarding the soil-  
 644 atmosphere interactions as characterized with our metric in the ensemble of  
 645 RCMs studied here.

646 Finally, it may be worth noting that the physiological forcing of  $CO_2$  is  
647 simulated by most GCMs (4 out of 6, section 2) but not by the RCMs studied  
648 in this paper to the best of our knowledge. Under higher  $CO_2$  concentra-  
649 tions, the stomata do not need to be as open to absorb  $CO_2$ , which reduces  
650 the water exchanges from the plant to the atmosphere and therefore trans-  
651 piration. It is increasingly clear that the reduction of evapotranspiration due  
652 the physiological  $CO_2$  forcing may be important for the future projection of  
653 evapotranspiration, as shown by Schwingshackl et al (2019) for a particular  
654 RCM, although the impact may largely differ between models (Swann et al.  
655 2016, Lemorant et al. 2018, Skinner et al. 2018). The physiological impact of  
656  $CO_2$  might therefore explain a part of the differences in evapotranspiration  
657 changes over land between GCMs and RCMs. Additionally, to the best of our  
658 knowledge, the RCMs analysed in this paper do not take into account land use  
659 changes contrary to most forcing GCMs. Some studies have shown that land  
660 use change may have an impact, although a limited one, on evapotranspiration  
661 changes (Quesada et al. 2017).

## 662 **6 Role of evaporation over sea**

663 Evapotranspiration is not only important locally because of evaporative  
664 cooling, but also through its impacts on atmospheric moisture, with potential  
665 impacts on cloud cover or precipitation. In this context, remote evaporation  
666 changes over adjacent seas may also be important, through the advection of  
667 moisture towards continents.

668 It is interesting to note that very large differences of evaporation changes  
669 over the Mediterranean sea (Figure 9) exist. The GCMs simulate only a mo-  
670 derate increase of evapotranspiration (generally close 0.2 mm/day) while the  
671 RCMs project a much larger increase (generally larger than 0.6 mm/day). It  
672 remains true excluding the IPSL-WRF331F model, which simulates a very  
673 strong and likely unrealistic increase in evapotranspiration (see Section 2).

674 This larger increase in RCMs than in GCMs confirms previous results re-  
675 ported in Sanchez-Gomez et al. (2009) and Planton et al. (2012) by comparing  
676 the CMIP3 GCM ensemble with the ENSEMBLES RCM ensemble (the RCMs  
677 being driven by CMIP3 GCMs). For the A1B scenario and the 2070-2099 per-  
678 iod, they obtain that Mediterranean Sea evaporation increases much more in  
679 the 25-km non-coupled RCM ensemble (+12%, about 0.4 mm/day) than in  
680 the low-resolution coupled GCM ensemble (+7%, about 0.2 mm/day). From  
681 their studies, it is impossible to conclude if the difference between both en-  
682 sembles comes from the difference in resolution, in air-sea coupling or in the  
683 uncertainty sub-sampling (the CMIP3 ensemble being much bigger than the  
684 ENSEMBLES one).

685 The larger increase in evaporation over the Mediterranean sea is very likely  
686 responsible for the larger increase in atmospheric humidity at 850 hPa in the  
687 RCMs over sea and adjacent land (Figure 12). Further inland, the differences of  
688 changes in specific humidity at 850 hPa between GCMs and RCMs are small.

**FIGURE 12** Ensemble mean change in specific humidity at 850 hPa (g/kg) in summer over Europe between 2099-2070 and 1999-1970 as (a) projected by the RCMs, as (b) projected by their driving GCMs, and (c) difference. The GCMs are weighted according to the number of RCMs they force.

689 A large inter-model correlation between the differences in specific humidity  
 690 changes over Europe and the differences of changes in both local (over land, see  
 691 previous section) and remote evapotranspiration over the Mediterranean sea  
 692 are noted (Figure 13). It supports the idea that the atmosphere becomes wetter  
 693 in some RCMs compared to their forcing GCMs partly because of smaller  
 694 decreases or larger increases of evapotranspiration, and that the Mediterranean  
 695 sea is an important source of moisture in that context.

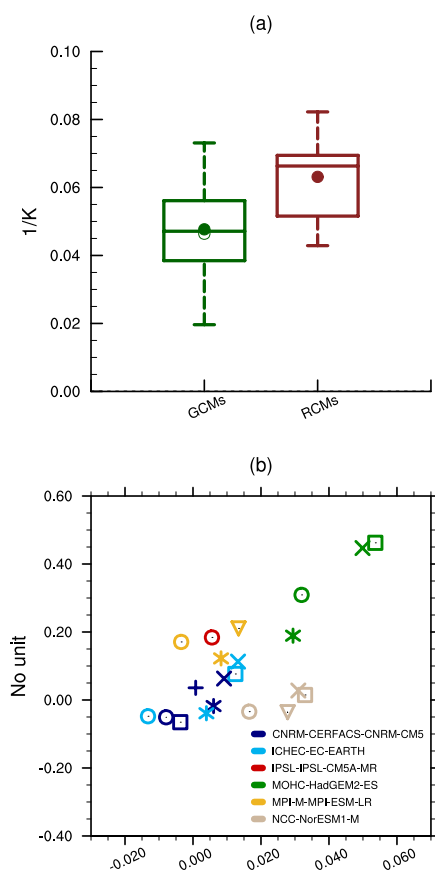

696 Note that as IPSL-WRF331F simulates very large changes in evapotranspi-  
 697 ration over the Mediterranean sea compared to the other RCMs (close to 3.15  
 698 mm/day, it does not appear on the scatter plot in Figure 13a. Note also that  
 699 the differences of both evapotranspiration and specific humidity changes are  
 700 especially large between HadGEM2-ES and the RCMs forced by HadGEM2-

**FIGURE 13** Difference of changes in specific humidity at 850 hPa (g/kg) versus difference of changes in evapotranspiration (mm/day) between the RCMs and their driving GCMs (RCMs-GCMs) in summer. For (a) and (b) the changes in specific humidity over Europe (land points within the red box in Figure 1e) are considered. For (a) the changes in evapotranspiration over the Mediterranean Sea are considered. For (b) the local changes in evapotranspiration over Europe are considered. The differences between 2070-2099 and 1970-1999 are calculated. Each symbol corresponds to a particular RCM (see Table 1) and each color to a particular forcing GCM.

701 ES. HadGEM2-ES is the driving GCM with the largest increase in tempera-  
 702 ture and the smallest increase in specific humidity at 850 hPa, both over the  
 703 Mediterranean sea and continental Europe (not shown). HadGEM2-ES also sim-  
 704 ulates the largest decrease in evapotranspiration over Europe. The increase  
 705 in evaporation over the Mediterranean sea in HadGEM2-ES is rather small  
 706 compared to the other GCMs (not shown).

707 With regard to summer climate changes, changes in relative humidity are  
 708 also very important (e.g. Boé and Terray 2014). For example, the lower the  
 709 relative humidity is, the harder it is to reach saturation and therefore poten-

**FIGURE 14** (a) Intermodel distribution of the ratio of relative specific humidity change to temperature change at 850 hPa ( $1/K$ ) averaged over Europe in summer (land points within the red box in Figure 1e) in the RCMs and their driving GCMs. (b) Differences in relative changes in summer precipitation (no unit) between the RCMs and the GCMs as a function of the difference in the ratio of relative specific humidity change to temperature change at 850 hPa ( $1/K$ ) over Europe in summer. The differences between 2070-2099 and 1970-1999 are calculated. Each symbol corresponds to a particular RCM (see Table 1) and each color to a particular forcing GCMs.

710 tially to form clouds and/or precipitation. The changes in specific humidity are  
 711 generally rather close between the RCMs and their forcing GCMs over land  
 712 away from the sea (Figure 12) but the warming is largely smaller in the RCMs  
 713 (Figure 1). As a result, the ratio between the change in specific humidity and  
 714 the change in temperature over land is generally smaller in the GCMs than in  
 715 the RCMs (Figure 14a). The larger differences are seen over the Balkans (not  
 716 shown), where the GCMs warm much more than the RCMs (Figure 1) and  
 717 where the specific humidity increases much more in the RCMs because of the  
 718 larger increase in evaporation over the Mediterranean sea (Figure 9).

719 Following the Clausius Clapeyron relation, the specific humidity at saturation  
720 increases approximately by  $7\%.K^{-1}$  (e.g. Held and Soden 2006). Therefore  
721 a ratio of specific humidity change to temperature change close to  $7\%.K^{-1}$  is  
722 equivalent to no change in relative humidity while a much smaller ratio indi-  
723 cates that a large decrease in relative humidity occurs. The RCMs therefore  
724 generally show small changes in relative humidity while the forcing GCMs  
725 show decreases and sometimes large decreases (Figure 14a).

726 The importance of the differences in relative humidity changes is highligh-  
727 ted by the link found over land between the differences in precipitation changes  
728 and the differences of the ratio of the change in specific humidity to the change  
729 in temperature at 850 hPa (Figure 14b).

730 Given the seemingly importance for climate changes over Europe of differ-  
731 ences in evaporation changes between RCMs and GCMs over the Mediterra-  
732 nean Sea, it would be important to understand their causes. First, some issues  
733 with the remapping of GCM SSTs to force the RCMs have been noted for  
734 some models (<https://euro-cordex.net/078730/index.php.en>). They may ex-  
735 plain larger evapotranspiration changes locally over sea near the coast in some  
736 RCMs. However, large differences are also seen away from the coasts (Figure  
737 9). These large differences are somewhat surprising. Indeed, for the calculation  
738 of evaporation over sea, the atmosphere component in a RCM and its forcing  
739 GCM use the same SST by construction, which plays an important role on  
740 evapotranspiration, through its impact on specific humidity at saturation at  
741 the surface. Differences in the parameterization of evaporation, e.g. the ex-  
742 change coefficients, may exist between the RCMs and the GCMs but there is  
743 no reason for the resulting differences in evaporation changes to be systematic  
744 (e.g. Figure 13) for all the RCMs / GCMs pairs.

745 Some differences in surface wind speed changes over sea in summer are  
746 noted between the RCMs and GCMs for which this variable is available, with  
747 generally somewhat larger decreases in the GCMs (a few percent, not shown).  
748 These differences are however likely insufficient to explain alone the large dif-  
749 ferences in evapotranspiration changes. Why such differences in wind speed  
750 changes exist in the first place is not clear. The representation of wind near  
751 the coast where the influence of orography can be felt is likely improved in the  
752 RCMs (Herrmann et al. 2011), but this impact is weaker far from the coast.  
753 Additionally, Herrmann et al. (2011) have shown that the coupling with the  
754 ocean has only a very weak mean impact on wind speed.

755 The impact of the coupled framework of the GCMs versus the forced frame-  
756 work of the RCMs should be considered more generally. Short-term negative  
757 feedbacks exist in a coupled framework but not in a forced framework. For  
758 example, very warm SSTs may result in strong evaporation and convection,  
759 with the development of clouds, which results in a reduction of shortwave ra-  
760 diation at surface and, in a coupled framework in a reduction of SSTs. Such  
761 a negative feedback does not exist in a forced framework. Unfortunately, it  
762 is not possible to go further without twin regional simulations based on the  
763 exact same RCM, with and without coupling over the Mediterranean sea. Such  
764 experiments have been done by Somot et al. (2008). Unfortunately, the eva-

765 potranspiration changes are not shown in the latter study but it shows that  
766 the coupling over the Mediterranean sea leads to a larger decrease of pre-  
767 cipitation over the south of eastern Europe, which could be consistent with  
768 the mechanisms described previously. Concerning evaporation over the Me-  
769 diterranean Sea, Planton et al. (2012) compared an Atmosphere-only RCM  
770 ensemble (ENSEMBLES project, Sanchez-Gomez et al. 2009) with a coupled  
771 Atmosphere-Ocean RCM model ensemble (CIRCE project, Dubois et al. 2012)  
772 for the A1B scenario and the 2020-2049 period. They obtain a larger increase  
773 with the non-coupled models (+4%, about +0.2 mm/day) than with the cou-  
774 pled models (+3%, +0.1 mm/day). Even if both ensembles are not directly  
775 comparable (the ensemble size is larger in ENSEMBLES than in CIRCE) and  
776 if the temporal horizon is different from the one we study, those results are  
777 consistent with our assumption about the ocean-atmosphere coupling effect in  
778 RCMs.

779 The differences of evapotranspiration changes over the Mediterranean sea,  
780 together with the differences in evapotranspiration changes over land between  
781 the RCMs and their driving GCMs discussed in the previous section, likely  
782 modulate the differential evolution of specific and relative humidity over land  
783 in the RCMs, with a possible impact on precipitation and cloud cover, and li-  
784 kely explain a part of the differences in surface warming. Local feedbacks may  
785 exist in that context as changes in cloud cover (through the modulation of  
786 shortwave radiation) and precipitation (through a modulation of evapotrans-  
787 piration via soil moisture) may impact in return surface temperature, which  
788 itself directly impacts relative humidity (Vogel et al. 2018).

789 Note that the differences of evapotranspiration changes over land discus-  
790 sed in the previous section could be driven by evaporation changes over the  
791 Mediterranean sea. As discussed, larger evapotranspiration changes over the  
792 Mediterranean sea may result in smaller decreases in relative humidity and  
793 then precipitation over land. These changes in precipitation would directly  
794 impact continental evapotranspiration.

795 Previous studies (e.g. Rowell et al. 2006) have highlighted the potential  
796 impact of the increased land-sea temperature contrast in the future climate.  
797 It leads to a larger increase in atmospheric water-holding capacity over land  
798 than over sea, so that air advected from the sea over the continent experiences  
799 a larger decrease in relative humidity in the future climate, with a potential  
800 associated reduction of clouds, precipitation and evapotranspiration. In the  
801 RCM simulations without time-varying aerosols, an inconsistency may exist  
802 between land and sea warming. The absence of aerosol variations leads to  
803 a smaller warming over land but it is not the case over sea as SST from  
804 the GCMs, which include variations in aerosols, are imposed. The absence  
805 of time-varying aerosols in a forced ocean framework therefore likely reduces  
806 the increase of the land-sea warming contrast in the future climate, with the  
807 potential consequences noted above.

## 7 Conclusion

In this study, we have shown that large differences exist in summer climate changes over Europe as projected by the 12 km EURO-CORDEX RCMs and their forcing CMIP5 GCMs, and more generally the full ensemble of CMIP5 GCMs. As an ensemble, the RCMs project over a large area of Europe at the end of the 21st century a summer warming 1.5-2 K colder and a decrease of precipitation roughly 4 time smaller (-20% versus -5%) than their driving GCMs.

Such inconsistencies between RCMs and GCMs projections, at large scales, are problematic. Such large differences may have profound consequences in terms of impacts and adaptation. It is therefore crucial to understand whether these differences may be related to an added value of higher resolution or to other factors, and therefore in the end whether more confidence should be given to current RCMs or GCMs results.

Our strategy has been to study in details the mechanisms responsible for the differences in precipitation and temperature changes and then to assess whether or not structural differences between GCM and RCM (e.g. differences of forcings, resolution, coupling etc.) may play on these mechanisms.

The forcing GCMs generally simulate a much larger increase in shortwave radiation at surface than the RCMs, as already noted by Bartok et al (2017) and Gutierrez-Escribano et al. (in review). Differences in changes of cloud cover alone cannot explain the totality of these differences and we argue that anthropogenic aerosols play a very important role in this context. The absence of time-evolving anthropogenic aerosol forcing in most RCMs (17 out of the 24 simulations) indeed leads to a smaller increase of downwelling shortwave radiation at surface in the RCMs than in their driving GCMs. It is clear based on our results that this mechanism plays an important role in the differences of projected changes between RCMs and GCMs, as confirmed by a dedicated sensitivity experiment, at least for solar radiation and temperature.

The future evolution of anthropogenic aerosols is uncertain, and the RCPs scenarios, as used in this study, do not necessarily capture the full range of possible evolutions (Bellucci et al. 2015; van Vuuren 2011). Given the great importance of anthropogenic aerosols for summer climate changes over Europe shown in this study or previous works (e.g. Boé 2016) more work is clearly needed to better explore the uncertainties associated with the future evolution of anthropogenic aerosols. Even if uncertainties exist, it is clear that until today the evolution of aerosols is much better captured by the historical + RCP (e.g. Klimont 2013) evolution of GCMs and ALADIN / RACMO, than by the constant aerosols concentrations of most EURO-CORDEX RCMs.

Note also that the absence of variation of  $CO_2$  in two RCMs (5 projections over 24) is also expected to have an impact on surface temperature changes (Jerez et al., 2018) and likely precipitation changes.

The RCMs also simulate a much larger increase in evaporation over the Mediterranean sea that likely leads to smaller relative humidity changes over the continent, which could then favor a smaller decrease in cloud cover, preci-

853 pitation and finally evapotranspiration, and a smaller increase in temperature.  
854 Causes of these differences in evaporation changes over sea are unclear, but it  
855 would be worth investigating the role of missing ocean-atmosphere coupling in  
856 RCMs. Larger decreases / smaller increases of evapotranspiration over Europe  
857 in GCMs are also projected over the continent, which is consistent with the  
858 larger warming and greater precipitation decrease projected by the GCMs. It  
859 is difficult to assess whether these differential evapotranspiration changes over  
860 land are simply the results of the mechanisms described above or whether spe-  
861 cific structural causes may exist. For example, the absence of the physiological  
862 effect of  $CO_2$  in RCMs that is taken into account by the majority of the forcing  
863 GCMs may play a role (e.g. Schwingshackl et al. 2019).

864 Several potential explanations exist to the differences of evapotranspiration  
865 changes between EURO-CORDEX RCMs and their forcing CMIP5 GCMs. For  
866 the time being, we think that there is no strong reason to suppose that the  
867 evapotranspiration changes in the RCMs are more realistic than the ones from  
868 their driving GCMs.

869 Dedicated numerical experiments would be necessary to go further, in par-  
870 ticular to better evaluate the impact of differential forcings and of ocean-  
871 atmosphere coupling. Some of these simulations are ongoing, within the MED-  
872 CORDEX project for the impact of coupling (CORDEX FPS-airsea), and for  
873 the impact of aerosols (CORDEX FPS-aerosol), following the same protocol  
874 as used in the sensitivity experiments described in section 4.2.

875 Our study highlights that greater care should be given to the characteri-  
876 zation and understanding of the potential discrepancies between RCMs and  
877 GCMs at large scales. We show that the EURO-CORDEX projections do not  
878 cover at large scales the full range of changes projected by the CMIP5 GCMs,  
879 with in particular no regional projection showing the strong summer war-  
880 ming and drying seen in a substantial number of GCMs (Figure 2). Given the  
881 caveats associated with regional climate projections discussed in this study,  
882 there is currently no rationale to discard the more severe changes projected by  
883 GCMs. We therefore urge climate change impacts studies to not simply focus  
884 on current EURO-CORDEX regional projections but to also consider the re-  
885 sults obtained with GCMs, in order to avoid a potential large underestimation  
886 of the uncertainties in projected impacts.
