13	Abstract.				
14	Thermal activation of new oxidant chemicals like Persulfate (PS) has recently gained attention in				
15	driving advanced oxidation processes (AOP) for a number of applications. Persulfate (PS) is an oxidant				
16	chemical likely to undergo thermal activation to drive advanced oxidation processes (AOP) with respect				
17	to a number of applications. On the other hand, addressing energy demand with carbon free and				
18	sustainable energy solutions represents an asset for new technologies in the modern society. This				
19	paper then investigates on the removal of pharmaceuticals residues in wastewater (WW), conducted				
20	with PS advanced oxidation reactions on a solar thermal pilot equipment. Hndoor preliminary				
21	investigations on small scale laboratory experimentations shows how increasing temperature has a				
22	direct positive impact on pollutants degradations rate (k_{app} value ranging from 0.4·10 ⁻³ s ⁻¹ at ambient				
23	to 10.4·10 ⁻³ s ⁻¹ at 75°C)., However, after an experimental screening methodology, carried out with a				
24	screening methodology, lead to 65 °C and 200 μ M appear as the appropriate target temperature and				
25	PS oxidant dosage to cope with both activation of PS oxidant and degradation of ten target				
26	micropollutants typically found in WW stream. Outdoor experimentations on the solar pilot equipment				
27	were operated conducted according to a batch running mode at a treatment capacity scale of a cubic				
28	meter. 95 % pollutant removal rate is achieved within 2 hours once the temperature has raised up to				
29	the target value (65 °C) in the bulk treated WW effluent. Series of treatment cycles under the natural				
30	day/night period demonstrate the reproducibility of the performance. As an early step result of the				
31	process optimization approach, heat recovery demonstration on the pilot equipment improves				
32	significantly the energetic balance over the now innovative thermal solar water treatment.

55 **1. Introduction**

Advanced oxidation processes (AOPs) are based upon the formation of highly reactive free 56 radicals species from different routes. Owing to the high redox potentials, the way free radicals 57 react and degrade soluble organics is highly relevant regarding environmental remediation 58 (Brienza et al., 2016; Marjanovic et al., 2018; Shawaqfeh and Al Momani, 2010; Vilar et al., 59 2011). Typically, free radicals catalyzed chain reactions readily make possible degradation 60 61 and/or mineralization of a wide range of hardly biodegradable organic molecules. Combined with the direct use of solar energy for radicals production, they offer a unique opportunity to 62 design an oxidative treatment process, at almost no additional energy cost, in agreement with 63 64 the concepts of green chemistry and sustainable development (Malato et al., 2016; 65 Strazzabosco et al., 2019). For many years since the discovery of free radicals potential for water decontamination, hydroxyl radicals (OH°) have been considered as the most attractive 66 (Brienza et al., 2014; Duran et al., 2010; Liu et al., 2018). In the late 1990s, OH° is successfully 67 used to run in situ chemical oxidation reaction, based upon utilization of oxidant reactants such 68 as ozone, potassium permanganate and hydrogen peroxide (Cai et al., 2018). Since then, 69 sulfate radicals (SO_{4^{-°}}), generated from a primary oxidant such as persulfate (PS) ions (S₂O_{8²⁻} 70) have also been progressively studied regarding major advantages such as the high redox 71 potential ($E^0 = 2.6$ V/SHE) and the longer lifetime of corresponding sulfate free radicals, i.e. 72 1000 fold more than OH° radicals (Cai et al., 2018; Matzek and Carter, 2016). For any of these 73 options, running the process with solar energy upon the well-known photo-Fenton ($Fe^{2+}-H_2O_2$, 74 Fe^{2+} -- $S_2O_8^{2-}$), has been so far the most popular and sustainable way to achieve radicals 75 production (Cuervo Lumbaque et al., 2019; Malato et al., 2016; Soriano-Molina et al., 2018). 76 77 However, the acidic pH conditions required to avoid iron ions precipitation for achieving Fenton 78 reaction, now appear as a serious bottleneck for process dissemination (Clarizia et al., 2017; 79 Johnson et al., 2008).

A number of publications have then addressed on the possibility to run AOPs under less acidic 80 or mild pH conditions. In the event of using Fe²⁺ chelates under neutral pH conditions, the 81 efficiency to achieve free radical chain reactions is still yet to be attractive (Clarizia et al., 2017; 82 83 Ike et al., 2018; Matzek and Carter, 2016; Wu et al., 2014). Iron free direct generation of OH° 84 from hydrogen peroxide has also been addressed very recently and seems promising, as far 85 as solar driven AOPs are concerned (Aguas et al., 2019; Ferro et al., 2015). Regarding sulfate 86 radicals (SO₄-°), iron free heat activation route of persulfate (schematically represented with Eq. 1) is also reported (Cai et al., 2018; Ghauch et al., 2015; Olmez-Hanci et al., 2013) but few 87 88 research studies addressed solar heat activation of PDS and the real advantages asset it could provide as a comparison with more conventional existing AOPs. 89

90
$$S_2 O_8^{2-} + Heat \longrightarrow 2SO_4^{-\circ}$$

The few recent papers dealing with the issue showed how successful is the activation of 91 persulfate (single used reactant) towards a wide range of biorefractory organic pollutants in 92 water (Cai et al., 2018; Ghauch et al., 2012; Johnson et al., 2008; Yang et al., 2017). The 93 94 results obtained on lab scale experiments are quite promising but the demonstration of the 95 technique on real pilot equipment needs further investigation, especially in the case of solar irradiation used as the only source of energy. Indeed, regarding heat energy needed to achieve 96 97 relevant target temperature, energy efficiency/profitability of what could be the future real processes is definitely relevant. Unlike conventional "in direct sunlight" photocatalysis scheme, 98 99 thermal activation based process appears more "robust" with respect to heat energy collected 100 (from sunlight) being stored over time for optimal usage, including during less fair weather 101 episodes.

This paper investigates on the capacity of a pilot equipment to run solar driven heat activation 102 of PS for water depollution. The system efficiency is investigated regarding emerging 103 104 contaminants found downstream wastewater (WW) plants. To the best of the author knowledge, this is the first time a pilot scale solar demonstration is used to run PS thermal 105 activation for the removal of micropollutant in real WW stream. In the south west of Europe, 106 some areas face overexploitation of water resources together with lack of precipitations. In the 107 perspective of achieving the new circular economic paradigm of water reuse, emerging and 108 biorefractory microcontaminants need to be discarded from WW effluents. However, most of 109 110 these microcontaminants are biorefractories molecules like pharmaceuticals and pesticides 111 constituents, which are hardly removed by existing biological treatments (Devi et al., 2016; Faraldos and Bahamonde, 2017; Oh et al., 2016). At the meantime, the high toxicity level and 112 113 bioaccumulation fate of a number of microcontaminants represent a real threat to public health 114 and environmental protection as well (Brienza and Chiron, 2017; Miralles-Cuevas et al., 2018). 115 The main objective of this study is to achieve PS thermal activation and then removal of emerging pollutants from WW, on a pilot scale newly designed solar equipment. Prior to real 116 117 pilot scale demonstrations, degradation of ten target molecules was lab scale investigated on 118 small wastewater samples. This was necessary to collect information on the influence of relevant experimental parameters on the depollution process. The ultimate aim was then to 119 120 set favorable conditions for running the pilot equipment under solar irradiated and optimal 121 basis.

122 123

2. Preliminary experiments

124 This section deals with indoor experiments, carried out in the laboratory prior to real solar pilot 125 scale experimentations. Working first on low WW volumes (500 mL) was necessary to 126 understand how impactful experimental parameters on degradation process are.

127 2.1. Wastewater and reagents

WW was used in this study to keep the pilot set up under "real life - like" experimental conditions. WW was collected downstream of a WW treatment plant in the south of France. Suspended materials were removed after an additional sand filtration and WW was stored for less than 2 days at 4 °C before usage. <u>On</u> Table 1 presents are the average values of some physicochemical parameters of WW samples.

135

For depollution experiments, WW samples were spiked with a cocktail of ten target molecules (**Table 2**) at μ g.L⁻¹ concentrations range. The molecules belong to different families of pharmaceuticals reportedly found in WW effluents in the south west of Europe (Brienza et al., 2016). They were obtained from *Sigma Aldrich* at more than 98% purities, together with potassium iodide (99.5%) and sodium bicarbonate (99₄₇7%). Potassium persulfate (99%) was purchased from *Acros Organics*. All the chemicals were analytical reagent grade.

142 For liquid chromatography, the reagents used in this study were of ultra-pure HPLC grade.

158 2.2. Analytical Apparatus and measurement procedures

An ultra-high performance liquid chromatography - electrospray - orbitrap mass spectrometer 159 (UHPLC-MS/MS) was used to determine the concentrations of contaminants in WW samples, 160 161 under both positive and negative modes of the ion spray source. The UPLC compartment 162 (Agilent 1290 infinity) is equipped with a C-18 analytical column under 0.2 mL.min⁻¹ flow rate of binary solvent mixture (water and acetonitrile). This was coupled to a MS/MS tandem 6460 163 164 triple quad mass spectrometer. The accuracy and sensitivity of the analysis system and then the corresponding protocol comply with the detection of pollutants at very low concentrations 165 (down to ng/L concentrations range). 166

- The residual persulfate concentration was determined according to a new spectrometric 167 168 method recently detailed in the literature (Liang et al., 2008; Zhao et al., 2015). The method is straightforward and less time consuming as a comparison with the conventional well known 169 iodometric dosage. A UV-vis spectrophotometer (VL-320 model) equipped with quartz cuvettes 170 (1 cm beam path) was used to read the absorbance of solutions after reaction of PS with 171 potassium iodide (KI). Calibration was carried out on a series of prepared standard solutions 172 (20 mL) with PS concentration ranging from 0 to 10 mg/L while keeping constant KI and 173 NaHCO₃ concentrations (respectively 1 and 0.1 g in 20 mL solutions, respectively). The 174 water/KI/PS/ NaHCO3 mixture was hand shaken and then allowed to react for about 30 min. 175 The intensity of the resulting yellowish color depending on the amount of PS which reacted 176 177 with the KI excess concentration. It's worth mentioning that NaHCO₃ is also added to prevent 178 air oxidation of KI reactant (Liang et al., 2008). Absorbance reading was carried out at 400 nm after sample solutions have followed the same protocol of calibration standards except PS 179 180 addition step. Dilution factors in the measurement solutions were considered for the 181 determination of concentrations.
- TOC measurements were performed with a TOC meter equipment (Shimadzu TOC VCSH/CSN) after total and inorganic carbons have been determined.
- 184

185 2.3. Depollution experiments

For indoor lab scale experiments, contaminated WW samples contained in 500 mL flasks were 186 187 prepared after proper dilution of corresponding reagents. For the 10 target molecules of this work, the concentration in the treated solutions was set at between $2.2 - 25 \,\mu g L^{-1}$, i.e. close 188 189 to naturally occurring concentrations (Brienza et al., 2016). Suitable dilutions were carried out from a 2 mM PS mother solution to get final treated solutions of different oxidant concentrations 190 191 (\leq 500 µM). Flasks containing the mixture were placed into a laboratory thermal water bath set 192 at a given temperature. At proper time interval frequency, 5 mL of samples were withdrawn for analytical measurements (target pollutants, PS and TOC) according to principles and 193 procedures described in section 2.2. Kinetic profiles were then obtained at different initial PS 194

concentrations and temperatures. <u>On a set of repeated experiments (triplicates), standards</u>
 <u>errors on quantification results were estimated lower than 6% (experimental reproducibility and</u>
 <u>instrumentation uncertainty).</u>

198

199

2.4. Influence of experimental parameters on pollutants degradation

200 - Effect of temperature

Fig. 1 sets out with average concentrations kinetics profiles at different temperatures, 201 202 considering all the ten target pollutants as whole taken together. At room temperature (20 °C), 203 pollutants degradation is almost negligible i.e. less than 8 % removed after 5 hours of reaction (overlapping with measurement accuracy threshold). Pollutants disappearance rate becomes 204 205 significant as the temperature of the treated solution increases. This is in agreement with PS concentration profiles at different temperatures (Fig. 2). They suggest that thermal activation 206 207 of persulfate for generation of free radical species is temperature dependent as reported in previous studies in the literature (Cai et al., 2018; Johnson et al., 2008). 208

209

Fig. 1. Kinetic profiles of μ -pollutants removal (average concentration) at different temperatures (Initial PS concentration 200 μ M, *C*_o average value= 5.2 μ g.L⁻¹)

Fig. 2. Kinetic profiles of PDS oxidant disappearance at different temperatures (Initial PS concentration 200 μ M)

Fig. 3 is the first order rate representation of kinetic profiles at different temperatures. One can 212 213 see that the more the temperature applied, the higher the pseudo-first-order rate constant of pollutants disappearance kinetics. The exponential trend on the increase of k_{app} rate constant 214 215 (from 0.4.10⁻³ s⁻¹ at 20 °C to 10⁻² s⁻¹ at 75 °C) is consistent with the fate of sulfate free radicals appearance under thermal activation conditions, reported in the literature (Deng et al., 2013; 216 Johnson et al., 2008). Regarding PS thermal decomposition under different experimental 217 218 conditions, Johnson et al., (Johnson et al., 2008) showed highlighted a pseudo first order profile 219 that of PSpersulfate thermal activation follows a pseudo first order profile. They also obtained an exponential increase of rate constant regarding sulfate ion production from PS within 30 -220 70 °C temperature range. Considering the short lifetime of sulfate radicals (SO₄-°), it is worth 221 mentioning that degradation of pollutants is correlated to the capacity of the system to generate 222 223 SO₄-° free radicals on a continuous basis. Activation energy has been calculated after setting a correlation ($R^2 = 0.86$) with respect to 1/T and then ln(k_{app}) according to Arrhenius equation, 224 225

$$Ln(kapp) = \ln A - E_a / R \cdot T$$

227

where *A* being the Arrhenius constant, E_a the activation energy (kJ.mol⁻¹), T the absolute temperature (K) and R the universal gas constant (8.314 J.mol⁻¹.K⁻¹). The linear regression obtained from experimental points is represented on Fig. 3 inserted panel.

231

Fig. 3. First order representation of kinetic profiles of pollutants elimination at different temperatures (Initial PS concentration 200 μ M, Co = 2.2 – 25 μ g.L⁻¹)

E_a calculated value obtained in this study, 44.39 kJ.mol⁻¹, is typically lower than what is found in a number of papers in the literature (Deng et al., 2013; Ghauch et al., 2015; Ji et al., 2015; Yang et al., 2017). Fan *et al.* (Fan et al., 2015) and Deng *et al.* (Deng et al., 2013) worked respectively on Sulfamethoxazole and Carbamazepine and obtained E_a values above 100 kJ.mol⁻¹, suggesting more difficulties in degrading these molecules as compared to results in this study. Actually, E_a value obtained at this stage is representative of the mean value of all the individual behaviors of the ten target molecules of this study.

240 Profiles of Individual target molecules under 75°C treatment temperature are presented in Fig. 241 4. One can observe how molecules react differently to thermal treatment activation. Ibuprofen and Diclofenac are totally removed after 60 mins of reaction. Molecules like Cafeine and 242 243 Tramadol need more than 2 hours for complete removal (Fig. 4.a). Nuflimic acid Bezafibrate and Trimetoprim are among the most harsh with about 85 % of removal rate achieved after 5 244 245 hours of reaction. However, regardless the pollutant without oxidant, less than 20% removal rate is attained under the same experimental conditions (Fig. 4.b), indicating a slight 246 thermolysis degradation of pollutants. Thermolysis contribution then stands for very little on 247 removal rate achieved under PS driven conditions. 248

Fig. 4. Kinetic profiles of elimination of individual target molecules (a) with and (b) without oxidant. PS oxidant concentration 200 μ M - Temperature 75 °C.

- 250
- 251

252 - Effect of oxidant concentration

Fig. 5 is a representation of the kinetics profiles of pollutant average concentration at four different concentrations of PDS oxidant (0, 100, 200 and 500 μ M). 8% removal rate is hardly achieved after 5 hours reaction without PDS reactant, indicating a slight thermolysis of the target molecules. In the presence of oxidant, pollutant concentration is significantly decreased to evince the main role of oxidant activation regarding pollutants disappearance in the solution.

Fig. 5. Kinetic profiles of pollutant removal at different concentrations of PS oxidant - Temperature 65 °C.

260 The increase of pollutants removal rate with PS concentration is in agreement with papers in 261 the literature (Cai et al., 2018; Marjanovic et al., 2018; Yang et al., 2017). Indeed, increasing oxidant concentration is favorable to organic removal as higher concentrations of sulfates 262 263 radicals are available for oxidation. However, the utilization of PS reactants should take into 264 account environmental norms and standards regarding release of sulfates in natural streams, 265 some health disorders being reportedly associated to high level of sulfates in water. Few 266 hundreds mg of sulfate ions are most often admitted in wastewater (Heizer et al., 1997). Later 267 on in this paper, only 200 µM of PS oxidant will be considered. A maximum of 40 mg/L of sulfate ions is likely to be released out, should initial PS oxidant being completely converted. 268

269

Comparison of the fate of coexisting chemical species

Fig. 6 is a comparison between kinetic breakthroughs of coexisting chemical species in the treated solution i.e. target pollutants, PS oxidant and organic charge represented by TOC. After 6 hours of reaction, less than 10 % of the gross initial TOC load (about 12.2 mg.L⁻¹) is removed. At the meantime, the target pollutants are completely discarded when 60 % of oxidant initially present has been consumed. This is a relevant example of the selective activity of sulfates free radicals towards target pollutants (in μ g.L⁻¹ concentrations range).

Fig. 6. Kinetic profiles of coexisting chemical species in treated solution. PS oxidant 200 $\mu M,$ Temperature 75 °C.

278

279 Sulfate selectivity is already reported in a number of studies in the literature. Cai et al., 2018, achieved a complete degradation of 2.4-dichlorophenoxyacetic acid from contaminated WW 280 281 with 65 % remaining TOC at the end of reaction. Working on winery wastewater, Amor et al. 282 (Amor et al., 2019) obtained similar results but succeeded in removing total TOC after combining thermal and UVC/iron activation of persulfates. In their research work with Titania 283 photocatalyst, Shawaqfeh and Al Momani (2010) needed two times longer period to achieve 284 TOC load as compare to time needed for removing some typical micropollutants. In this study, 285 after 5 hours of reaction, 60 % of initial PS concentration is being consumed. Assuming PS 286 287 being completely consumed over degradation reactions, this accounts for about 20 mg.L⁻¹ residual concentration, very low value regarding standards on WW effluents release (Heizer 288 289 et al., 1997).

290

291 **3. Pilot scale experiment**

292 3.1. Pilot experimental set up

A picture of the pilot is presented in figure 7, together with a descriptive diagram. It is mainly 293 294 composed of two tanks (upper and lower) of 1 m³ capacity, three flat solar panels (3 x 2 m² 295 light harnessing surface) set in series and a heat exchanger (plate type model). Irradiation 296 conditions were monitored with a radiometer (Kimo CR-110) and temperatures of WW in the 297 upper tank, at the outlet of the panels and the inlets/outlets of the heat exchanger were 298 measured with thermocouples (*K type*) connected to a data acquisition system. For simulation 299 of naturally occurring conditions, the inlet concentration of the ten target pollutants stood 300 between $12 - 22 \mu g.L^{-1}$.

Treatment consisted in two successive phases. First, heating of the WW effluent to a target 301 temperature and then oxidation reactions conducted with PS reactant, introduced from a 302 303 reagent vessel. For running the process, a volumetric pump (Pumprec) allows WW recirculation 304 over a closed fluid loop connecting the upper tank with the thermal receiver (solar heating 305 panels). For optimization purposes regarding solar energy utilization, recirculation takes place only when WW temperature straight at the thermal receiver outlet is above a representative 306 307 value in comparison to the temperature in the upper tank (ΔT threshold setting). The same regulation approach is used in traditional solar water heating system for preventing preheated 308 309 effluent to undergo reverse cooling off under poor irradiation condition (cloudy periods & 310 nights). Raising WW to 65°C was the target to achieve before injection of PS oxidant (solenoid 311 dosage with Verderdo VE1-C pump). Periodically, few amounts of WW effluent were collected 312 from the system for analysis.

313

Fig. 7 Water treatment solar pilot picture and descriptive diagram

314

After completion of degradation, an integrated heat exchange system is used to transfer heat from the outflowing hot treated WW to a new contaminated WW volume entering the system. First, the treated WW effluent in the treatment tank (upper tank) is transferred to a lower tank. From the lower tank, treated WW effluent is cooled down before leaving the system and the energy released is used for heating new contaminated WW volume filling in the upper tank at the meantime. This "heat energy management system" is a reliable way to tackle the issue of energy saving and low investment on nominal surface area of thermal panel.

324 3.2. Wastewater depollution on solar pilot

Figure 8 shows the variation of WW temperature over six days in the row, on the month of June in Perpignan. The corresponding solar irradiation (W.m²) is also presented. For better illustration and interpretation of results, night periods data have been removed as well as earlier time in the morning and later in the afternoon, i.e when irradiation is quite poor (looping pump off).

330

Fig 8. Effluent temperature and solar irradiation in 6 days in the row, heat and oxidant
 management between one batch treatment to another (800 L of WW effluent)
 334

Higher solar irradiation was registered on day 1 and 2, typical to summer weather in this part of Europe, with a daily average of the incident radiation energy ranging around 6.8 kWh/m² (between 7 a.m. to 5 p.m.). Day 3 witnessed some cloudy episodes and day 5 was definitely cloudy, with significant decrease on radiation energy collected into heat form.

Day 1 starts first by filling the treatment tank with 800 L WW prior to data collection (Fig. 8). 339 Starting from ambient temperature of WW (25 °C), a day of irradiation was not sufficient to 340 achieve 65 °C threshold of WW temperature. At the end of the first day, the treated effluent 341 342 caps at around 60°C and because of heat losses over the equipment during night window, a slight decrease (2-3 °C) is observed before solar heating resumed the second day (Fig. 8). 343 Thereafter, 3 to 4 hours were needed to reach the expected 65°C. Theoretically, about 37 344 kWh_{th} of thermal energy are expected for elevation of 800 L of WW from 25 to 65 °C. In 345 practice, the required solar energy backing this temperature elevation is the amount of 346 347 radiation received right on top of active surface of the solar panels, according to Eq. 3,

348

$$Q_e = \sum G_i \cdot \Delta t_i \cdot S$$

350

where S (m²) is the solar receiver surface, G_i (W.m⁻²) the global irradiation registered within Δt_i (s) period of time.

The calculated value of Q_e corresponding to the first treated batch was about 52 kWh. Assuming that heat losses and thermal inertia of the tank are negligible, the thermal efficiency of the whole system was estimated to around 0.7. This value is in agreement with the use of flat collector thermal panels at working temperature within the range from ambient to few tens of Celsius degrees.

As PS oxidant is injected after 65 °C has been reached, up to 95 % pollutants removal rate was achieved right away after 1.5 h of reaction (**Fig. 9**). However, one can observe that more than 60 % global removal rate (regardless individual pollutant) was rapidly achieved within the first 15 min of treatment, indicating relative high rate of degradation oxidation reactions. As expected from preliminary studies, the degradation of pollutants is very effective should the required condition of temperature is met.

364 If persulfate was injected below 65 °C, preliminary experiment (results not presented) showed 365 an important activity regarding oxidant consumption as WW bulk temperature increased slowly 366 under solar streaming heating. By the meantime, very little activity and low rate degradation of 367 pollutant was obtained. This result points out the necessity of injecting the oxidant at the right 368 temperature to guarantee a minimum rate of sulfate radicals production. The issue will be 369 discussed with more details on a future paper.

After completion of treatment on Day 2, solar energy accumulation kept going on until the end

of the day, together with elevation of the effluent temperature (Fig. 8).

372

Fig. 9. Pollutants kinetic profile on Day 2 (Fig. 8)

On Day 3, heat energy recovered from the WW effluent treated the day before was used to raise temperature of new polluted WW batch entering in from 25 °C of ambient to about 50 °C (Fig. 10). This simple heat exchange operation took about 4 h to bring a preheated new polluted WW batch at the level of the treatment tank. Afterward, few hours of solar irradiation were needed to reach 65 °C and achieved degradation of pollutants on a second new WW batch in the row, as soon as PS oxidant was injected in.

380

Fig. 10. Temperature profile over the heat exchange system with volumetric flow rates of the fluids equal to 200 L.h⁻¹.

381

Interestingly, thanks to the heat exchange system, it then takes less time (about 6 h including heat exchange time) under solar irradiation to reach 65 °C target temperature, as compared to the time needed for the first batch (Fig. 8). Within the two hours that immediately follow, pollutant degradation takes place (Fig. 11.a) after PS oxidant has been injected. A third and fourth additional batch treatment were achieved after repeating the same transfer-heat exchange procedure on day 4 and day 5 (Fig. 11.b).

Fig. 11. Pollutants kinetic profiles on (a) Day 3 and (b) Day 5 (Fig. 8)

390 For day 3 and 4 (Fig. 8), the mean value of the amount of solar energy collected to drive pollutant degradation (i.e. periods between time of injection on day n-1 and the injection time 391 392 on day n) is about 38 kWh, corresponding to 47 Wh/L. This value is 25% smaller than solar energy needed on a process without heat energy recovery (52 kWh required for the first treated 393 394 batch). This is a promising finding of what stands as the energy optimization approach. 395 However, more efficiency is likely to be achieved regarding energy balance, together with some 396 improvements over the heat management system. Some of these improvements deal with a more suitable sizing of heat exchanger and minimization of energy losses due to inertia of 397

398 materials the effluent is in contact with, and, more basically, an improvement of the system399 compactness.

400

On the other hand, it's worth mentioning that the heat management system copes with the discontinuous feature of sun light energy as applicable on Day 5 (Fig. 8). Despite a poor solar irradiation conditions of this day, energy collected by the system was sufficient to raise WW effluent up to the target temperature, and to treat a fourth batch of 800 L WW (Fig. 11.b). More than 80% of pollutant global charge is removed after PS oxidant injection.

4. Conclusion

409 Persulfate thermal activation can be effective in removing emerging contaminants in water via advanced oxidation reactions. In this paper, persulfate is thermally activated on a solar pilot to 410 drive degradation of ten target pollutants typically found in wastewater streams. Preliminary 411 412 studies were first carried out prior to outdoor experimentations on real solar pilot equipment of 413 1000 L capacity. Indoor preliminary experiments highlighted how increasing temperature and oxidant concentration has a positive effectimpact on pollutants degradations rate. A slight 414 variation of degradation rate can be observed from one individual pollutant to another. 415 416 However, out of the ten, only Cafeine and Tramadol is still found in very few residual amount 417 in the treated solution after 2 hours of treatment (at 70°C with 200 µM PS concentration). Regarding pilot scale equipment, experiments were carried out on batches of several hundreds 418 419 of liters to make a proof of concept demonstration under real solar irradiation. The degradation 420 of pollutants is effective onver a bulk treated volume (800 L) heated under solar irradiation 421 above the 65 °C target temperature. Similarly to the small scale laboratory tests, around two 422 hours were needed to achieve high removal rate of the 10 micropollutants cocktail within a real 423 waste water effluent. The heat recovery system on the pilot definitely plays a key role to 424 improve the energy balance and a smart use of solar energy collected on the top of basic solar 425 panels. Since the heat energy collected can be stored over time, it allows an optimal running of the system, in particular during days with less fair weather episodes. The next critical step 426 427 will be the optimization of energy balance to make the process competitive for the treatment 428 of micropollutants in WW, with low investment on the extent of solar panels. Anyway, the 429 general principle of a solar thermal activation of persulfate is experimentally demonstrated on 430 a pilot scale set up.
