Abstract

To mimic the activity of hyaluronidase in natural environment, the hydrolysis of hyaluronic acid (HA) by hyaluronidase was investigated for the first time in the presence of crowding agents using capillary electrophoresis (CE) as a simple and reliable technique for conducting enzymatic assay. Polyethylene glycol (PEG) 6000 was selected as a model crowder and the hyaluronic acid degradation catalyzed by bovine testes hyaluronidase (BTH) was carried out at different PEG concentrations (0%, 10%, and 17%). After optimization of the CE analytical method and enzymatic assay, the degradation products were monitored at different HA concentrations. At 10% of PEG and 0.3 mg mL⁻¹ of HA, the activity of the enzyme was significantly reduced showing inconvenient interactions of PEG with the hyaluronidase blocking the release of hydrolysis products. A similar reduction of hyaluronidase activity was observed at 1 mg mL⁻¹ of HA due to the presumable formation of the BTH-substrate complex. The experimental curves obtained by CE also evidence that the overall kinetics are governed by the hydrolysis of hexasaccharide intermediates. Finally, the effect of PEG on hyaluronidase activity was evaluated in the presence of natural or synthetic inhibitors. Our results show a significant difference of the inhibitors' affinity toward hyaluronidase in the presence of PEG. Surprisingly, the presence of the crowding agent results in a loss of the inhibition effect of small polycyclic inhibitors, while larger charged inhibitors were less affected. In this work, CE analyses confirm the importance of mimicking the cellular environment for the discovery and development of reliable inhibitors.

Introduction

Historically, enzymatic studies were assayed *in vitro*, in dilute conditions, without considering the complexity of real *in vivo* conditions such as the cellular environment. A wide variety of biomolecules (proteins, nucleic acids, ribosomes, and carbohydrates) occupy 20–40% of the total volume of a typical cell [1–3]. The activity of an enzyme in such crowded media can be very different in comparison to dilute conditions [3–5]. This may be evaluated experimentally by using concentrated solutions of model “crowding agents” such as polyethylene glycol (PEG), dextran, Ficoll (branched carbohydrate derivative), or inert proteins [5]. Most of the enzymatic studies carried out *in vitro* under macromolecular crowding (MC) conditions have been monitored either by UV-visible spectroscopy, fluorescence, or far UV-circular dichroism spectroscopy [6–9]. Some other studies have used isothermal titration calorimetry and turbidimetric methods to study the effect of crowders on enzymatic activity [10, 11].

Capillary electrophoresis (CE) is a well-established separative technique that enables fast, highly efficient, cost-effective analyses of a wide range of molecules [12]. Several detection tools may be used in conjugation/hyphenation with CE such as UV, fluorescence, contactless conductivity, and mass spectrometry [13–20]. CE offers the possibility to carry out enzymatic assays using two main homogeneous approaches, in which neither the enzyme nor the substrate is immobilized: (i) off-line or pre-capillary mode and (ii) on-line or in-capillary mode. For the off-line assays, the enzymatic reaction is performed in a vial, before the introduction of the reaction mixture into the capillary. The on-line mode implies that the reaction takes place directly inside the capillary that plays the role of an enzymatic nanoreactor [14, 21]. In this work, we study for the first time the effect of crowding media on hyaluronidase activity using two techniques, a referenced one based on neocuproine spectrophotometry [22] and a pre-capillary CE-UV-based assay previously developed by our laboratory [17]. The hyaluronic acid (HA) or hyaluronan is a major component of the extracellular matrix (ECM) and is especially abundant in loose connective tissue [23–25]. It is a linear polysaccharide that forms long, worm-like filaments in aqueous solutions allowing to hold/trap approximately 1000 times its weight of water giving tissues such as the skin its viscoelasticity, hydrophilicity [6, 26], and plasticity [27]. HA is increasingly used as a non-immunogenic and a non-inflammatory filler and scaffolding material in cosmetic dermatology [6]. It is a non-sulfated glycosaminoglycan with repeating disaccharide units of D-glucuronic acid ($\beta 1 \rightarrow 3$) and N-acetyl-D-glucosamine ($\beta 1 \rightarrow 4$). The size and abundance of HA are controlled by hyaluronidases. Bovine testicular hyaluronidase (BTH) and all human hyaluronidases specifically split the β 1,4-glucosaminidic bond between C1 of the glucosamine moiety and C4 of the glucuronic acid [28]. This produces

oligosaccharides of an even number of repeating monosaccharide units (n). The tetrasaccharide (Tet, $n = 4$) is considered as the final product of the BTH hydrolysis reaction [24, 29]. The products of HA degradation are implicated in different pathological processes including inflammation, tumor progression [30, 31], epidermal homeostasis, and skin aging [25]. For this, searching for inhibitors of hyaluronidase is of great interest [28, 31].

BTH activity is conventionally monitored by spectrophotometry and viscosimetry methods [22, 32]. These techniques are prone to interferences and only allow the determination of the total hyaluronidase activity and not the quantification of the different oligomeric species. In order to quantify precisely the obtained products of BTH degradation, HPLC and size exclusion chromatography with UV and/or mass spectrometry detection have been explored [4, 33–36]. CE-UV was also used to obtain a complete identification of the HA degradation products after electrophoretic separation and quantitative detection [17, 19, 21, 37–40].

This study was focused on the evaluation of the effect of a typical crowding agent, namely PEG 6000, on HA degradation by BTH. The activity of hyaluronidase was monitored by following the concentration of oligomer products during kinetic runs at different concentrations of the crowding agent. Several optimizations were performed concerning the injection conditions and reaction time for CE-UV. The optimized conditions were then applied to follow the reaction in different enzymatic media with CE-UV and the neocuproine assay in parallel. Since CE separation provides information on free concentrations of reaction intermediates and final products, a better insight into the mechanism of HA degradation at different crowding conditions has been obtained. Finally, natural inhibitors, epigallocatechin gallate (EGCG) and quercotriterpenoside-I (QTT-I), as well as two original synthesized inhibitors were tested in order to evaluate their effect on hyaluronidase activity in the presence of PEG 6000.

Experimental

Materials and methods

Chemicals

All reagents were of analytical grade and used as received without any further purification. Ammonium acetate ($\text{CH}_3\text{COONH}_4$, purity $\geq 98\%$), epigallocatechin gallate (EGCG, purity $\geq 95\%$), hyaluronidase type I-S from bovine testes (BTH, 400–1000 units mg^{-1} solid, CAS 37326-33-3, sodium acetate (CH_3COONa , purity $\geq 99\%$), sodium hydroxide (NaOH, purity $\geq 98\%$), and oligohyaluronic acid (oligo-HA4 or tetrasaccharide (Tet), $\text{C}_{28}\text{H}_{44}\text{N}_2\text{O}_{23}$) were purchased from Sigma-Aldrich (Saint-Quentin Fallavier, France).

Hyaluronic acid, sodium salt, and *Streptococcus pyogenes* (HA, CAS 9067-32-7 – Calbiochem) were purchased from Merck Millipore (Molsheim, France). Glacial acetic acid (CH₃COOH) and ammonia (NH₄OH, 28%) were purchased from VWR International (Fontenay-sous-Bois, France).

Biotinylated 4-sulfated (CS-A) and 6-sulfated (CS-C) chondroitin tetrasaccharides, two original synthetic oligosaccharides, were synthesized in our laboratory [41] and tested as inhibitors of hyaluronidase activity.

Polyethylene glycol (PEG) 6000 was purchased from Merck, USA. Hydrochloric acid (HCl) was purchased from Fisher (Thermo Fisher Scientific Corp., USA). Potassium carbonate (Aldrich, USA), glycine (Aldrich, USA), cupric sulfate pentahydrate (Merck, USA), and 2,9-dimethyl-1,10-phenanthroline hemihydrate (neocuproine) were purchased from Alfa Aesar (Thermo Fisher Scientific Corp., USA).

Quercotriterpenoside-I (QTT-I) or 23-*O*-galloyl arjunenin 28-*O*-β-glucopyranosyl with the molecular formula C₄₃H₆₂O₁₅ was isolated from an extract of *Quercus petraea* wood using centrifugal partition chromatography fractionation and high-performance liquid chromatography purification according to the procedure described by Marchal and coworkers [42].

Ultrapure water (18.2 MΩ-cm) was produced from an Elga apparatus (Elga, Villeurbanne, France). Syringes and hydrophilic polyvinylidenedifluoride (PVDF) Econo Syringe Filters, pore size 0.2 μm, were purchased from Agilent, USA.

Solutions

All buffer solutions, with and without crowders, were freshly prepared every day in ultrapure water. Then, their pH was adjusted before being filtered and stored at 4 °C.

Buffers The incubation buffer (IB) was prepared by dissolving the appropriate amount of sodium acetate in ultrapure water to make a 2 mM solution and the pH was adjusted to 4.3 with 1 M glacial acetic acid. The background electrolyte (BGE) for capillary electrophoresis was prepared by dissolving the appropriate amount of ammonium acetate in ultrapure water to make a 50 mM solution. The pH was adjusted to 8.9 with 1 M ammonia.

Stock solutions Stock solutions of BTH, HA, EGCG, and tetrasaccharide were prepared in the IB at a concentration of 10 mg mL⁻¹ and diluted to the appropriate concentrations in the same buffer. The enzyme stock solution was prepared at 10 mg mL⁻¹ and then aliquots of 2 mg mL⁻¹ were stored at -20 °C. Stock solutions of CS-A and CS-C were prepared at 10 mg mL⁻¹ in ultrapure water and then diluted in the IB to the appropriate concentration. QTT-I stock solutions were prepared at 40 mg mL⁻¹ in pure methanol and then diluted in ultrapure water to the appropriate concentration.

Stock solutions of PEG 6000 were prepared by dissolving the appropriate amount in the IB to have 7%, 14%, and 25% (w/w) solutions in order to have a final concentration in the reaction media equal to 5%, 10%, and 17%, respectively. The pH of this mixture was adjusted to 4.3 with 1 M or 5 M of glacial acetic acid. The solutions were then homogenized with the homogenizer 850 (Fisher Scientific, USA) seven times for 3 min at 11,000 rpm, with 1 min between cycles to prevent overheating as optimized in our previous work [9]. This step helps preventing the formation of aggregates but no breakdown of PEG was observed as shown by dynamic light scattering. The dimensions of the homogenizer probe were 7 mm × 115 mm. Finally, the solutions were filtered through 0.2 CHROMAFIL Xtra regenerated cellulose syringe filters (Macherey-Nagel, Germany) and stored at -20 °C before use.

Instrumentation and operating conditions

Neocuproine spectrophotometric assay

The assay was performed as described in the work of Vercruysse et al. [22] with the exception of using potassium carbonate instead of sodium carbonate. Briefly, two reagents, named C and D in the work of Vercruysse, were prepared as follows: 19.5 mg of neocuproine was dissolved in 10 mL of ultrapure water followed by adding 1 M HCl until neocuproine is dissolved (reagent C). To prepare reagent D, 521 mg of potassium carbonate, 160 mg of glycine, and 4.5 mg of cupric sulfate pentahydrate were dissolved in 10 mL of ultrapure water. Both reagents were stored at 4 °C.

In this assay, Cu²⁺ is reduced to Cu⁺ that binds to neocuproine resulting in the shift of the absorption spectrum of this compound. Reagent and sample volumes were optimized in this study. Forty microliters of reagent C and 40 μL of reagent D were added to 20 μL of the reaction mixture. After 12 min of incubation at 100 °C and cooling down, 100–200 μL of water was added to the assay mixture. Then, 200 μL of the mixture was pipetted on a 96-well plate. The absorbance at 450 nm was measured with a Mithras plate reader (Berthold, Germany).

Capillary electrophoresis analysis

All enzymatic reactions were conducted by off-line assays based on the protocol previously developed by our laboratory [17, 37, 40]. Bovine testes hyaluronidase (BTH) was chosen since it is commercially available and presents a similar activity to that of the human hyaluronidase [43].

For all the reactions, unless otherwise stated, 35 μL of incubation buffer or PEG solution was pre-incubated with an appropriate volume of HA (10 mg mL⁻¹) for

10 min at 37 °C and then 5 μ L of enzyme solution was added to the reaction mixture, so that the final concentration of the enzyme in the mixture was 0.2 mg mL⁻¹. Reactions were incubated at 37 °C for 180 min and then stopped by increasing the temperature using a water bath to 90 °C for 10 min. For the inhibition assay, the reactions were carried out and stopped using the same protocol described above. More precisely, 25 μ L of IB or PEG solution was pre-incubated with 10 μ L of HA and 10 μ L of inhibitor before adding 5 μ L of enzyme. All reactions were carried out in duplicate.

The reaction mixtures were analyzed on a Beckman P/ACE MDQ (AB Sciex, USA) CE apparatus equipped with a photodiode array detector. The control of CE was performed using the Beckman 32 karat software (Beckman Coulter, USA). Uncoated fused silica capillaries purchased from Polymicro Technologies (Phoenix, AZ, USA) were used. The total length of the capillary was 57 cm (47 cm to the detector) with 50- μ m inner diameter. The detection wavelength was set at 200 nm (bandwidth 10 nm). New capillaries were conditioned by performing the following rinsing cycles: 1 M NaOH (10 min), water (10 min), and BGE (10 min). At the start of each working day, the capillary was rinsed with 1 M NaOH (5 min), water (5 min), and BGE (5 min), followed by applying +15 kV (10 min) [44]. Between the runs, the capillary was flushed with NaOH (5 min), water (0.5 min), and BGE (3 min) to ensure a good cleaning of the inner capillary surface. At the end of each day, the capillary was rinsed with NaOH (10 min) and water (10 min), both at 50 psi and stored overnight in water at 25 °C. All rinse cycles were carried out at 30 psi.

Electrokinetic and hydrodynamic injections were performed from the anodic side of the capillary. The electrokinetic injections were tested at different voltages. On the other hand, the hydrodynamic injection conditions were optimized to achieve consistency and comparability. For both types of injection, the separation was performed in normal polarity mode at +15-kV separation voltage. The corrected peak area (CPA), which is the ratio of area over the migration time, was used as a reliable mean for the quantification of different electropherogram peaks. It is assumed that the absorbance measured at 200 nm is proportional to the number of dimeric motifs within the HA oligomer.

For inhibition assays, all inhibitors were tested at 1 mg /mL: (i) EGCG, a well-known inhibitor of hyaluronidase [37]; (ii) CS-A and CS-C, original synthesized inhibitors previously assayed for their hyaluronidase inhibition using CE by our laboratory [40]; and (iii) quercotriterpenoside-I (QTT-I), a natural compound we isolated from an oak wood extract [42]. For all

tested inhibitors, the percentage of inhibition was calculated according to Eq. 1.

$$\%I = \left(1 - \frac{A_x}{A_0}\right) \times 100 \quad (1)$$

where A_x is the CPA of the tetrasaccharide product formed in the presence of the inhibitor and A_0 is the CPA of the tetrasaccharide product formed in the absence of an inhibitor.

Results and discussion

Hyaluronidase activity was investigated in the absence and in the presence of PEG 6000 using the conventional neocuproine spectrophotometry technique as well as capillary electrophoresis (CE). The neocuproine assay enables the determination of the total amount of reducing ends of HA hydrolysis by measuring absorbance at 450 nm. CE allows the separation and the quantitative detection of different products obtained after the HA hydrolysis leading to a better understanding of BTH activity in a crowded environment and in the presence of inhibitors.

Capillary electrophoresis-based enzymatic assays

CE-UV was used to investigate the influence of PEG 6000 on HA hydrolysis. Tests were conducted at different concentrations of crowders, between 5 and 30%. The activity of hyaluronidase was determined by following the formation of the tetrasaccharide (Tet) fraction (oligo-HA4) which is the final product of HA hydrolysis by hyaluronidase. Our previously developed pre-capillary CE assay was adapted and used for this study [17]. Firstly, the influence of PEG 6000 on the repeatability of the injections into the capillary and on the electrophoretic separation of the obtained products was evaluated. Secondly, the hyaluronidase activity was monitored in the presence of the crowder.

Optimization of injection

The addition of PEG 6000 to the reaction media will inevitably increase its viscosity [45] which will result in inaccurate and unreproducible injections of representative samples into the capillary [13]. Consequently, being known to be well adapted for viscous samples [44], electrokinetic injection was tested by applying 5, 10, and 15 kV (positive and negative polarities) for 5 s. Hydrodynamic injection was also employed and optimized by applying a pressure of 0.5 psi or 1.5 psi for 5 s (respectively corresponding to 5 nL and 15 nL when using dilute solutions with a viscosity comparable to water according to Poiseuille equation). The hyaluronidase activity was assessed in the absence of PEG and in its presence at 10 and 17%. Working with higher concentrations of PEG (25% and 30%) was excluded

because the high viscosity of the solutions prevented an accurate preparation of the incubation media (pipetting issues for example). The influence of the crowders on the injection quality was evaluated at different concentrations of HA between 0.1 and 1.2 mg mL⁻¹. Other conditions were similar to those presented above. The CPA value of the tetrasaccharide product peak was monitored in the different conditions.

Using the electrokinetic injection, the detected peaks were of low intensity and poor CPA repeatability even in the absence of the crowding agent. These results indicate that this approach is not suitable for the injection of the hyaluronidase reaction mixture. Indeed, it is known that the electrokinetic injection is less suitable for anions since it depends on the magnitude of the electrophoretic mobilities compared with the electroosmotic flow (EOF). When performing hydrodynamic injections at 0.5 psi for 5 s, results were not repeatable in the presence of PEG 17%. Using 1.5 psi for 5 s ensured good repeatability of the CPA of the tetrasaccharide peak for the different substrate concentrations. However, when the HA concentration was higher than 0.5 mg mL⁻¹, the CPA values decreased in the presence of PEG at 17%. This is due to the high viscosity of the injected reaction media engendered by the presence of both polymers, PEG and the HA at high concentrations.

Based on these results, the hydrodynamic injection was fixed at 1.5 psi for 5 s for the rest of the study.

Influence of PEG on the electrophoretic separation of reaction products

The electropherograms recorded in the presence of PEG 6000 show that the overall separation is not affected by the presence

of PEG regardless of its concentration (Fig. 1). Nevertheless, the peaks are wider and less intense, and the analysis time increases with the increase of PEG concentration. More precisely, the EOF decreased from $4.38 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ at 0% of PEG to $4.08 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ at 10% PEG to reach $3.82 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ at 17% PEG. This corresponds to a decrease of the electroosmotic flow of 6.8% and 12.8% in the presence of 10% and 17% PEG, respectively. This decrease of μ_{eof} may be associated to the relatively high viscosities of the analyzed samples and a possible non-covalent neutral coating of the inner capillary wall formed by hydrogen interactions between PEG and the silanol groups. However, this coating is known to be unstable when using an alkaline BGE, such as pH 8.9 in this study [44, 46, 47]. On the other hand, the migration time of the substrate HA also increases in the presence of PEG. The electrophoretic mobilities of HA (μ_{eph}) in the absence of PEG was $2.16 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$. Adding 10% PEG had a negligible effect on μ_{eph} ($2.13 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$) while adding 17% PEG caused a decrease of 6.9% of the μ_{eph} ($2.01 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$). These results suggest that HA interacts with higher concentrations of PEG, which changes the charge-to-size ratio of HA and hence its apparent mobility.

Enzymatic assays in the presence of PEG

A series of enzymatic assays were conducted at standard conditions and in the presence of PEG 6000, at 10% and 17%. The separation of hydrolysis products at different concentrations of HA between 0.1 and 1.0 mg mL⁻¹ was carried out by CE-UV. Assays were conducted using the previously

Fig. 1 Electropherograms of HA hydrolysis by hyaluronidase at different concentrations of HA at 0% PEG (a), 10% PEG (b), and 17% PEG (c). Reaction mixture in IB: 0.2 mg mL⁻¹ hyaluronidase and HA (0.1 to 1.18 mg mL⁻¹). Incubation at 37 °C for 180 min. IB: 2 mM sodium acetate (pH 4.3). Blank assay conducted in the absence of hyaluronidase in the reaction mixture. Electrophoretic separation

conditions: BGE: 50 mM ammonium acetate (pH 8.9); anodic injection: 1.5 psi for 5 s; separation: + 15 kV at 25 °C; detection: $\lambda = 200 \text{ nm}$; rinse between analyses at 30 psi: 5 min NaOH (1 M), 0.5 min water, and 3 min BGE; bare-silica capillary: 57 cm total length, 47 cm detection length, 50 μm i.d. Peak identification: electroosmotic flow (EOF) and tetrasaccharide (Tet)

Fig. 2 Corrected peak area (CPA) values obtained by CE for tetrasaccharide (Tet), hexasaccharide (Hex), and octasaccharide (Oct) to monitor the influence of different concentrations of PEG 6000 on hyaluronidase activity: 0% (a), 10% (b), and 17% (c). The total CPAs of short

oligosaccharides obtained as the sum of CPAs for Tet, Hex, and Oct species detected and quantified during a single CE run are presented in (d). Incubation time: 180 min. Other conditions: Fig. 1. The dashed lines in the figures are guide for the eye

optimized conditions (incubation time of 180 min at 37 °C). The quantity of the three main products obtained by HA hydrolysis, viz. Tet, hexasaccharide (Hex, $n = 6$), and octasaccharide (Oct, $n = 8$), was evaluated by monitoring their CPAs. The CPA of dimeric (Dim) species during these analyses was zero or negligible to be analyzed here. The relative evolution of species concentrations in the absence of PEG (Fig. 2a) shows that Tet, a hydrolysis product that cannot be hydrolyzed further, is the major species at low HA concentrations, since higher oligomers have been already degraded. The evolution of CPA of Tet indicates that the hydrolysis rate increases up to $\sim 0.3 \text{ mg mL}^{-1}$ of HA and significantly decreases for higher substrate concentrations whereas Hex and Oct intermediates are still detected in the solution. This observation can be related to the inhibition of BTH at high substrate concentrations, presumably due to the formation of an electrostatic BTH-HA complex. Indeed, Lenormand et al. [48] have shown that the main reason of a reduced BTH activity when the substrate concentration increases was the formation of an inactive form of BTH due to its complexation with the HA. To confirm this observation, the authors have used BSA (bovine serum albumin) to complex the HA. The formation of the novel HA-BSA complex liberates the enzyme as observed by a resurgence of its activity. Moreover, the increasing viscosity at high HA concentration of 1 mg mL^{-1} would be suspected to diminish the available water (binding water). Water plays a major role in the hydrolytic event since the

enzymatic breakdown of HA involves both HA and water. However, a very recent study [49] showed using near-infrared (NIR) spectroscopy that HA actively interacts with water and the difference in interaction with water at 0.1 and 1 mg mL^{-1} of HA was not significant.

The addition of PEG 6000 into the reaction mixture globally slows down the HA degradation as shown by the levels of short oligomers in Fig. 2b and c, especially in the presence of 10% PEG. While the HA is almost completely hydrolyzed for total concentrations below $\sim 0.3 \text{ mg mL}^{-1}$ independent of crowder concentration, the total amount of shorter oligomers decreases at higher concentrations of HA in a similar fashion for the three PEG concentrations (Fig. 2d), although the system with 10% PEG is more affected than the one with 17%. This global evolution presumably points out to the combination of (i) the inhibition by excess HA described above and (ii) non-specific interactions of the enzyme with PEG hindering its activity and/or the diminution of the enzyme/substrate diffusion coefficient in the crowded reaction media. The increase of the total viscosity was described by Han and coworkers and reviewed by Mittal and coworkers [45, 50]. The partial recovery of BTH activity at higher HA concentrations and 17% PEG may possibly occur due to an increase of the effective enzyme concentration, when the enzyme is released from the BTH-HA complex being in competition with PEG, or by the excluded volume effect [48].

Fig. 3 Neocuproine spectrophotometric assay of the hydrolysis of HA by hyaluronidase at different concentrations of HA incubated for 180 min (the trends correspond to hyperbolas supposing Michaelis-Menten kinetics) (a); the evolution of total absorbance with time at 0.3 mg mL⁻¹ HA

(b) and at 1 mg mL⁻¹ (c). Latter fits correspond to a simple exponential increase. The recovered samples were diluted 1.5 times for (b) and 4 times for (c). Other conditions: see experimental section (“Neocuproine spectrophotometric assay”)

The overall HA degradation by BTH in the absence and in the presence of PEG at 10% and 17% was evaluated in parallel with the neocuproine assay (Fig. 3a). It appears that the total number of reducing ends increases up to ~ 0.3 mg mL⁻¹ of HA with a little influence by PEG, in agreement with the concentration evolution of short oligomers evaluated by CE-UV. However, for higher HA concentration, the total amount of oligomers is much lower in the presence of PEG, which suggests the effective inhibition of the enzyme. The apparent $v_{\max}$ fitted according to the Michaelis-Menten kinetics decreases in the presence of 10% PEG (dotted lines in Fig. 3a), while the decrease is moderate at 17% PEG.

The speciation of HA oligomers with the time course

HA degradation by the BTH activity was investigated, at 37 °C, over a long incubation time at two fixed substrate concentrations of 0.3 mg mL⁻¹ and 1 mg mL⁻¹, respectively, which represents one low and one high substrate concentrations according to different reaction modes discussed above. Again, the experiments were carried out in the media without

PEG and at two concentrations of PEG (10% and 17%). The electrophoretic separation allows to plot the CPA of each oligomer vs. incubation time. Results are presented in Fig. 4 for [HA] at 0.3 mg mL⁻¹ and in Electronic Supplementary Material (ESM) Fig. S1 for [HA] at 1 mg mL⁻¹.

The speciation diagrams at 0.3 mg mL⁻¹ (Fig. 4a–c) show a rapid and successive disappearance of oligomeric species. After ~ 15 min, the mixture contains only short separated oligomers (up to ~ 20 –30 monomeric units) depending on the PEG concentration. These species reach their maximum level at some point and start to be hydrolyzed relatively rapidly. At short oligomer length, HA fragments become worst substrates for the BTH enzyme and their degradation is slower [28]. The HA degradation is additionally slowed down in solutions with PEG and this effect is more pronounced at 10% PEG compared with 17% PEG. After ~ 60 –100 min of incubation, the CE separation of all three mixtures shows only five detectable low molecular weight oligomers (Dim, Tet, Hex, Oct, and Dec). While Oct and Dec decay relatively rapidly, the Hex species accumulates and then degrades slowly into the final products Tet and, to a lesser extent, Dim. When the effect of

Fig. 4 Evolution of oligosaccharide species resulting from HA degradation ($[HA] = 0.3 \text{ mg mL}^{-1}$) at different PEG concentrations: 0% (a); 10% (b); 17% (c). Relative molar concentration C of low molecular

weight oligomers ($n = 2, 4, 6, 8, \text{ and } 10$; $C = \sum cn$) with time (d), as estimated from their individual CPA (for CE conditions, see Fig. 1). The dashed lines in the figures are guide for the eye

PEG on the evolution of Tet is followed by checking the linearity zone (Fig. 5), it can be seen that the initial slope is reduced by a factor of 5 in the presence of 10% PEG and only by a factor of 2 in the presence of 17% PEG. Moreover, the formation of Tet product proceeds at a rate which is linear with time for 200 min in the absence of PEG ($r^2 = 0.9992$). In the presence of 10% PEG, the linearity zone is larger by a factor of 1.5 (300 min, $r^2 = 0.9971$), while in the highly crowded media (17% PEG), the linearity is reduced to only 150 min. This is probably due to the high viscosity of the media, the interaction

between PEG and the HA, as well as the increase of the local enzymatic concentration [51].

Similar speciation studies have been performed at a high HA concentration (1 mg mL^{-1}) (ESM Fig. S1). The reaction mixtures were continuously followed for 7 h. The control analyses were done after 23 and 24 h after mixing. In this case, the peak distribution and the quantity of species for 17% PEG are rather close to those for 10% PEG and clearly different in comparison with the reaction without PEG. The evolution of oligomeric species ($CPA \sim \text{mass concentration mg mL}^{-1}$) with

Table 1 Influence of PEG concentrations on the inhibition of hyaluronidase as monitored by CE-UV. Reaction conditions: hyaluronidase 0.2 mg mL⁻¹; HA 0.3 mg mL⁻¹; 180 min; 37 °C. Other conditions: Fig. 1

Compound	Structure	% of Inhibition at 1 mg mL ⁻¹		
		0 % PEG	In the presence of 10 % PEG	Subtracting the effect of 10 % PEG*
EGCG (487g/mol)		9 8 %	31 % ↓ by a factor of 3	11 % ⇒ Loss of inhibition
QTT-I (818g/mol)		6 6 %	22 % ↓ by a factor of 3	2 % ⇒ Loss of inhibition
CS-A (1406g/mol)		3 7 %	80 % ↑ by a factor of 2.2	60 % ↑ by a factor of 1.6
CS-C (1406g/mol)		3 9 %	62 % ↑ by a factor of 1.5	42 % ⇒ Same inhibition

* 10% of PEG inhibits the hyaluronidase by 20%

incubation time is shown in ESM Fig. S1 for three PEG concentrations. The reactions at $[HA] = 1 \text{ mg mL}^{-1}$ show a similar degradation scheme to that of $[HA] = 0.3 \text{ mg mL}^{-1}$ although the species evolve over a much longer duration. This effect could be correlated to a lower free concentration of BTH available for the reaction [48]. Concerning the effect of PEG, the obtained speciation data are similar and in agreement with the observations made for $[HA] = 0.3 \text{ mg mL}^{-1}$, where both PEG solutions inhibit the reaction, with 10% PEG having a stronger effect. The evolution of the total molar concentrations of shorter oligosaccharides determined with CE is represented in Fig. 4d and ESM Fig. S1 d, respectively. The emergence of these species in PEG-containing solutions is clearly delayed and globally much slower with respect to uncrowded conditions.

The determination of the total amount of reducing ends with the neocuproine assay shows the expected exponential increase with time (Fig. 3b, c). For the reactions with 0.3 mg mL^{-1} , the kinetic curves at all conditions (0% PEG, 10% PEG, and 17% PEG) have similar shapes. The hydrolysis is faster in the absence of PEG and the fitted global rates are 0.028 min^{-1} , 0.022 min^{-1} , and 0.026 min^{-1} for 0, 10, and 17% PEG, respectively. Because of some uncertainty concerning the last point (ESM Fig. S1), the kinetic curves at 1 mg mL^{-1} HA were satisfactorily fitted up to 420 min to give the rates 0.0098 min^{-1} , 0.0056 min^{-1} , and 0.0060 min^{-1} for 0, 10, and 17% PEG, respectively. These reaction rates are about 3–5 times lower compared with $[HA] = 0.3 \text{ mg mL}^{-1}$. This difference is tentatively attributed to the inhibition effect at a high substrate concentration combined with the effect of crowding that slows down the release of hydrolysis products and simultaneously favors species recombination.

Influence of PEG concentrations on the inhibition of hyaluronidase

Four inhibitors of hyaluronidase were evaluated in the presence of 10% PEG in order to simulate a complex cellular/extracellular matrix. The first tested inhibitor was the EGCG since it is a well-known natural reference inhibitor of hyaluronidase ($IC_{50} = 0.03 \text{ mg mL}^{-1}$) [37]. Secondly, an original natural molecule extracted from oak wood used for wine aging [42] was also tested for the first time. Finally, we tested two original synthesized inhibitors (see Experimental section), 4- and 6-biotinylated chondroitin tetrasaccharides (CS-A and CS-C), previously revealed to be efficient inhibitors of hyaluronidase by our laboratory: $IC_{50} = 1.46$ and 2.1 mg mL^{-1} , respectively [40]. For comparison, all four inhibitors were tested at the same concentration of 1 mg mL^{-1} in the reaction mixture. The obtained results are summarized in Table 1 and show that the referenced inhibitor, EGCG, lost 69% of its inhibition effect when 10% PEG was added to the reaction media. If the effect of the presence of PEG is subtracted from

the total inhibition—which is around 20% of inhibition—the inhibition of hyaluronidase by EGCG in the presence of 10% PEG would be around 11%. In other terms, the inhibition effect of EGCG is almost insignificant in a crowded medium. The same result was observed with the purified natural compound, QTT-I. This compound has been identified as a natural sweetener in wine. However, its biological effect has not been assessed yet. In this study, this compound was identified for the first time as a relevant inhibitor of the hyaluronidase in the absence of PEG. However, it lost 60% of its effect in the presence of 10% PEG, which corresponds to a null inhibition if the effect of PEG on hyaluronidase activity is subtracted. Remarkably, inhibition of CS-A and CS-C was increased in the presence of 10% PEG by a factor of 2.2 and 1.5, respectively. This increase may be correlated to the results obtained in our previous study where CS-A had higher inhibition ($IC_{50} = 1.46 \text{ mg mL}^{-1}$) than CS-C ($IC_{50} = 2.21 \text{ mg mL}^{-1}$). Nevertheless, if we subtract the contribution of PEG, CS-A inhibition was slightly increased whereas the effect of CS-C remained constant (Table 1).

The effect of PEG 6000 on hyaluronidase inhibitors is most likely due to its interaction with the tested inhibitors. On the one hand, EGCG and QTT-1 have comparable neutral polycyclic structures that probably interact significantly with PEG and lead to the loss of their inhibition potential. On the other hand, the larger and negatively charged molecules CS-A and CS-C (1406 g mol^{-1}) have a linear scaffold probably involving weak interactions with PEG, which does not affect (or only slightly) their inhibition potential. Such linear inhibitors will bind to the BTH active sites, partially hindered by PEG or HA, more efficiently than EGCG.

Conclusions

For the first time, the activity of hyaluronidase was assessed in vitro under crowding conditions using conventional neocuproine spectrophotometry and high-performance capillary electrophoresis. The first technique allows one to determine the overall quantity of oligomeric species and requires no specific optimizations. CE on the other hand has demonstrated to be a powerful technique to follow hyaluronidase activity under different experimental conditions after appropriate optimizations. CE provided an accurate and quantitative detection of the individual products of HA degradation, which warrants a more detailed survey of the hyaluronidase activity.

The kinetic studies show that the initial fast hydrolysis of HA of relatively high molecular weight substrates is followed by slower reactions involving shorter-length substrate chains, in agreement with previous observations [52]. The CE separation of oligomers containing up to 16 monomers clearly evidences a sequential degradation of low molecular weight substrates in agreement with the fact that the stability of the

active BTH-substrate complex decreases with the substrate length [28]. The speciation at the late stage of hydrolysis is reminiscent to the observations made by other authors for the degradation of short oligomers (Dec, Oct, Hex, and Tet) as starting substrates [47, 52, 53]. Indeed, the tetramers and dimers are accumulated as the final products of the hexamer slow cleavage, since Hex acts as the shortest but the worst substrate of the BTH.

The activity of BTH depends on the PEG concentration in the reaction media. Indeed, the presence of PEG crowding clearly results in slowing down of the global kinetics compared with standard diluted conditions. This is attributed to a combination of two inhibiting contributions as supported by our recent work [9]: (i) a non-specific interaction of PEG with the BTH-substrate complex and (ii) hindrance of product release from the BTH binding sites during the substrate cleavage and pushing toward the species recombination. Consequently, the reverse reaction, i.e., transglycosylation, is favored in the presence of PEG, and even more for short-length substrates [28]. It turns out that the overall degradation rate decreases, especially for the rate-limiting cleavage of Hex. It is evident that the presence of PEG definitively influences the subtle balance between hydrolysis and transglycosylation, both catalyzed by BTH. A stronger inhibition systematically occurs for 10% PEG comparing with 17%, but it was not possible to trace back the origin of this difference from our data. In addition, at high HA concentrations, the BTH activity is reduced by the substrate inhibition, which decreases the molar fraction of the free enzyme available for the catalysis [48]. This is compatible with much slower kinetics at 1 mg mL⁻¹ of HA, where the degradation mechanism remains similar to that observed at lower HA concentrations.

More interestingly, the inhibition of hyaluronidase by natural and synthesized compounds is affected by the presence of crowders, depending on the inhibitors' structure and their ability to interact with PEG. EGCG and QTT-1, both of which are neutral and relatively small and compact molecules, lost their influence on hyaluronidase in the presence of 10% PEG. The original synthesized inhibitors, CS-A and CS-C, which are charged linear compounds were affected differently and did not lose their inhibition potential. This promotes these compounds to be used as potential *in vivo* inhibitors of hyaluronidase.

Accordingly, our results confirm the importance of designing novel assays that would include mimicking the cellular environment for the development of new therapeutic drugs or cosmetic products screening. The effect of crowded media on enzyme activity is difficult to predict in a systematical manner, but crowding should be definitively included among the key factors to be considered for the development of reliable inhibitors of hyaluronidase. With the speciation data in hand, we intend to develop, in the near future, a global kinetic

model for better understanding of the relevant molecular reaction mechanism.
