Abstract

Oxide Dispersion Strengthened (ODS) steels are candidates for nuclear applications. ODS are produced by mechanical alloying of Fe-14Cr, Y₂O₃ and TiH₂ powders and consolidation at 1100°C, resulting in finely dispersed nano-oxides. Their precipitation kinetics has been quantitatively determined by in-situ Small Angle X-ray Scattering during continuous heating up to 1100°C. Clusters, found in the as-milled state start growing at 450°C until 1100°C, while almost no coarsening was recorded during subsequent isothermal annealing. The nano-oxides resulting from these in-situ experiments were found to be representative of those in materials processed by hot isostatic pressing and hot extrusion.

Graphical abstract

Main matter

Ferritic Oxide Dispersion Strengthened (ODS) steels were developed for applications where a good resistance to harsh environment is required such as generation IV nuclear fission [1] or nuclear fusion power plants [2]. Their Fe-Cr ferritic matrix gives them a good swelling resistance under irradiation [3,4] as well as a good corrosion resistance [5,6]. Nano-precipitates of Y-Ti-O lead to high yield strength and high improvement of thermal creep resistance [7–10] as these nano-oxides act as strong pinning points for both grain boundaries and dislocations, even at high temperatures [7–9,11–13].

The ODS nanostructure is achieved by Mechanical Alloying (MA) where powders of Fe-Cr steels are milled with Y_2O_3 and TiH_2 . During MA, powders undergo severe plastic deformation, fragmentation and cold welding resulting in a dissolution of the Y_2O_3 and Ti into the matrix in optimized processing conditions [14–18]. After MA, Hot Extrusion (HE) or Hot Isostatic Pressing (HIP) at temperature around $1100^\circ C$ generates a dense material and induces the precipitation of Y-Ti-O oxides. The nano-oxides found after consolidation have been mainly reported as $Y_2Ti_2O_7$ pyrochlore or defective NaCl structure by Transmission Electron Microscopy (TEM) [19–22], Atom Probe Tomography (APT) [23,24], and Small Angle X-ray/Neutron Scattering (SAXS/SANS) [16,25]. The Y_2TiO_5 orthorhombic structure has also been reported [16,26,27]. Most of these characterizations were performed on HIPed or HEed materials, and the precipitation kinetics of the nano-oxides is still not completely understood. Thermokinetic models developed to predict the kinetics of the nano-oxide formation [28–30], lack so far quantitative data to establish their validity.

By heating Fe-9Cr ODS powders, Kim *et al.* showed a significant size change of the nano-precipitation between $600^\circ C - 4h$ and $800^\circ C - 4h$ [31]. Oono *et al.* followed a similar methodology on a Fe-15Cr ODS [32]. They detected the presence of clusters after 4h at $600^\circ C$ by SAXS and APT and a good resistance to precipitates coarsening up to 4h at $1150^\circ C$. Alinger *et al.* performed SANS on a Fe-14Cr ODS after powder annealing, HIP and HE at 850, 1000 and $1150^\circ C$ [16]. Precipitates were found in all specimens and were observed to coarsen slightly with increasing temperature. On a Fe-10Cr-11.5Al-Zr-Y ODS alloy, Massey *et al.* observed the nucleation and growth of Y-Al-O precipitates from $200^\circ C$ to $600^\circ C$ by in-situ SANS analysis [33]. He *et al.* performed in-situ isothermal holding with temperature ranging up to $1000^\circ C$ using SANS on a Fe-9Cr ODS steel [34], however the limited flux of the neutron source resulted in sparse data in terms of time resolution. The first in-situ study of precipitation kinetics in ODS steel was carried out using synchrotron SAXS by Deschamps *et al.* [35], however only until $900^\circ C$ due to technical limitations. There is to date still no comprehensive quantitative dataset available of ODS precipitation kinetics from as-milled powders up to temperatures of further processing.

In this study, we will present such data, describing the precipitation kinetics of nano-oxides in an ODS steel during in-situ heating until $1100^\circ C$, using in-situ synchrotron SAXS. The in-situ data will be validated by ex-situ heat treatments, and compared to samples processed by classical HE and HIP routes.

For this purpose, a steel powder of atomized Fe-14Cr-1W-0.3Mn-0.3Si-0.15Ni was MA at CEA Saclay with 0.3% wt of Y_2O_3 and 0.3% wt of TiH_2 powders for 10 hours under a 99.9999% Ar atmosphere. As-MA powders were Cold Pressed (CP) under 3 GPa in order to achieve cylindrical specimens, 4 mm in diameter, with a relative density around 85% without triggering the nano-precipitation. Subsequently, CP specimens were ground down to a thickness of 60 to 90 μm to achieve a suitable X-ray transmission. Then, in-situ experiments consisted in a heating ramp at $10^\circ C/min$ or $30^\circ C/min$ until $1100^\circ C$ and subsequent isothermal holding for about 1 hour under primary vacuum. These two heat treatments were designed to be close to conventional processes of HIP and HE.

During heating, CP specimens were observed in-situ by Small Angle X-ray Scattering performed on the D2AM-BM02 beamline at the European synchrotron (ESRF). The detector-to-sample distance was set to 0.4 m and SAXS patterns were acquired every 10 seconds. Measurements were carried out switching between two X-rays energies 16.829 keV and 17.009 keV just below the Y K-edge, aiming at using the

anomalous effect to extract information on precipitate chemistry. However, the evaluation of this anomalous effect is beyond the scope of this article and will be reported in a forthcoming paper. The specimen transmission was measured every minute using the scattering of a retractable kapton window.

To demonstrate the validity of the in-situ measurements, particularly of the temperature control at the X-ray beam location, several CP specimens were heated ex-situ using a different furnace under Ar atmosphere following the same thermal pathway, interrupted at given temperatures (500°C, 700°C ...). Then, the specimens were fast cooled and measured by a laboratory SAXS setup at room temperature with a detector-to-sample distance of 0.8 m and an incident X-ray energy of 17.44 keV (Mo rotating anode).

To ensure the representativity of the specimens compared to conventional processes, HE and HIP grades were also investigated. For both processes, the as-MA powder was sealed into a low carbon steel can and outgassed at temperature around 400°C for 4 to 8 hours. HIP was performed following an average heating rate of 4°C/min until 1100°C with a pressure increase up to 1.9×10^8 Pa followed by 2 hours of isothermal holding. The as-MA powders were exactly the same than those used for the in-situ experiments. For HE, the can containing the ODS powder was heated until 1100°C following a heating ramp of ~40°C/min. Then, an isothermal holding at 1100°C was applied for 40 min and the can was moved to the extrusion press. A post-treatment at 1050°C for 1h was applied to release the residual stresses. Two HE specimens were investigated, HE-1 which was processed with a similar powder than the in-situ sample and HE-2, using a slightly different milling process operated by PLANSEE.

TEM observations were performed on electro-polished specimens using a JEOL 3010 and a JEOL 2100 microscopes operating at 300kV and 200kV respectively. Electron Backscatter Diffraction (EBSD) and Transmission Kikuchi Diffraction (TKD) were performed to investigate the grain microstructure, both using a JEOL 7001-FLV microscope.

Each SAXS measurement consists in a 2D pattern, which was azimuthally integrated, corrected for background noise, and normalized by incident beam flux, specimen transmission, thickness and solid angle viewed by the detector. Intensity was reduced to absolute units thanks to a glassy carbon secondary standard. SAXS data were then fitted using the simulated pattern from a lognormal distribution of spherical precipitates with a dispersion fixed at a classical value of 20% [36].

The fitting procedure also takes into account a power-law contribution, arising from the Porod contribution of large features (precipitates, porosities ...) and from the high density of dislocations. This contribution was fitted as $A \times q^{-n}$, n being restricted between 3 and 4. A n -value close to 3 or 4 matches with a high density of dislocation or with large precipitates respectively [37]. Moreover, a constant contribution was considered, coming from the matrix solid solution and other various factors. Further details on fitting method and data treatment can be found in previous studies [35,38].

Then, a mean square fitting algorithm allowed extracting of the precipitates mean radius and their volume fraction. Converting the integrated intensity into volume fraction was made according to Eq. 1, under the assumption of specific precipitate structures and chemistry.

$$f_v \approx \frac{\int_{q=0}^{q \rightarrow +\infty} I_p(q) q^2 dq}{2\pi^2 (\rho_m(\lambda) - \rho_p(\lambda))^2} \quad \text{Eq. 1}$$

Where f_v is the volume fraction, q the scattering vector, λ the incoming wavelength of X-ray, ρ_m and ρ_p the electronic density of the matrix and the precipitates respectively and I_p the precipitates contribution fitted to the experimental data.

Experimental data are plotted in Fig. 1, with fitted model as a solid line. Fig. 1a and 1b display as a baseline the signal from a CP specimen prepared from the atomized Fe-14Cr-1W powder without addition of Y, Ti and O (grey curves). This unstrengthened steel followed the same thermal path for the 30°C/min heating rate. In all strengthened specimens, the precipitation contribution is observed to evolve consistently with temperature/time, illustrating the precipitate evolution. In parallel, the power-law exponent n evolves from values close to 3 to values close to 4, consistently between unstrengthened and ODS steels. This comforts the scenario of an initial high density of dislocations, which decreases during heating, and of the formation of coarse carbides and oxides which are known to occur in these steels [31,39–42]. The power-law contribution is greater than average on the ex-situ CP specimens heated until 500°C and 1100°C at 10°C/min (Fig. 1d). This anomaly could be due to a higher porosity on these particular CP samples, or a difference in coarse precipitation.

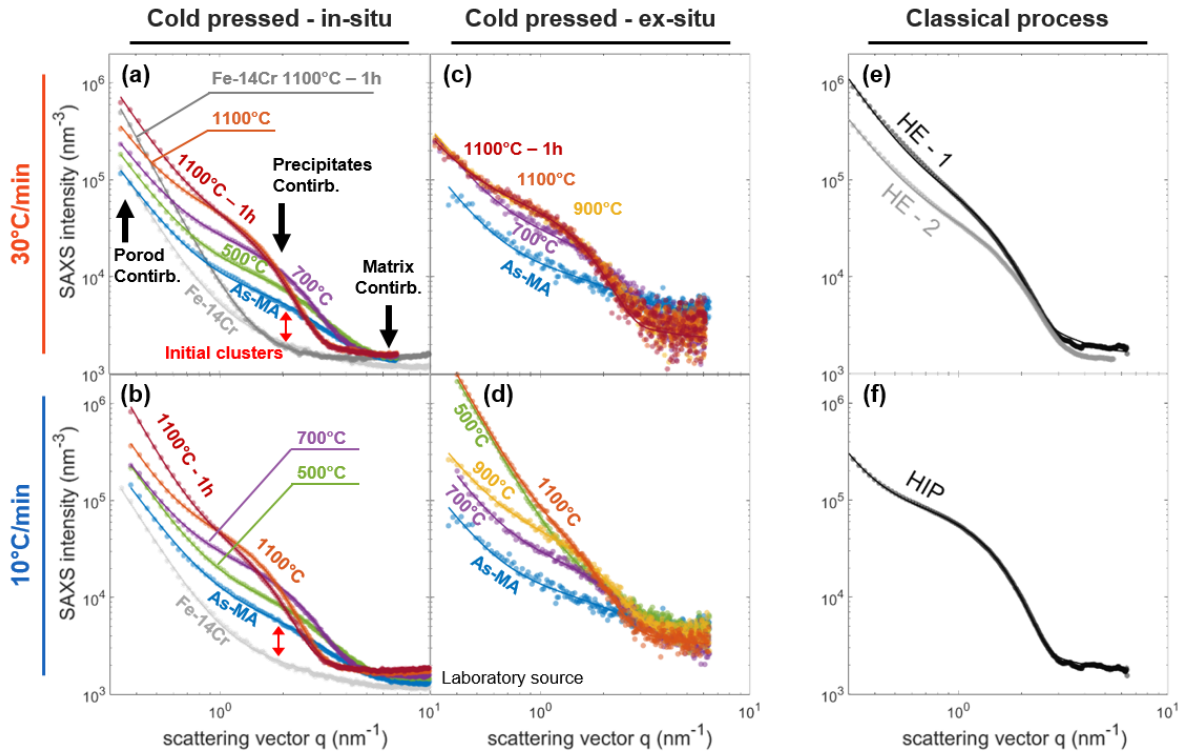

Fig. 1. Experimental SAXS data and fit (in solid line) for in-situ heating CP specimens heated at 30°C/min (a), and 10°C/min (b), for ex-situ CP specimens heated at 30°C/min (c), and 10°C/min (d), for HE specimens (e), and HIP (f).

The mean radius evolution is given in **Fig. 2**. The mean radius is represented as a function of temperature during the heating ramp and as a function of the holding time during the 1100°C isothermal. A similar

plot configuration was applied to **Fig. 3**, showing the evolution of the precipitates volume fraction f_v calculated from Eq. 1. The electronic contrast between the precipitates and the matrix has been calculated using 2 hypotheses on the nature of the nano-oxides: $Y_2Ti_2O_7$ pyrochlore and Y_2TiO_5 orthorhombic (**Tab. 1**), the two most common precipitates observed in ODS [16,19–27]. These two apparent f_v are plotted in **Fig. 3** under the assumption that their composition and structure remains constant along the heat treatment. Therefore, a mixture between both phases would result in intermediates values of the apparent f_v . For visibility purpose the f_v corresponding to the Y_2TiO_5 of as-MA specimens were not plotted. In addition, the maximum reachable volume fraction were calculated from the alloy composition, considering Y as the limiting element (displayed in dashed lines).

Tab. 1. Properties of the nano-precipitates and matrix take into account in the SAXS apparent volume fraction calculation.

Nature	Structure (space group)	Mean atomic volume ($\times 10^{-30} \text{ m}^3$)	SAXS electronic density ($\times 10^{30} \text{ m}^{-3}$)
Fe-14Cr-1W matrix	Body centered cubic (Im-3m)	11.70	2.24 (16.829 keV)
			2.24 (17.009 keV)
			2.24 (17.44 keV)
$Y_2Ti_2O_7$	Pyrochlore (Fd-3m)	11.69	1.04 (16.829 keV)
			1.02 (17.009 keV)
			1.06 (17.44 keV)
Y_2TiO_5	Orthorhombic (Pnma)	13.36	1.11 (16.829 keV)
			1.08 (17.009 keV)
			1.13 (17.44 keV)

The as-milled stage displays some degree of decomposition of the solid solution when compared to the unstrengthened CP specimen (Fig. 1a and 1b). These small clusters are assumed to come from the milling step. The characteristics of these clusters are visible in Fig. 2 and in **Fig. 3** showing a very small initial radius and an initial volume fraction that is clearly non-zero. This finding was already observed by APT analysis on as-MA powder grains [32,43]. Kim et. al [31] and Oono et al. [32] also observed these inhomogeneous as-MA microstructures by SAXS as well as Alinger et al. [16] by SANS, who compared as-MA and unstrengthened materials. He et al. did not observe inhomogeneities until 10 min annealing at 600°C was achieved [34]. However, their maximum q-value of 2 nm^{-1} could explain the impossibility to observe such small clusters. These initial clusters could arise both from fragmentation and certainly amorphization of Y_2O_3 until nanometric scale and/or formation of clusters of Y and O, possibly stabilized thanks to vacancies introduced by MA [44–47]. At this initial stage, the clusters may be at the limit of validity of our interpretation model (spherical precipitates with a uniform composition and lognormal size distribution), but the presence of these very small objects is undeniable.

Surprisingly, the precipitation kinetics was found very similar between the 10°C/min to 30°C/min heating rates (**Fig. 2a** and **2b**, see supplementary material for superimposed curves). Moreover, the ex-situ measured samples show a remarkable agreement with the in-situ sequence (**Fig. 2** and **Fig. 3**). The mean radius of precipitates starts increasing at temperatures as low as 450°C followed by a growth rate close to $1 \times 10^{-3} \text{ nm}/^\circ\text{C}$ until 1100°C. This is in agreement with previous studies that already detect precipitates after annealing at 600°C [31,32,34] and gives the onset of precipitation with an unprecedented precision. Massey et al. demonstrated a similar continuous increase of scattering between

200, 400 and 500°C related to the nucleation and growth of Y-Al-O precipitates, different in terms of chemistry but close in terms of manufacturing process [33]. Simultaneously, the apparent volume fraction increases. However, it is difficult to assess the reasons of this increment as this apparent volume fraction is correlated to the hypothesis made of constant precipitate structure and chemistry. These are very likely to evolve during the thermal treatment as the initial clusters are unlikely ordered nor stoichiometric after MA. Particularly, it is unlikely that the apparent volume fraction decrease observed around 900°C is caused by a dissolution of the precipitates, since the Y solubility in the matrix is extremely low at these temperatures [48,49]. This drop could be due to a decrease of the electronic density contrast between precipitates and matrix and thus a change in chemistry and/or structure of the precipitates.

During the subsequent isothermal treatment at 1100°C, the precipitates display outstanding size stability with a coarsening rate as low as 0.05 nm/h for the 10°C/min sample and even imperceptible for the 30°C/min specimen. Moreover, the final value of mean radius attained by the in-situ heat treated CP samples was found representative to the HEed or HIPed specimens (**Fig. 2**). Either CEA Saclay (HE-1) or PLANSEE (HE-2) milled samples display similar mean radii and apparent volume fractions, consistent with the final CP specimens (**Fig. 2a** and **Fig. 3a**). However, for an unknown reason, the HIP specimen shows a higher apparent volume fraction than the CP experiment (**Fig. 3b**), despite the use of the exact same powder and milling process for both.

Mean radii of precipitates were extracted from TEM images using Weka trainable segmentation algorithm of ImageJ software [50] (**Fig. 2**). The associated error bars correspond to the standard deviation between different analyzed areas. These measurements demonstrate a good agreement with SAXS results.

Fig. 2. Evolution of the mean radius of precipitates measured by SAXS data fitting and TEM measurements on CP specimens heated at 30°C/min with corresponding HE specimens (a), and 10°C/min with corresponding HIP specimen (b).

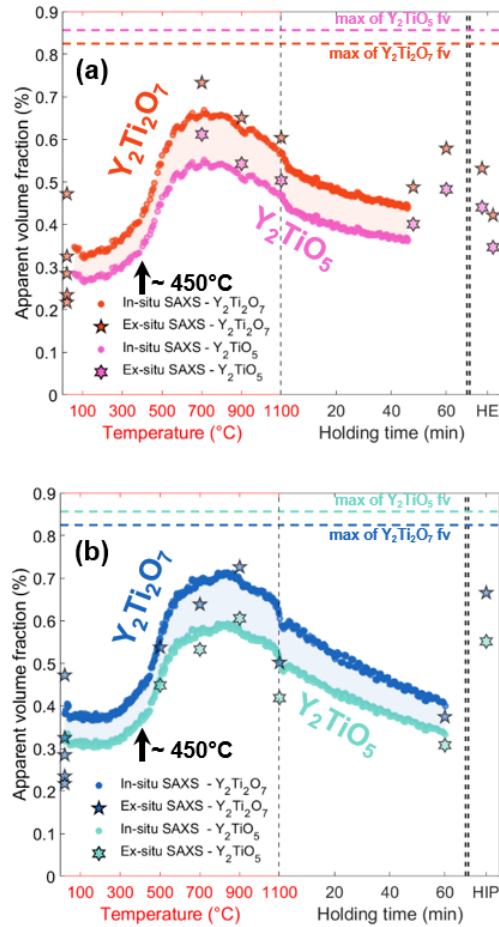

Fig. 3. Evolution of the apparent volume fraction of precipitates measured by SAXS and calculated for $Y_2Ti_2O_7$ and Y_2TiO_5 type precipitates on CP specimens heated at $30^\circ\text{C}/\text{min}$ with corresponding HE specimens (a), and $10^\circ\text{C}/\text{min}$ with corresponding HIP specimen (b).

Both CP specimens after annealing and HIPed samples display similar grain microstructure with a bimodal grain size distribution (Fig. 4a and c). The HE material showed elongated grains (Fig. 4e and e') certainly displaying a strong $\langle 110 \rangle$ texture along the extrusion direction as observed in many studies before [51,52]. Moreover, TEM micrographs show similar sizes and morphologies of the nano-oxides between both conventional processed ODS (HIP/HE) and annealed CP specimens (Fig. 4b, 4d, and 4f), in agreement with the SAXS results. Thus, the severe plastic deformation occurring during HE processing does not seem to affect the nano-precipitates size or volume fraction.

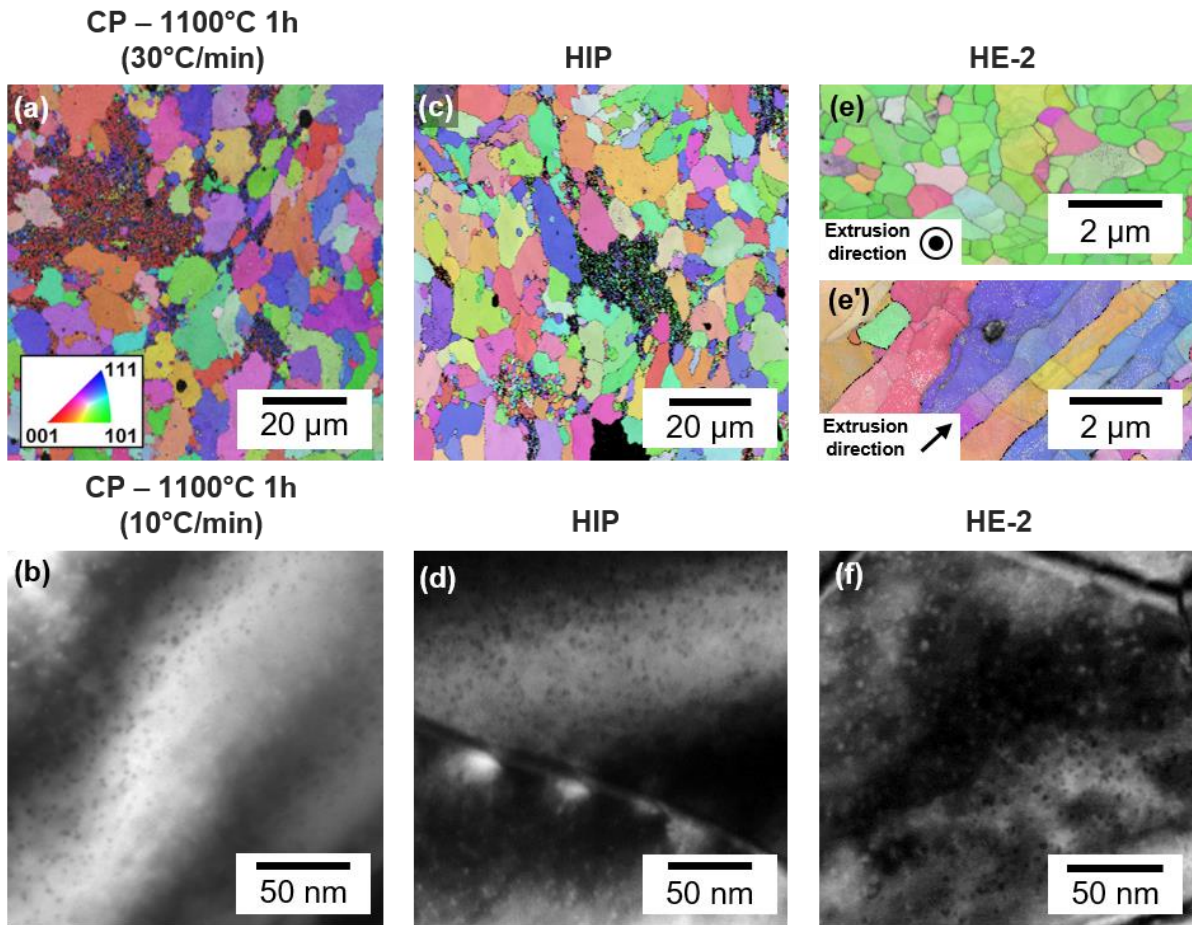

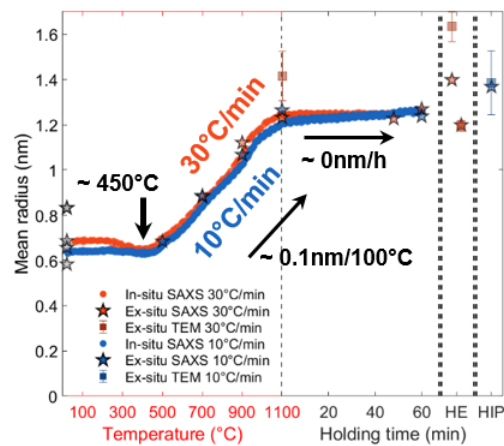

Fig. 4. Micrographs showing the grain microstructure by EBSD orientation maps on specimens and nano-oxides by TEM on specimens CP (a, b), HIP (c, d), and TKD orientation maps acquired in the plane orthogonal and parallel to the extrusion of the HE-2 specimen (e, e'), with TEM micrograph (f).

In summary, this study demonstrates the presence of clusters in the as-milled states of ODS Fe-14Cr-1W steel. Subsequently the kinetics of precipitation has been monitored, and was found independent of the heating rate applied (10°C/min and 30°C/min). The clusters growth has been shown to start at low temperature, around 450°C. The following growth rate during heating ramp was of the order of 1×10^{-3} nm/°C and outstanding stability during isothermal holding at 1100°C has been observed with a maximum recorded growth rate of 0.05 nm/h. Precipitation in CP specimens has been shown to be representative of both HE and HIP processes, which demonstrates that the deformation induced by HE does not influence the nano-oxides properties. Finally, our results suggest an evolution of the chemistry and / or structure of the precipitates around 900°C. This will require a careful analysis which is under way by combining anomalous SAXS and atom probe tomography.
