26

27 The impact of Arctic sea-ice loss on the ocean and atmosphere is investigated focusing on a gradual
28 reduction of Arctic sea-ice by 20% on annual mean, occurring within 30 years, starting from
29 present-day conditions. Two ice-constraining methods are explored to melt Arctic sea-ice in a
30 coupled climate model, while keeping present-day conditions for external forcing. The first method
31 uses a reduction of sea-ice albedo, which modifies the incoming surface shortwave radiation. The
32 second method uses a reduction of thermal conductivity, which changes the heat conduction flux
33 inside ice. The reduction of the thermal conductivity inhibits winter oceanic cooling and sea-ice
34 basal growth, thereby reduces seasonality of sea-ice thickness. For similar Arctic sea-ice area loss,
35 decreasing the albedo induces larger Arctic warming than reducing the conductivity, especially in
36 spring. Both ice-constraining methods produce similar climate impacts, but with smaller anomalies
37 when reducing the conductivity. In the Arctic, the sea-ice loss leads to an increase of the North
38 Atlantic water inflow in the Barents Sea and Eastern Arctic, while the salinity decreases and the
39 gyre intensifies in the Beaufort Sea. In the North Atlantic, the subtropical gyre shifts southward and
40 the Atlantic meridional overturning circulation weakens. A dipole of sea-level pressure anomalies
41 sets up in the cold season over Northern Siberia and the North Atlantic, which resembles the
42 negative phase of the North Atlantic Oscillation. In the tropics, the Atlantic Intertropical
43 Convergence Zone shifts southward as the South Atlantic Ocean warms up, Walker circulation
44 reorganizes and the Southeastern Pacific Ocean cools down.

45

46

47

48

49 **1. Introduction**

50 The Arctic is a region of pronounced climate change. Since the mid 20th century, the Arctic has
51 warmed more than twice as fast as the rest of the planet (e.g., Bluenden and Arndt, 2012), a
52 phenomenon referred to as Arctic Amplification. The Intergovernmental Panel on Climate Change
53 (IPCC) Special Report on the Ocean and Cryosphere in a Changing Climate (Pörtner et al., 2019)
54 concluded that over the 1979-2018 period the Arctic sea-ice extent has shrunk in all months of the
55 year with a maximum decrease in September, with a reduction of about 13 % per decade. Also, the
56 Arctic sea-ice has thinned and the area of multi-year ice has declined by about 90 %. These trends
57 are expected to increase in the future. The multi-model mean of the representative concentration
58 pathway (RCP) 8.5 scenario projected a summer ice-free Arctic in the coupled model
59 intercomparison project version 5 (CMIP5; Stocker et al., 2013) by 2060 and in the version 6
60 (CMIP6; SIMIP community, 2020) by 2050.

61 The influence of Arctic sea-ice decline on global climate remains under debate (Cohen et al., 2014),
62 in particular its influence on mid-latitudes (Overland et al., 2013). Observational studies have linked
63 Arctic sea-ice loss in late autumn to a negative North Atlantic Oscillation in winter (NAO; King et
64 al., 2016; Garcia-Serrano et al., 2015; Simon et al., 2020), but there is still discussion on the
65 robustness and pathway of this sea-ice influence. As the observational records are short, climate
66 models have been extensively used. Among atmospheric general circulation model (AGCM)
67 studies, there is no consensus on the atmospheric response to sea-ice loss. Some studies (Singayayer
68 et al., 2006; Strey et al., 2010) found no NAO-like pattern as a response to Arctic sea-ice loss, while
69 others found a positive NAO response in winter (Screen et al., 2014) or both autumn and winter
70 (Cassano et al., 2014). Besides, others studies show a negative NAO response to Arctic sea-ice
71 decline, but with different seasonality: larger in early spring (Seierstad et al., 2009; Sun et al. 2015),
72 in winter (Magnusdottir et al., 2004; Peings and Magnusdottir, 2014) or only in February (Deser et
73 al., 2010b). Among atmosphere-ocean general circulation model (AOGCM) studies, there is a
74 broader consensus on a negative NAO-like response in winter (Deser et al., 2015; Blackport and
75 Kushner, 2016; Blackport and Kushner, 2017; McCusker et al., 2017; Oudar et al., 2017; Smith et

76 al., 2017; Suo et al., 2017; Screen et al., 2018). In the ocean, observational and modelling studies
77 found a strengthened North Atlantic inflow and weaker stratification in the Barents Sea and the
78 Eastern Arctic, a phenomenon called “Atlantification”, reinforcing the sea-ice loss (Årthun et al.,
79 2012; Polyakov et al., 2017; Barton et al., 2018). However, it is still unclear how and at which rate
80 the Arctic ocean salinity, temperature and stratification will be modified (Wassmann et al., 2015;
81 Lind et al., 2018). In AOGCMs, the Arctic sea-ice decline also weakens the Atlantic Meridional
82 Overturning Circulation (AMOC; Oudar et al., 2017; Sévellec et al., 2017; Suo et al., 2017; Sun et
83 al., 2018; Wang et al., 2018; Liu et al., 2019) because of freshwater release and modified surface
84 heat fluxes in the Arctic-North Atlantic region. However, the relative importance of each process
85 remains unclear.

86 The impacts of Arctic sea-ice loss are not confined to the North Atlantic in coupled models where
87 ocean-atmosphere coupled feedbacks are accounted for. Deser et al. (2015) showed that the impact
88 of Arctic sea-ice loss then becomes global. However, the large-scale response is not unanimous.
89 Most previous studies (Deser et al., 2010b; Deser et al., 2015; Blackport and Kushner, 2016;
90 Sévellec et al., 2017; Oudar et al., 2017; Suo et al., 2017; Monerie et al., 2019; Screen et al., 2018,
91 Sun et al., 2018, Liu and Fedorov, 2019; England et al., 2020; Sun et al., 2020) found a tropical
92 warming with the largest warming in the Central Pacific, similar to the greenhouse gas-driven
93 warming. This warming called "mini-global warming" in Deser et al. (2015), is associated with an
94 intensified Aleutian Low in winter. However, the fast transient response to sea-ice loss was found to
95 be less robust when the ocean circulation is not fully adjusted, typically after one to five decades
96 following a sea-ice perturbation. Blackport and Screen, 2019 found no change in the Aleutian Low
97 with 5-years-long simulations. In Wang et al. (2018), the Equatorial Pacific and the Southern Ocean
98 are hardly modified in the first decades of their AOGCM simulation or when using a slab-ocean
99 instead of a full ocean model. Cvijanovic et al. (2017) rather found a cooling of the Southeastern
100 Pacific, with their climate model simulations based on both slab-ocean and full-ocean
101 configurations. Blackport and Kushner (2016), as well as Liu and Fedorov (2019), also found
102 different oceanic and atmospheric responses in the early (first decades) and late period (after one

103 century) of their simulations, while Sun et al. (2018) found generally similar responses. The reason
104 for the discrepancy in the transient Pacific response is still under debate.

105

106 Some of these studies used a relatively large sea-ice perturbation yielding an ice-free Arctic during
107 two to four months (Deser et al., 2015; Blackport et al., 2017; Oudar et al., 2017; Suo et al. 2017;
108 Sun et al., 2020). However, there is also a need to estimate the impact of smaller Arctic sea-ice loss,
109 for which the Arctic Ocean in September is not ice-free in September, as in (Blackport et al., 2016;
110 Blackport et al., 2017; Cvijanovic et al., 2017; Blackport and Screen, 2019). As the climate of the
111 next decades is an important threshold for a wide range of climate impacts (Masson-Delmotte et al.,
112 2018), we investigate next a moderate Arctic sea-ice loss, corresponding to a loss of 20% on annual
113 mean and 50% reduction in September. As we will detail later, this corresponds to a reduction
114 expected to occur in approximately 2040.

115 Another open question concerns abrupt versus gradual sea-ice reduction. One can argue that the
116 transient climate response to an abrupt Arctic sea-ice retreat occurring within a few years would
117 change if the climate system had more time to adjust. As in Sun et al. (2018), we will impose a
118 gradual sea-ice loss, comparable to that found in scenario simulations.

119 Many different methods have been used to constrain sea-ice in AOGCMs: nudging (McCusker et al.
120 2017; Smith et al., 2017; Suo et al., 2017), flux adjustment (Oudar et al. 2017; Monerie et al.,
121 2019), ghost forcing/ice-nudging (Deser et al., 2015; Deser et al., 2016; Tomas et al., 2016; Sun et
122 al., 2020), sea-ice/snow albedos or emissivity modifications (Deser et al., 2015; Blackport et al.,
123 2016; Blackport et al., 2017; Sévellec et al., 2017; Blackport and Screen, 2019; Liu and Fedorov,
124 2019), Arctic Ocean albedo modification (Cvijanovic et al., 2015) or changing sea-ice physics
125 parameters with large uncertainties (Cvijanovic et al., 2017). However, sea-ice and snow thermal
126 conductivity is also a key parameter for melting and growth, and we evaluate next the ability of
127 thermal conductivity modification to constrain sea-ice. Also, the sensitivity of the climate response
128 to the methodology remains poorly evaluated, as most previous studies use a single model and only

129 use one method. Recently Sun et al. (2020) compared the albedo method with ice-flux nudging and
130 found an identical equilibrium global climate response. Blackport and Screen (2019) impose two
131 different albedos parameters (albedo of cold deep snow on top of sea-ice or albedo of snow-free ice)
132 which leads to different seasonal cycles of Arctic sea-ice extent. We will similarly investigate two
133 different methods but focusing on the fast climate response. We show that both methods induce
134 qualitatively similar local and remote transient climate responses, but with different magnitude of
135 Arctic warming. The remote responses to sea-ice reduction simulate in both cases a relative cooling
136 of the Southeastern Pacific Ocean.

137 In section 2, the methodology and experimental protocol are detailed. Two ice-constraining methods
138 are presented, and their similarities and differences are discussed. The Arctic and North Atlantic
139 responses to the Arctic sea-ice retreat are discussed in section 3, while section 4 focuses on global
140 changes. Conclusion and discussion follow in section 5.

141

142 **2. Methodology**

143 2.1. Model description

144 We perform simulations with the coupled atmosphere-ocean general circulation model IPSL-
145 CM5A2 (called here CM5A2; Sepulchre et al., 2019), a modified version of IPSL-CM5A-LR
146 (called here CM5A; Dufresne et al., 2013) which was used for CMIP5. CM5A2 uses the same
147 resolution and physical package as CM5A, but it includes an optimized hybrid parallelization to
148 obtain better computing performances, and a modified tuning to reduce the cold bias of CM5A in
149 global surface air temperature.

150 The atmospheric component is the LMDZ5A model (Hourdin et al., 2012), with a resolution of
151 $\sim 3.7^\circ$ in longitude and $\sim 1.9^\circ$ in latitude and 39 vertical levels up to 4 Pa. The land surface module is
152 ORCHIDEE (Krinner et al., 2005). The ocean and sea-ice are simulated by the NEMOv3.6 model
153 (Nucleus for European Modelling of the Ocean; Madec et. al, 2008), using the ORCA2 grid with
154 182×149 cells, corresponding to a nominal resolution of 2° , and 31 levels. The ocean biochemistry

155 is modelled by PISCES (Aumont and Bopp, 2006). Sea-ice dynamics and thermodynamics are
156 represented by the LIM2 model (Fichefet and Maqueda, 1997; Fichefet and Maqueda, 1999), a
157 single ice-category model with three layers (one for snow and two for sea-ice) for heat storage and
158 vertical heat conduction.

159 As shown in Sepulchre et al. (2019), CM5A2 is realistic in many aspects but, as in many low-
160 resolution coupled models, the Gulf Stream and the North Atlantic current are too zonal, generating
161 a cold bias in the North Atlantic sea-surface temperature (SST) of about -2°C and up to -5°C . The
162 AMOC is underestimated with a mean value of 12 ± 1.1 Sv (from 30°S to 60°N) in pre-industrial
163 conditions, compared to observational estimates around 19 Sv (Cunningham et al., 2007). This
164 weak AMOC has been linked to a lack of convection in the Labrador Sea, which is covered by sea-
165 ice in winter. The main deep-water formation sites are instead located in the Greenland Sea and
166 south of Iceland.

167 The rainfall in CM5A2 is largely similar to CM5A (Sepulchre et al. 2019). In both versions, there is
168 an overestimation of rainfall in the Southern Tropics, leading to the “double ITCZ” (Intertropical
169 Convergence Zone), and an underestimation in the mid-latitudes (20°N - 40°N).

170 In the version CM5A, September (minimum) and March (maximum) Arctic sea-ice area and
171 thickness are overestimated, albeit this remains within the range of CMIP5 models (Maslowski et
172 al., 2012; Stroeve et al., 2012; Kirchmeier et al., 2017). In the updated version CM5A2, sea-ice
173 extent has been improved in the North Atlantic sector. During the 1979-2005 period of a historical
174 run, the September mean Arctic sea-ice extent is about $5.8 \cdot 10^6$ km² (Fig. 1) and the annual
175 thickness is 2.5 m (not shown). The sea-ice extent is calculated as the total area of all grid cells with
176 at least 15% sea-ice concentration. This compares well with the respective observed value for the
177 same period: $5.5 \cdot 10^6$ km² (Fig. 1; Cavalieri et al., 1996) and about 2 m (Schweiger et al., 2011).

178 2.2 Experimental protocol

179 For reference, we first run a control ensemble of 10 members with CM5A2 for 30 years, called
180 CTRL. The greenhouse gases, aerosols, ozone and land-use are kept constant at the level of the year

181 2000. Ten initial atmospheric conditions are chosen randomly from a stabilized present-day control
182 run starting from a 500-yr spin-up simulation in pre-industrial conditions. Oceanic initial conditions
183 are identical and correspond to year 90 of this control run. In a 2500-years pre-industrial control of
184 the CM5A model, the indices of Pacific Decadal Oscillation (PDO), Atlantic Multidecadal
185 Oscillation (AMO) and AMOC have autocorrelation with e-folding time smaller than 10-yr (Fig.
186 S1). Therefore, we speculate that oceanic initial conditions would not affect the 10-30 year response
187 investigated here. Hereafter, we discard the first 10 years unless stated otherwise.

188

189 Figure 1 displays the observed sea-ice extent calculated from the monthly sea-ice concentration
190 (SIC) based on passive microwave measurements with a 25-km resolution from January 1979 to
191 February 2017 from *National Snow & Ice Data Center* (NSIDC; Cavalieri et al., 1996). The
192 missing values of December 1987 and January 1988 are set to November 1987. It shows that over
193 the last 40 years, the September sea-ice extent has reduced by about 50%. The CTRL simulation
194 and the existing historical experiments both show similar mean September sea-ice extent, with
195 values corresponding to that occurring in the 1980-2005 period. As no scenario runs were available
196 with the CM5A2 version, we use the ones done with CM5A for CMIP5. To meet a 50 % September
197 reduction, we use as a target the sea-ice extent simulated in the ensemble mean of the four CM5A
198 RCP8.5 members averaged over the period 2035-2055, called TARGET. As CM5A shows a large
199 cold bias in the Arctic, the sea-ice target is only slightly larger to the reduction occurred in the last
200 40 years.

201 Two reduced Arctic sea-ice ensembles are then constructed by modifying Arctic sea-ice properties,
202 while the Southern Hemisphere sea-ice remains unconstrained. To induce sea-ice melt while
203 ensuring energy and water conservation, we either modify the sea-ice and snow above the sea-ice
204 (the continental snow properties are unconstrained) albedos or their thermal conductivity. Reducing
205 the ice and snow albedos increases sea-ice melt in spring and summer, while reducing the thermal
206 conductivity mainly reduces the sea-ice growth in winter. Indeed, when thermal conductivity is
207 reduced, the sea-ice and snow more effectively insulate the ocean from the atmosphere, so the ocean

208 (which is at the freezing point) loses less heat in winter and sea-ice basal growth reduces.

209 To determine the sea-ice and snow albedos needed to reproduce the targeted Arctic sea-ice loss
210 without changing the external forcing, we first use linear regressions, as described in Deser et al.
211 (2015). Starting from the same initial conditions than the CTRL, we run eight 30-year simulations
212 with sea-ice and snow albedo reductions ranging from 0% to 70%. After excluding the first 10
213 years, linear regressions between August-September-October (ASO) Arctic sea-ice area (SIA) and
214 albedo reduction (blue dots in Fig. 2) provide a rough first estimate of the albedo reduction needed
215 to reproduce the ASO Arctic SIA value of TARGET ($\sim 3.5 \cdot 10^6 \text{ km}^2$; Fig. 2 top-left). We then repeat
216 simulations with albedos closer to this initial estimate. To reduce the uncertainty associated with
217 internal climate variability, we use 5-member ensembles (green squares in Fig. 2), then 10-member
218 ensembles (yellow stars in Fig. 2) with albedo values close to the first estimated value. A reduction
219 of -22.6% for the albedo of Arctic sea-ice and snow best reproduces the targeted SIA. The same
220 process is followed for the reduced thermal conductivity (Fig. 2, top-right), and a reduction of 33%
221 is then needed from the thermal conductivity of Arctic sea-ice and snow.

222 In the following, we will therefore focus on two experiments based on the previous results. The first
223 ensemble is identical to CTRL except for the Arctic sea-ice and snow albedos reduced by 22.6%
224 and is called ALB. The second one is identical to CTRL, but with Arctic sea-ice and snow thermal
225 conductivity reduced by 33% is called THCD. Both ensembles consist of 10 members of 30-yr. The
226 first 10-yr is discarded. In the following, the impact of the Arctic sea-ice reduction is assessed by
227 comparing the ensemble-means between ALB (or THCD) and CTRL. Statistical significance is
228 estimated using Student *t*-tests for the difference of means, assuming all members are independent.

229 Lastly, we note that the sensitivity of winter January-February-March (JFM) SIA to albedo and
230 thermal conductivity is different (Fig. 2, bottom). As the albedo modification is acting mostly in
231 summer, a larger albedo reduction of about -45% is needed to reproduce the winter sea-ice area.
232 Interestingly, a reduction of thermal conductivity of about -30% is needed to simulate the JFM sea-
233 ice area, a value similar to that found when using ASO as a target (-33%), suggesting that the
234 seasonal cycle of sea-ice loss is best reproduced with the thermal conductivity method.

235 2.3 Evaluation of ice-constraining methods

236 The time evolution of the annual Arctic sea-ice area in ALB, THCD, TARGET and CTRL are
237 displayed in Fig. 3 (left). In the CTRL simulations, there is a weak drift with increasing Arctic sea-
238 ice extension, but it remains small compared to internal variability. The annual sea-ice areas of ALB
239 and THCD are declining gradually at a rate comparable to that of the TARGET simulation. The
240 results are similar when focusing on summer or winter (Fig. S2). This contrasts with previous
241 studies that found an abrupt sea-ice decline after sea-ice albedo modification, as in Blackport and
242 Kushner (2016) or Liu and Fedorov (2019). In ALB and THCD, the decline is gradual because the
243 perturbation is small. Indeed, reducing the albedo with a stronger value (70%) simulates an abrupt
244 decline, where the September sea-ice disappears within 5 years (Fig. S3).

245
246 Figure 3 (right) compares the seasonal cycles of the Arctic SIA for the different ensembles. The
247 values for both ALB and THCD remain close to that of TARGET for all months. When
248 investigating the differences with TARGET, only May and June in THCD are different from
249 TARGET at the 90% confidence level. We also note that the sea-ice loss is slightly underestimated
250 in February-March for ALB (and THCD), which is consistent with the smaller sensitivity of the
251 JFM SIA illustrated in Fig. 2. The annual (September) sea-ice extent is $9.8 \cdot 10^6 \text{ km}^2$ ($5.4 \cdot 10^6 \text{ km}^2$) in
252 CTRL and $7.5 \cdot 10^6 \text{ km}^2$ ($2.5 \cdot 10^6 \text{ km}^2$) in the two reduced-ice ensembles which correspond to a 23%
253 (53%) reduction. Also, the sea-ice loss equal to $0.9 \cdot 10^6 \text{ km}^2$ ($\sim 7 \%$) during December-January-
254 February (DJF). Figure 4 compares the spatial patterns of the reduction of winter (DJF) and summer
255 (JJA, from June to August) Arctic sea-ice concentration (SIC) in TARGET, ALB, and THCD. The
256 spatial distributions of the sea-ice retreat are relatively similar, especially between ALB and THCD
257 in winter (and spring; not shown): sea-ice melts mostly in the Barents, Labrador and Chukchi Seas.
258 Compared to TARGET, more ice melts in the Barents Sea in ALB and THCD, and less in the
259 Labrador Sea. In summer, the Arctic sea-ice melts almost everywhere with a minimum around the
260 Queen Elizabeth Islands, with only subtle differences between the ensembles.

261 The similar seasonal sea-ice areas in the two reduced-ice ensembles hide larger differences in sea-ice

262 thickness (Fig. 5, left). While ALB weakly underestimates the ice thickness compared to TARGET,
263 THCD has a significantly reduced seasonality. During winter and spring, THCD has thinner ice than
264 ALB or TARGET, while in summer it has slightly more. ALB strongly melts the surface sea-ice in
265 summer when the incoming shortwave surface radiation is largest, and THCD decreases the basal
266 sea-ice growth in winter (as less ocean heat is transferred to sea-ice). In summer, changing thermal
267 conductivity has limited consequences. Indeed, the heat flux in the sea-ice is small, as the sea-ice is
268 isothermal. In both cases, the sea-ice reduction persists and reemerges in the next season, owing to
269 coupled interactions among sea-ice thickness, sea-ice concentration and ocean temperature
270 (Blanchard-Wrigglesworth et al., 2011a). For both ALB and THCD, the greatest thinning occurs
271 where sea-ice is thickest (Central Arctic; not shown), following the growth-thickness feedback
272 described in Bitz et al. (2004). In ALB and THCD, a thinner snow layer above ice is simulated
273 throughout the year when compared to CTRL (Fig. 5, right). This is explained by a larger snow
274 melting rate, as the snow-to-ice conversion is similar to CTRL (not shown). In ALB, the Arctic snow
275 thickness resembles that of TARGET, except in spring when more incoming solar radiation rapidly
276 melts the snow. THCD underestimates snow thickness throughout the year, possibly because, when
277 the thermal conductivity is reduced, more heat is available to melt the snow.

278 To illustrate how the atmosphere/ocean exchanges are modified, Fig. 6 presents the total surface
279 heat flux (short-wave, long-wave, sensible and latent fluxes; positive downward) over the Arctic. In
280 the Central and Western Arctic, all three ensembles show anomalous downward heat flux into the
281 ocean, but with different amplitudes: ALB overestimates while THCD underestimates the heat flux
282 compared to TARGET (see also Fig. S4, top-left). This is mostly explained by the differences in
283 surface albedo resulting in different short-wave absorption. Note that the surface albedo in THCD
284 also decreases over sea-ice (much less than in ALB; not shown) due to the reduction of sea-ice and
285 snow thicknesses. Most total surface heat flux differences between ALB and THCD are found off
286 Queen Elisabeth Islands (Fig. 4, bottom). This coincides with the location of multiyear ice, where
287 summer sea-ice albedo is important. As the sea-ice retreats in the Barents and Chukchi Seas, the
288 winter oceanic heat loss strengthens near the sea-ice edges (Fig. 6, top), mostly due to sensible and

289 latent heat fluxes (not shown). Over the sea-ice edges, the ALB and THCD ensembles exhibit
290 similar heat flux changes as they have similar sea-ice losses.

291

292 The area-weighted surface heat flux without short-wave (i.e. turbulent and long-wave fluxes; Fig. 6,
293 bottom-left) and near-surface air temperature (Fig. 6, bottom-right), averaged north of 70°N display
294 negative (upward) anomalous heat flux and warmer temperatures for TARGET, ALB and THCD
295 throughout the year. The annual-mean warming is significantly more pronounced in ALB (1.63°C
296 north of 70°N) than in THCD (1.16°C north of 70°N; Fig S4, top-right). The radiative budget at the
297 top of the atmosphere (TOA) shows that the incoming shortwave radiation flux north of 70°N is
298 doubled in ALB when compared to THCD (not shown). Consistently, the net downwelling
299 shortwave radiative fluxes increase at the surface, so that the total downward heat flux in the
300 Canadian Archipelago in ALB is larger than in THCD (Fig. S4, top-left).

301 The Arctic warming is seasonally dependent. Even though the sea-ice cover shows its largest
302 reduction in summer, the warming over the polar cap in TARGET is maximum in autumn. This
303 lagged seasonal response, which is reproduced in ALB and THCD, is caused by the upward
304 turbulent fluxes over the newly opened water, as found previously (Serreze et al., 2007; Screen et
305 al., 2010; Deser et al. 2010b; Screen et al., 2013; Blackport and Kushner, 2016; Yoshimori et al.,
306 2018; England et al., 2018). In spring, ALB produces another warm peak, which is significantly
307 distinct from TARGET. April sea-ice concentration is very similar among ALB, THCD and
308 TARGET (not shown). The warming mainly occurs near Queen Elisabeth Islands where multiyear
309 sea-ice is located (not shown), which is likely related to the albedo reduction. The THCD ensemble
310 is colder in winter, as the reduced conductivity leads to a decreased heat conduction through the ice.
311 As a consequence, ALB is warmer than THCD, which lead to larger outgoing longwave radiation.

312 **3. Arctic and North Atlantic responses**

313 **3.1. Winter atmospheric changes**

314 Atmospheric changes occurring over the North Atlantic are shown for winter, one-to-three months

315 after the maximum heat flux anomalies. Figure 7 (top) displays the DJF sea level pressure (SLP)
316 changes in ALB and THCD. In ALB, there are broad anticyclonic anomalies over Northern
317 Siberia/Eastern Arctic and Greenland, and a low-pressure anomaly over the North Atlantic. This
318 pattern projects on the negative phase of the NAO. We also see an anticyclonic anomaly in the
319 Northern Pacific, near the west coast of North America, which is discussed in section 4. In THCD, a
320 similar pattern is simulated, but with much weaker amplitude, so that the anomalies are not
321 significant except off west America and above Greenland. As sea-ice loss produces enhanced
322 warming in the lower troposphere (Deser et al., 2010b; Cattiaux and Cassou, 2013), we also show
323 the geopotential height at 500 hPa (Z500; Fig. 7, bottom) to illustrate the mid-tropospheric changes.
324 A broad anticyclonic anomaly appears over the North Pole, consistent with low-tropospheric
325 warming in both ALB and THCD. The negative Z500 anomaly over the North Atlantic is only
326 slightly significant in ALB, while the positive anomaly is significant off the northwestern coast of
327 North America in ALB and THCD. An investigation of the difference between ALB and THCD in
328 winter further indicates a significant barotropic anticyclone in North Siberia (Fig. S4, bottom-
329 middle), which is consistent with the anomalous downward heat flux in autumn in this region (Fig.
330 S4, top-middle). A significant depression over Eurasia is also found (Fig. S4, bottom-middle). The
331 negative NAO-like pattern is significantly stronger in ALB compared to THCD (Fig. S4, bottom-
332 left) due to the stronger Arctic warming which enhances the pole-to-equator gradient temperature.
333 At 50-hPa, in the lower stratosphere, ALB shows a weaker polar vortex than THCD (Fig. S4,
334 bottom-right). Weak polar vortex anomalies classically propagate downward and are followed by
335 negative Arctic Oscillation (AO) events in winter (Hartmann et al., 2000; Baldwin and Dunkerton,
336 1999; Baldwin et al. 2003; Kidston et al., 2015). Therefore, it is likely that the stratospheric changes
337 also contribute to the stronger negative NAO-like anomalies in ALB when compared to THCD.
338 Nevertheless, such influence on the NAO may be larger in early spring, as found by Sun et al.,
339 (2015).

340

341 Figure 8 displays the DJF zonal-mean temperature and winds over the North Atlantic sector (80°W-

342 20°E). A clear temperature increase in lower to mid-troposphere is simulated above the Arctic
343 (60°N-90°N) as heat is released from the ocean. ALB undergoes a higher and larger Arctic
344 warming, reaching about 400-hPa compared to 600-hPa for THCD. Significant warming in the
345 troposphere is also seen between 20°N-40°N up to 200-hPa in both simulations. Weak warming is
346 found in the free tropical troposphere, resembling what would produce a mini-global warming. The
347 lower stratosphere north of 60°N is only modified in THCD, with a significant cooling. Consistent
348 with the weaker meridional temperature gradient, the zonal wind weakens north of 55°N from the
349 surface up to 100-hPa. The North Atlantic subtropical jet core is amplified around 40°N, 200-hPa.
350 However, the winds are weaker in the equatorward flank of the jet (30°N to 0°N). For both
351 ensembles, westerlies at 850-hPa are shifted south in the North Atlantic sector, as the meridional
352 temperature gradient weakens north of 50°N. The global zonal-mean (not only Atlantic) winds also
353 show an amplified subtropical jet, but with a small northward shift (not shown). In section 4, we see
354 that this difference is consistent with the anomalies simulated over the Pacific Ocean.

355 3.2 Oceanic response

356 In the ocean, changes induced by melting sea-ice are less seasonal and therefore depicted here as
357 annual-mean changes. Figure 9 presents the ocean temperature changes averaged over the upper
358 300 m. The Arctic warms near the summer sea-ice edges, as new open waters have a smaller surface
359 albedo and allow more incoming solar radiation. A small cooling is simulated in the Barents and
360 Greenland Seas, where the winter oceanic cooling of the ocean is amplified as sea-ice retreats (Fig.
361 4, top), which is detailed below.

362 Figure 10 displays oceanic properties for ALB only, as THCD results are similar, albeit with smaller
363 magnitude (Fig. S5). In the Central Arctic, salinity decreases (Fig. 10, left) and the Beaufort gyre
364 intensifies (Fig. 10, middle). The cause of these two related features might be the decreased
365 freshwater export toward the North Atlantic, especially through ice transport at Fram Strait, as
366 shown by Zhang et al. (2016). On the contrary, a positive salt anomaly is seen around the Eastern
367 Arctic (Barents, Kara, Laptev, East Siberian, Chukchi Seas), possibly caused by a larger inflow of

368 North Atlantic water into the Arctic. In the Barents Sea, the 0-300 m temperature decreases slightly,
369 (Fig. 9), but the top 100 m warms. As the salinity increases (Fig 10, left), the overall density
370 stratification is reduced, which can lead to increased mixing and a release of the Arctic subsurface
371 heat, consistently with the cooling of the 0-300m layer. These changes are due mostly to anomalous
372 horizontal advection rather than to surface fluxes (not shown). The barotropic stream function also
373 shows a negative anomaly north of the Barents Sea (Fig. 10, middle), consistent with a northward
374 extension of the Norwegian current bringing more salt up to the north of Barents Sea. All these
375 changes are consistent with the so-called “Atlantification” found in observations (Årthun et al.,
376 2012; Polyakov et al., 2017; Lind et al. 2018). It suggests that such a process is linked to the Arctic
377 sea-ice loss.

378

379 In Central North Atlantic, a cold and fresh anomaly is simulated along the North Atlantic current
380 (around 45°N) while warm and salty anomalies are found in the subpolar gyre (see Figs. 9 and 10).
381 These changes are consistent with the southward shift of the surface westerlies found previously.
382 This shift of the westerlies can impact the ocean through the changes of the wind speed and its
383 impacts on turbulent heat fluxes (Deser et al., 2010a; Suo et al. 2017) and by forcing an “inter-gyre
384 gyre” (Marshall et al., 2001) through a shift of the wind stress curl and Ekman pumping (Fig. 10,
385 middle). Indeed, we found that an anomalous gyre is found between Newfoundland and the British
386 Isles (Fig. 10, center), which cools and decreases the salinity in the southern subpolar gyre by
387 anomalous advection.

388 For both reduced sea-ice ensembles, the seawater density is slightly reduced over the 0-300 m layer
389 in the north branch of the subpolar gyre. However, while the surface reduction is due to warming,
390 deeper density changes are due to a fresh anomaly found in the Greenland Sea, downstream of the
391 outflow of Arctic water from Fram Strait. The mixed layer depth is shallower in the Greenland Sea
392 and South of Iceland, at the location of the main deep water formation site in this model (see section
393 2.1.2). This is consistent with a weakening of the AMOC (see Fig. 11 and S6) that is maximum near
394 55°N. The AMOC at 55°N, computed by the maximum Atlantic meridional stream function

395 between 500m and 2500 m, indeed exhibits a steady slowdown with a mean weakening of about 0.8
396 Sv in ALB.

397

398 **4. Global-scale response**

399 The sea surface temperature (SST) anomalies induced by sea-ice loss in ALB (Fig. 12, left) indicate
400 significant warming both in the South Tropical Atlantic (0°S-20°S) and in the subtropical North
401 Atlantic (20°N-40°N). The SST changes in the subtropical southeast Pacific are similar but more
402 significant than those in Wang et al. (2018) who analyzed the impact of Arctic sea-ice loss in the
403 first decades using the ghost forcing method. The Atlantic pattern is consistent with a decrease of
404 the AMOC (Figs. 11 and S6), which brings less heat from the Southern Hemisphere to the North
405 Atlantic (Latif et al., 2006; Mignot et al., 2007; Keenlyside et al., 2008; Kageyama et al., 2009).
406 Besides, the decrease of low-cloud cover in the Southern Atlantic amplifies the warming (not
407 shown). The North Pacific presents broad warming extending to the western American coasts, with
408 a maximum north of the Kuroshio Extension. In the South Pacific, the SST pattern resembles the
409 South Pacific Meridional mode (Zhang et al., 2014), with cooling from 10 to 30°S in the Central-
410 East Pacific and warming from 20°S to 40°S in the Central-West Pacific. A cooling band is also
411 simulated at 60°S. The THCD ensemble (Fig. 12, right) shows similar SST anomalies, except for a
412 warming in the Gulf of Mexico and South Atlantic between 40°S and 50°S.

413

414 In ALB and THCD, the Z500 changes (Figs. 13 and S7, top-left) indicate a weakening of the
415 Aleutian Low, anticyclonic anomalies centred over the South Pacific and a larger Amundsen Low.
416 To illustrate the changes in the large-scale tropical atmospheric circulation, the 200-hPa velocity
417 potential was calculated (Figs. 13 and S7, top-right). This shows the regions of large-scale ascents
418 for negative velocity potential and descents for positive values, smoothing the smaller scales
419 apparent in the vertical velocity. In CTRL, ascents are simulated over the Maritime continent and
420 the Indo-Pacific warm pool (Figs. 13 and S7, top-right, contours) and descents occur from Eastern

421 Pacific to Africa. With reduced sea-ice extent, the Walker cell is shifted westward with more ascent
422 from the Indian Ocean to the Gulf of Guinea and more descent in the Central and Eastern Pacific
423 Ocean. Even though there is no significant SST cooling in the equatorial Pacific, ALB shows a
424 small equatorial east Pacific cooling with an enhanced zonal SST gradient across the equatorial
425 Pacific. The associated atmospheric circulation anomalies, therefore, resemble those usually
426 associated with La Niña (e.g. Sterl et al. 2007) or the cold Interdecadal Pacific Oscillation phase
427 (Henley et al., 2015; Gastineau et al., 2019).

428

429 Previous work argued that, as Arctic sea-ice melts, the TOA incoming shortwave radiation into the
430 Arctic increases and the inter-hemispheric northward energy transport should decrease when the
431 climate is at equilibrium. This leads to an anomalous Hadley cell with northward cross-equatorial
432 surface winds (Kang et al. 2008; Cvijanovic and Chang, 2013; Yoshimori et al., 2018; Wang et al.
433 2018), shifting the ITCZ northward. However, we found in ALB and THCD that the atmospheric
434 meridional energy transport increases in both simulations from 40°S to 65°N (not shown), while
435 south of 65°N the oceanic meridional energy transport decreases, as the AMOC decreases (Figs. 11
436 and S6). This leads to southward cross-equatorial surface winds in the equatorial Atlantic. A
437 southward shift of the ITCZ is simulated in the Atlantic Ocean, as well as in the south Pacific
438 convergence zone. Nevertheless, we also found intensified South Pacific trades winds (Figs. 13 and
439 S7, bottom-left) and anomalous northward cross-equatorial winds are simulated in the Central and
440 Eastern Pacific, as found by Wang et al. (2018) in the first decades of their simulations. This results
441 in Hadley circulation changes that are small and insignificant (Fig. S8). We conclude that the
442 atmospheric northward energy transport changes are complex, as the ocean is not in equilibrium.

443 We also note an increase of precipitation in Brazil and Northeast Australia and drier conditions in
444 much of North America in boreal winter. The precipitation changes are consistent with the cross-
445 equatorial wind changes and the Walker circulation anomalies, with a significant southward
446 (northward) ITCZ shift in the Atlantic (Pacific) Ocean (Figs. 13 and S7, bottom-right). Besides, the
447 SST in the Pacific tends to project on the negative phase of the IPO, even though not significant, is

448 also consistent with the increase of rain in Brazil (Villamayor et al., 2018). The decrease of
449 precipitation over California is also seen by Cvijanovic et al. (2017) and explained by large-scale
450 atmospheric reorganization due to Arctic sea-ice loss. Lastly, the annual precipitation response also
451 shows a southward shift of the South Pacific Convergence Zone.

452

453 **5. Conclusion and Discussion**

454 We investigate the influence of Arctic sea-ice loss on both local and global climate using the IPSL-
455 CM5A2 model. We focus on the fast transient responses, occurring within 20 years following 10
456 years of adjustment. We study a relatively moderate Arctic sea-ice loss, corresponding to a 20%
457 (50%) annual (September) sea-ice extent reduction. Two different methods are implemented to melt
458 the Arctic sea-ice from a control simulation (CTRL) to assess the robustness of the associated
459 climate impacts: reducing the sea-ice and snow above it by altering their albedo (in ALB) or thermal
460 conductivity (in THCD). We adjust their values in order to reproduce the targeted summer Arctic
461 sea-ice area. The resulting sea-ice areas and sea-ice concentration patterns are largely similar in
462 TARGET, ALB and THCD. However, an underestimation of the winter sea-ice loss is
463 systematically produced when reducing the albedo, while thermal conductivity reduction is more
464 able to reproduce the target sea-ice area in both winter and summer. Most previous studies also
465 found that decreasing the albedo leads to overestimated winter sea-ice (Deser et al., 2015; Blackport
466 and Kushner, 2016; Screen et al., 2018; Sun et al., 2020). The fact that the ensemble ALB only
467 simulates a small underestimation of sea-ice loss in winter is consistent with the effect of internal
468 variability.

469

470 The physical mechanisms reducing the ice are different in the two methods. While albedo modifies
471 the incoming solar radiation, thermal conductivity modulates the transfer of heat from the ocean to
472 the atmosphere, controlling the winter sea-ice growth. This induces significant local differences
473 even if the mean Arctic sea-ice areas are similar. For the reduced albedo simulations, there is a

474 stronger and less confined Arctic warming, especially in spring (as in Blackport and Kushner,
475 2016), when sea-ice cover is large. The thermal conductivity method simulates a thinner sea-ice and
476 snow in winter/spring due to reduced air-sea fluxes.

477 The climate responses are mostly similar with the two methods. However, the magnitude of the
478 anomalies is larger in the Northern Hemisphere with the albedo ensemble (ALB). Nonetheless, the
479 Tropical and Southern Hemisphere SST and SLP responses in South Atlantic and South Pacific are
480 of similar magnitude or larger in THCD. The origin of these small differences between the two
481 methods remains to be understood using larger ensembles to increase to signal to noise ratio.

482

483 The Arctic sea-ice loss creates a positive sea level pressure anomaly over Northern Siberia and a
484 negative anomaly in the Central Atlantic in winter, resembling a negative NAO-like pattern. In
485 winter, the North Atlantic lower-tropospheric jet (the eddy-driven jet) is shifted southward which is
486 consistent with the reduced low-tropospheric temperature gradient and the simulated negative
487 NAO-like pattern (Screen et al., 2018). The subtropical jet in the North Atlantic is also shifted
488 southward. However, the global mean zonal-wind shows a small northward shift, due to a strong
489 Pacific contribution. At 40°N, the zonal mean changes are dominated by the weakening of the
490 Aleutian Low in the Pacific. Even though the warming mostly occurs near the surface, the SLP and
491 Z500 over the Arctic have a barotropic structure, suggesting strong eddy-mean flow interactions, as
492 found in Deser et al. (2016) and Wang et al. (2018).

493

494 In the past few decades, the Arctic Ocean freshwater content has increased, which has been
495 explained by the accumulation of freshwater from sea-ice melt and river runoff. Zhang et al. (2016)
496 linked this accumulation to less sea-ice export as the Beaufort gyre has intensified. This is
497 consistent with our study as the Beaufort gyre intensifies, while its salinity decreases. In the
498 observations, the reason for the spin-up of the gyre has been linked to an anomalous anticyclone
499 over the Beaufort gyre (Giles et al., 2012). In our study, such anomalous anticyclone is absent (not
500 shown), therefore further investigation would be needed to quantify the mechanisms for the

501 Beaufort gyre intensification. In addition, the salinity increases in the Barents Sea due to stronger
502 North Atlantic inflow. This is consistent with the so-called Atlantification that is usually invoked to
503 explain sea-ice variability (Årthun et al., 2012; Polyakov et al. 2017; Barton et al., 2018; Lind et al.
504 2018). Our results suggest that Atlantification could be amplified by Arctic sea-ice loss within two
505 or three decades. The freshwater and heat exchanges between the Arctic and North Atlantic are
506 modified. The subtropical gyre shifts south and an intergyre gyre develops due to wind changes
507 (Marshall et al., 2001). The AMOC decreases, which is associated with a shallower mixed layer at
508 the main convection site. According to previous studies, Arctic sea-ice loss might play a dominant
509 role in AMOC weakening. For instance, Sévellec et al. (2017) suggested that 75% of the observed
510 AMOC decline is driven by Arctic sea-ice changes and Sun et al. (2018) found that about 50% of
511 AMOC decline produced at the end of the 21st century in a scenario simulation is due to Arctic sea-
512 ice loss. However, the relative importance of surface heat and freshwater flux in weakening the
513 AMOC in future climate is still an open question. There is a cold and fresh anomaly in the mid-
514 latitude around 45°N, which resembles the projected warming minimum (or warming hole) in the
515 subpolar North Atlantic (Collins et al., 2013) and has been linked to AMOC decrease (Drijfhout et
516 al, 2012; Sévellec et al., 2017; Suo et al., 2017; Sun et al. 2018). However, as ALB and THCD show
517 different magnitude of ocean surface cooling (respectively 0.3 °C and 0.08°C) with the same
518 intensity of weakening of the AMOC, we suggest that most of the changes are associated with the
519 southward shift of the westerlies. Lastly, the Atlantic is warmer at 0°S-25°S, which is consistent
520 with the AMOC weakening (Mignot et al., 2007).

521

522 Even if the equatorial Indo-Pacific shows no significant change associated with sea-ice loss,
523 warming is simulated in the South subtropical Pacific around 30°S, encircled by cooling around
524 20°S and 60°S. The pattern resembles the South Pacific meridional mode (Zhang et. al., 2014). It
525 also broadly resembles a cold IPO (Henley et al., 2015; Gastineau et al., 2019) but with no
526 significant anomalies in the equatorial band. The cooling around 20°S and South Atlantic warming
527 is associated with a westward shift of the Walker cells, with more ascent over the Atlantic and more

528 descent over the Pacific. This suggests that the fast decadal response to sea-ice loss is dominated by
529 the sea-ice-driven AMOC changes in the Atlantic, which are then driving the Pacific changes
530 through atmospheric bridges, although the causality was not fully determined. It would be
531 consistent with previous works where that Atlantic warming leads to a cold IPO phase through
532 modification of the Walker cells (Li et al. 2016; Ruprich-Robert et al. 2017; Martin-Rey et al.,
533 2018). However, such mechanism found here might be model-dependent. For instance, Wang et al.
534 (2018) found a large influence of the North subtropical ocean, while in our case the South Atlantic
535 is key.

536

537 Previous studies found that sea-ice loss is typically associated with a “mini-global warming” at
538 equilibrium, after several decades of oceanic circulation adjustment. However, in this paper, the
539 transient changes after a 10-yr adjustment to sea-ice loss show contrasting results, with a North
540 Pacific warming and a Southeast Pacific cooling, somewhat resembling those found in the transient
541 studies of Cvijanovic et al. (2017) and Wang et al. (2018). The reason for the different response in
542 the Pacific is an open question. The ocean dynamics could be an important aspect. Wang et al.
543 (2018) find indeed a smaller warming in a climate model fully coupled than coupled with an ocean
544 mixed layer, especially in Northern Hemisphere. Furthermore, the oceanic initial state was not
545 varied in our simulations, although it could affect the transient response (Sévellec and Federov,
546 2017; Germe et al., 2018). Lastly, as suggested by Monerie et al. (2018) and Smith et al. (2017), the
547 response to Arctic sea-ice loss could also depend on the mean state. As different components (ice,
548 AMOC, global temperature) have different adjustment scales, the global response could change
549 over time. We argue that the fast response to the sea-ice loss of the coming decades could be quite
550 different from the equilibrium response to sea-ice loss (Liu and Federov, 2019). This could be
551 clarified by coordinated sensitivity experiments with different climate models.

TARGET - CTRL

ALB - CTRL

THCD - CTRL

920 Figure 6: Anomalies of the annual-mean total heat flux with respect to CTRL (positive downward), in W/m^2
 921 for TARGET (top-left), ALB (top-middle) and THCD (top-right). The lines indicate the sea-ice edge (i.e. 15
 922 % in concentration threshold) for the corresponding ensemble (black for TARGET, blue for ALB and green
 923 for THCD). The signal north of this line is significant at the 90% confidence level. Mean seasonal cycle of
 924 the anomalies with respect to CTRL, averaged north of $70^\circ N$ for the surface heat flux without short-wave
 925 (i.e. sensible, latent and long-wave heat fluxes; positive downward; bottom-left), in W/m^2 and air
 926 temperature at 2 m (bottom-right), in K. Bars illustrate the 90% confidence interval for the ensemble-mean.

1048 Figure S1: Autoregression of the AMO (Atlantic Multidecadal Oscillation) index (black), AMOC (Atlantic
 1049 Meridional Overturning Circulation) index (red) and PDO (Pacific Decadal Oscillation) index (green) for a
 1050 2500 year pre-industrial control of the IPSLCM5A model (CMIP5). The AMO index is defined as monthly
 1051 area-weighted SST* anomalies averaged over the North Atlantic (0:60°N, 80°W:0°E). The AMOC index is
 1052 defined as the leading principal component (PC) of the annual averaged Atlantic meridional streamfunction
 1053 (Sv) from 30°S to 90°N. The PDO index time-series is defined as the leading PC of monthly North Pacific
 1054 (20:70°N, 110°E:100°W) area-weighted SST* anomalies. The SST* denotes that the global mean SST
 1055 anomaly has been removed from the local SST anomalies at each time step. A 12-month running mean has
 1056 been applied to the AMO and PDO times series. The grey dashed line indicates e^{-1} value to illustrate the e-
 1057 folding time.
