Dear Author,

Below are the queries associated with your article; please answer all of these queries before sending the proof back to AIP.

**Article checklist:** In order to ensure greater accuracy, please check the following and make all necessary corrections before returning your proof.

1. Is the title of your article accurate and spelled correctly?
2. Please check affiliations including spelling, completeness, and correct linking to authors.
3. Did you remember to include acknowledgment of funding, if required, and is it accurate?

Location in article	Query / Remark: click on the Q link to navigate to the appropriate spot in the proof. There, insert your comments as a PDF annotation.

## ABSTRACT

Thanks to their unique combination of semiconducting properties and a large cross section for energetic photons, metal halide perovskites could theoretically achieve high x-ray to charge carriers conversion rates, making them materials of high interest for the direct x-ray detection. In this work, we focus on the transport properties of methylammonium lead tribromide ( $\text{MAPbBr}_3$ ) single crystals. Time of Flight measurements and x-ray focused experiments along the edge of the samples were carried out. We report homogenous holes transit throughout the thickness of the samples as well as poor electrons transit. We also report the continuity of the electric field throughout the thickness of the  $\text{MAPbBr}_3$  samples, and we present preliminary fitting results to discuss its nature.

Published under license by AIP Publishing. <https://doi.org/10.1063/5.0011713>

Semiconducting metal halide perovskites have gained a lot of interest for solar cells applications. In the last decade, the reported efficiency perovskite based solar cells has increased from 3.81% to 25.2%.<sup>1,2</sup> However, the main concern for such mainstream application, as mentioned by Li *et al.*, is the presence of heavy metals in the ionic crystal.<sup>3</sup> On the other hand, heavy atoms like lead have large x-rays cross sections. Therefore, heavy metal halide perovskites could be perfectly suited for confined applications such as direct x-ray detectors for medical imaging. In addition to the cross section, efficient x-ray detection also requires good charge carriers' transport properties in order to optimize charge collection and reduce ghosting effect.

In this work, we investigated the photocarriers' transport properties of thick methylammonium lead tribromide ( $\text{MAPbBr}_3$ ) single crystals. We studied the electron and hole mobilities with laser Time of Flight. The continuity of the electric field throughout the thickness of the samples was then tested by x-ray focused experiments, the first to be reported to our knowledge.

Several  $\text{MAPbBr}_3$  single crystals of controlled quality were grown individually by a seeded Inverse Temperature Crystallization method. The growth procedure and crystal quality are detailed in a previous

publication by Amari *et al.*<sup>4</sup> The obtained single crystals had a typical size of  $4\text{ mm} \times 4\text{ mm} \times 2\text{ mm}$ . Their top and bottom (100) faces were optically polished (roughness below 30 nm r.m.s), and chromium electrodes were thermally evaporated on both sides (100 nm on one side, 30 nm on the other to ensure semi-transparency). Six samples were prepared in that way, and their individual properties and  $I$ - $V_{\text{dark}}$  curves can be found in Figs. S1 and S2 of the [supplementary material](#).

Time of Flight (ToF) is widely used to measure the mobility of carriers in semiconductors. Published ToF mobility values of  $\text{MAPbBr}_3$  single crystals range from 14 to  $217\text{ cm}^2\text{ V s}^{-1}$  for holes and  $25$ – $190\text{ cm}^2\text{ V}^{-1}\text{ s}^{-1}$  for electrons.<sup>5–12</sup> When conducting ToF experiments (Fig. 1), the mobility is deduced from the transit time ( $t_t$ ) of the charge carriers. In laser ToF, the carriers are photogenerated by a laser pulse in the immediate vicinity of a semi-transparent electrode: the incident wavelength is selected so as to be absorbed at depths negligible when compared to the thickness of the sample. That way, only one type of charge carriers contributes to the photocurrent by transiting through the thickness ( $L$ ) of the sample to reach the opposite electrode. For a sample biased at voltage  $V$  with no trapping mechanism and a homogenous electric field, the drift mobility  $\mu$  is defined as

FIG. 1. Laser ToF experiment in a hole measurement configuration.

$$\mu = L^2 / (V \times t_t) \text{ (cm}^2 \cdot \text{V}^{-1} \cdot \text{s}^{-1}\text{)}. \quad (1)$$

In ToF experiments, because a large number of charge carriers are created in a narrow volume ( $\approx 10^{-2} \text{ cm}^3$ ) near the irradiated electrode, the concentration of charges can lead to a drastic drop of the internal electric field that would reduce the transit time measured. To probe this point, the ToF photocurrent for holes for different amounts of photocarriers generated (estimation of which can be found in page 2 of the supplementary material) was measured. To that end, the incident laser intensity was varied using optical filters with transmittance ( $T$ ) between 0.1 and 0.5. From the resulting photocurrent transit curves presented in Fig. 2, three observations can be made. First, the transit time of holes in sample 1 ( $t_{h+} \sim 7.5 \mu\text{s}$ ) does not depend on the light intensity for the range of fluxes used. This ensures that under our experimental conditions the photocarriers created by the laser do not perturb the internal electric field. Second, the photocurrent increases from anode to cathode independently of the transmittance (see normalized Fig. S3). Knowing that the instantaneous mobility establishes a link between the photocurrent and the position of the photocarriers at every moment in time, we can attribute the increase in the photocurrent to an increase in the internal electric field from anode to cathode. A more detailed discussion on the nature of the electric field is presented in the x-ray focused experimental section and in the supplementary material. Third, there is a sharp peak at the beginning of the photocurrent. It was attributed it to fast trapping mechanisms in a previous publication.<sup>13</sup>

So, in agreement with these first observations, to characterize the charge carriers mobility, we illuminated our samples with 800 ps

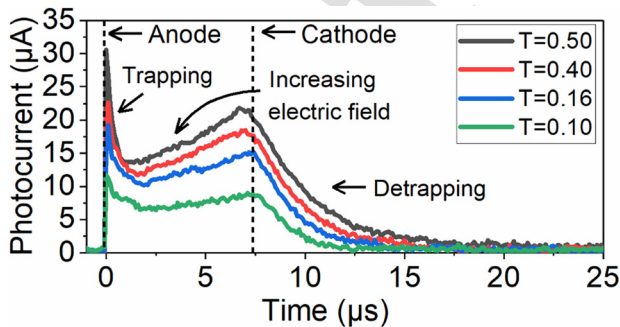

FIG. 2. Hole transit photocurrent of sample 1 biased at  $-100 \text{ V}$  as a function of the transmittance of the optical filter.

pulses from a nitrogen laser (337 nm), using the optical filter with a transmittance of 0.16. Results for our six samples are detailed in the supplementary material (Fig. S4 for holes and Fig. S5 for electrons). Figure 3(a) shows the hole transit photocurrent of sample 1 polarized between  $-60 \text{ V}$  and  $-140 \text{ V}$ . The inflection indicating hole collection at the cathode is clearly visible, and the longest transit time measured is  $13 \mu\text{s}$ . This value corresponds to a minimum value of the holes' lifetime in our experimental conditions. Holes' mobility measurements were reproducible among our six samples of the same crystal quality with an average of  $13 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1} \pm 2 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ . Figure 3(b) shows the electron transit photocurrent of sample 1 for bias voltages between  $+100 \text{ V}$  and  $+140 \text{ V}$ . Electrons' mobility could not be measured satisfactorily, because the inflection of the transit photocurrent was not visible even in a log-log representation (Fig. S6). This indicates that the mobility lifetime product of electrons ( $\mu_e \tau_e$ ) is not large enough to allow all the electrons to fully transit even at polarization fields as high as  $1500 \text{ V cm}^{-1}$ . To estimate a maximal value for the electrons' lifetime, a Ramo's model was used [Eq. (2)]:

$$i(t) = n e \mu V \times \exp\left(-\frac{t}{\tau}\right) / L^2. \quad (2)$$

In this equation,  $n$  is the number of photocarriers created,  $e$  is the elementary charge,  $\mu$  is the charge carrier mobility,  $V$  is the bias voltage,  $L$  is the thickness of the sample, and  $\tau$  is the charge carrier lifetime. Using Eq. (2) and our experimental conditions, we tried to fit the measured photocurrent for different electron lifetimes. For lifetimes above  $1.25 \mu\text{s}$ , it was impossible to model the experimental data regardless of the mobility and the bias voltage used. Therefore, we hypothesize that in our experimental conditions the electron lifetime is smaller than  $1.25 \mu\text{s}$ . The inset of Fig. 3(b) displays the electron photocurrent at  $+140 \text{ V}$  and the corresponding Ramo model for a lifetime of  $1.25 \mu\text{s}$ .

For the case at hand, we conclude that  $\mu_e \tau_e \ll \mu_{h+} \tau_{h+}$ . This conclusion as implications on the commonly used Hecht fittings, which we discuss in the supplementary material (Fig. S7).

Using ToF experiments, a non-homogenous, anode to cathode increasing electric field was hypothesized. However, because ToF measurements are not spatially resolved, the continuity of the electric field in the volume and the position of the cathode are not assured. Therefore, additional x-ray focused experiments were conducted (Fig. 4) to verify the continuity and homogeneity of the electric field. They consist in scanning the thickness of a sample with an x-ray beam limited by  $100 \mu\text{m}$  slit. The irradiation starts at one edge of the

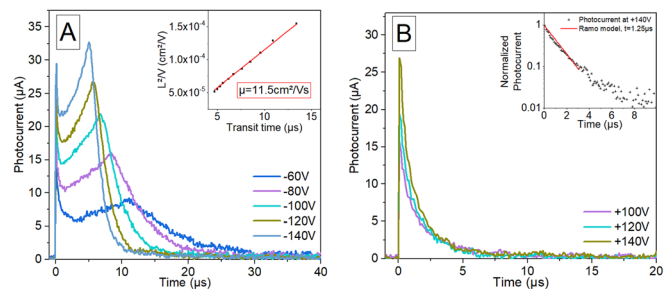

FIG. 3. (a) ToF hole photocurrent of a MAPbBr3 sample (inset: mobility calculation). (b) ToF electron photocurrent of a MAPbBr3 sample (inset: photocurrent at  $+140 \text{ V}$  and Ramo model for  $\tau_e = 1.25 \mu\text{s}$ ).

FIG. 4. X-ray focused experiment setup.

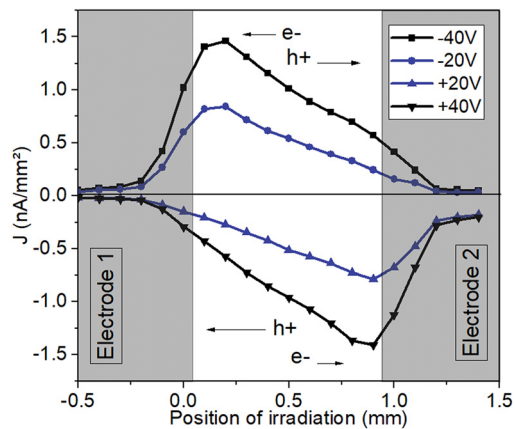

FIG. 5. Photocurrent density as a function of the position of the irradiation.

128 sample and moves along the thickness by 100 μm steps increments  
 129 until it reaches the opposite edge. Because of the slit's width, only the  
 130 samples thicker than 0.8 mm were tested. At each step, the sample is  
 131 irradiated by ten pulses of x-rays generated by a varian tube using the  
 132 characteristic medical radiography setups (Table I) as described in IEC  
 133 62220 International Standard.<sup>14</sup> The x-ray pulses were recorded via a  
 134 Keithley 428 picoammeter. The experiment was reproduced using differ-  
 135 ent bias voltages. For each sample and each bias voltage, the average  
 136 photocurrent density was plotted as a function of the position of the  
 137 irradiation along the thickness of the sample.

138 It is worth noting that the measurement duration (100 ms) is five  
 139 orders of magnitude higher than the characteristic ToF measurement  
 140 duration. This allows us to probe both the photocarriers transit and  
 141 the effect of long irradiation times used in medical imaging applica-  
 142 tions. It can also be noted that the number photocarriers generated  
 143 ( $\approx 10^{10}$ , supplementary material page 5) is smaller, and the volume in  
 144 which they are generated is larger ( $\approx 10^{-1}$  cm<sup>3</sup>) than in the ToF  
 145 experiments. This justifies the non-perturbation of the electric field by  
 146 the photocarriers generated in the x-ray focused experiments.

147 Figure 5 shows the results for sample 1, those for all the other  
 148 samples tested are available in the supplementary material (Fig. S8).

149 The photocurrent density of sample 1 is linear for all voltages and  
 150 decreases as the charges are generated closer the cathode.

151 The experimental results may be modeled by expressing the drift  
 152 photocurrent measured in x-ray focused experiment for our cuboid  
 153 sample with planar electrodes [Eq. (3)]. The photocurrent is then  
 154 defined as the sum of the charges induced on the electrodes by the  
 155 Ramo intensity of each type of photocarriers over the duration of the  
 156 measurement

$$I_{mes}(X) = \frac{1}{t_{mes}} \times \left[ \int n_{e^-}(x(t)) \exp\left(\frac{-t}{\tau_{e^-}}\right) \times \frac{e\mu_{e^-}E(x(t))}{L} dt + \int n_{h^+}(x(t)) \exp\left(\frac{-t}{\tau_{h^+}}\right) \times \frac{e\mu_{h^+}E(x(t))}{L} dt \right], \quad (3)$$

157 where  $X$  is the irradiation position,  $t_{mes}$  is the measurement time,  $n$  is  
 158 the number of charge carriers created,  $x(t)$  is the instantaneous posi-  
 159 tion of the charge carriers,  $\tau$  is the charge carrier lifetimes,  $e$  is the ele-  
 160 mentary charge,  $\mu$  is the charge carrier mobilities,  $E$  is the electric field,  
 161 and  $L$  is the thickness of the sample.

162 Equation (3) shows that the photocurrent depends on both the  
 163 photocarriers' transport properties and the electric field distribution  
 164 along the thickness of the sample. With the ToF measurements, we  
 165 have established that the charge carriers' transport properties are dis-  
 166 symmetric ( $\mu_{e^-}\tau_{e^-} \ll \mu_{h^+}\tau_{h^+}$ ). If we hypothesize a constant electric  
 167 field, we expect to see a maximum of the photocurrent when the materi-  
 168 al is irradiated near the anode and a minimum when it is irradiated  
 169 near the cathode. This is indeed what is observed on the photocurrent  
 170 profiles displayed in Figs. 5 and S8.

171 Here, electrode 1 is grounded while electrode 2 is biased. In the  
 172 case of charge creation near the anode (positive bias), the electrons are  
 173 collected almost immediately while the holes transit through the entire  
 174 thickness of the sample and account for most of the photocurrent  
 175 measured. In the case of charge creation near the cathode (negative  
 176 bias), the holes are collected almost immediately and, since the elec-  
 177 trons cannot transit through the entire thickness of the sample (as  
 178 demonstrated by the ToF experiments), the charge induced at the elec-  
 179 trode is lower than in the previous case.

180 In Fig. 5, it can also be observed that the photocurrent has non-  
 181 zero continuous values throughout the sample indicating a continuous  
 182 and non-null electric field.

183 In the discussion above, a constant electric field was hypothesized  
 184 to explain the shape of the photocurrent. However, the ToF data in  
 185 Fig. 2 have shown that a linear field, increasing from anode to cathode  
 186 is more likely. To get a better idea of the shape of the electric field,  
 187 Eq. (3) was used to model the x-ray focused and ToF experimental  
 188 results of sample 1 in the case of a constant electric field and a linear  
 189 electric field, increasing from anode to cathode (Figs. S9 and S10).

TABLE I. X-ray tube setups.

Tube voltage	70 kVp
X-ray minimum energy	50 keV
Tube current	100 mA
Filtration	0.8 mm Be, 23 mm Al
Work distance	1 m
Pulse width	100 ms
Pulse frequency	4 Hz

190 We found that the x-ray focused experimental data could be modeled  
191 by either of those fields. However, only the linear electric field allowed  
192 modeling the ToF experimental data. This is in contradiction with the  
193 homogenous electric field hypothesis of Eq. (1). Nonetheless, the use  
194 of a constant electric field to model our data only leads to a 5% under-  
195 estimation of the mobility, which is negligible compared to the 15%  
196 measurement uncertainty. More in depth modeling is under progress  
197 to achieve better fitting for both types of experimental data.

198 In conclusion, we have measured reproducible hole mobility of  
199 MAPbBr<sub>3</sub> single crystals of controlled quality with laser ToF at 13 cm<sup>2</sup>  
200 V<sup>-1</sup> s<sup>-1</sup> ± 2 cm<sup>2</sup> V<sup>-1</sup> s<sup>-1</sup>. We have also seen that both ToF and x-ray  
201 focused results are consistent with poor electrons' transport properties  
202 in MAPbBr<sub>3</sub> single crystals. We can only hypothesize that the lack of  
203 electrons transit is due to either deep trapping levels or recombination  
204 centers, as shown by Musiienko *et al.*<sup>9</sup> In the case of a deep trapping  
205 level, the detrapping constant would be higher than 100 ms, our typical  
206 measurement duration. Finally, we have shown that the internal elec-  
207 tric field exists throughout the thickness of the samples, and our pre-  
208 liminary modeling results point toward it being linear and increasing  
209 from anode to cathode. Knowing the nature of the electric field is  
210 essential and will therefore be the topic of follow-up studies.

211 See the [supplementary material](#) for detailed samples properties,  
212 ToF and x-ray focused measurements of samples 1–6, discussion about  
213 Hecht fitting, and discussion about the constant electric field  
214 hypothesis.
