**Abstract:** Graphene is a key material of interest for modification of physicochemical surface properties. However, its flat surface is a limitation for applications requiring a high specific surface area. This restriction may be overcome by integrating 2D materials in a 3D structure. Here, a strategy for the controlled synthesis of Graphene-Mesoporous Germanium (Gr-MP-Ge) nanomaterials is presented. Bipolar electrochemical etching and chemical vapor infiltration were employed for, respectively, nanostructuring of Ge substrate and subsequent 3D nanographene coating. While Raman spectroscopy reveals tunable domain size of nanographene with the treatment temperature, transmission electron microscopy data confirm that the crystallinity of Gr-MP-Ge is preserved. X-ray photoelectron spectroscopy indicates the non-covalent bonding of carbon to Ge for Gr-MP-Ge. State-of-the-art molecular dynamics modeling allows for a deeper understanding of the synthesis process through the presence of radicals. The successful synthesis of this nanomaterials offers integration of nanographene into a 3D structure with a high aspect ratio and light weight, thereby opens avenues to a variety of applications for this versatile nanomaterial.

## 1. Introduction

Initially known as a fundamental object of study, graphene has evolved to become one of the most important research fields in materials science with a significant potential in a wide variety of applications.<sup>1,2</sup> However, a major challenge for such applications is large-scale synthesis of graphene and its implementation in 3D systems.<sup>3</sup> In fact, its 2D-planar structure is a limitation preventing large-scale applications requiring high specific surface. It is then of the first interest to bring graphene into a 3D structure but not at the detrimental of the graphene quality and properties. Graphene has already been handled into different forms such as quantum dots<sup>4-7</sup> and nanoribbons<sup>8</sup> for use in semiconductor devices or else as foams<sup>9</sup> and hydrogels<sup>10</sup> for energy and biological applications. It is important for some applications to have a high specific surface area in a small volume (ratio surface/volume high) as for energy storage in portable electronics and drug delivery applications, and such a characteristic appeared to be the source of promising or enhanced performance.<sup>11-13</sup> Nevertheless, the integration of graphene inside the 3D structure via a simple and direct method is challenging. In addition, nanostructured materials showed the emergence of new properties with the decreasing sizes, a catalytic surface for the graphene growth and combination with graphene offers hybrid properties.<sup>14,15</sup>

The strategy developed in this work proposes to use mesoporous semiconductor to increase the specific surface area with a 3D structure. For this purpose, we used germanium (Ge), as it is one of the semiconductors that plays an important role in development of solid-state devices, mainly due to its specific characteristics that distinguish it from other group IV and III-V materials.<sup>16</sup> Besides, it has attracted a lot of interest for direct growth of graphene. Primarily, Ge has catalytic activity allowing a decrease of the energy barrier for the decomposition of the carbon precursor.<sup>17</sup> Moreover, carbon has a low solubility in Ge even at its melting temperature ( $\approx 10^8$  atoms/cm<sup>3</sup> at the melting point) and, lastly, there is a small difference between the thermal expansion coefficients of Ge and carbon.<sup>18,19</sup> These characteristics drastically decrease the wrinkle formation in graphene layers when synthesized over a Ge surface.<sup>20</sup> All these aspects make Ge a prominent candidate for the growth of graphene with a direct approach.

Before the direct growth of graphene, a nanostructuring step is necessary in order to increase the specific surface area of germanium. Electrochemical etching has already been used in industrial manufacturing and it is quite compatible with semiconductor manufacturing processes. Electrochemical etching or anodization has offered one of the leading platforms for well-controlled fabrication of porous silicon<sup>21</sup> and this method has been extended to the Ge substrates using direct current.<sup>16,22</sup> Further works led to development of a method based on bipolar pulses, known as

Bipolar Electrochemical Etching (BEE), to induce pore formation and pore passivation with cycles of positive and negative current pulses.<sup>23</sup> Recently, different electrochemical regimes have been developed for anodization of Ge and optimizing lateral homogeneity of the MP-Ge films.<sup>24–26</sup>

The preceding discussion points out that combination of mesoporous Ge (MP-Ge) and graphene is an avenue to use the large specific area of graphene in a semiconductor, in order to design a versatile 3D nanostructured material. The targeted material consists of an MP-Ge substrate, with crystalline structure, coated with a thin layer of graphene encapsulating all the porous structure (See Figure 1). In this work, we demonstrate a new path for the synthesis of 3D nanographene within a MP-Ge substrate. Our strategy is a two-step process using bipolar electrochemical etching of germanium wafers followed by a Chemical Vapor Infiltration (CVI) of acetylene, at atmospheric pressure. On this subject, Chemical Vapor Deposition (CVD) was demonstrated in 2009 for large-area graphene growth synthesis, but some issues still remain unresolved.<sup>27–30</sup> At the moment, CVD is considered as the most promising method for growth of single-crystal and large-area graphene with higher quality of the graphene compared with most other methods.<sup>18</sup>

Extensive characterizations have been performed to fully describe the resulting materials. First, the graphene coating was confirmed with Raman spectroscopy analyses. Then, the crystalline structure and chemical compositions of the produced nanomaterials were investigated using Transmission Electron Microscopy (TEM) and X-ray Photoelectron Spectroscopy (XPS) measurements. To further clarify the growth mechanism at different temperatures, molecular dynamics modeling was carried out.

We anticipate that the material we developed and optimized will be of great interest in diversified applications. For instance, tuning the crystalline quality of the graphene coating will allow for controlling associated properties such as electric and thermal conductivity. In addition, the nanocomposite is well adapted to the microelectronics industry as the synthesis is compatible with microfabrication line industry. This may be a way to introduce graphene in microelectronic devices.

## **2. Experimental**

Synthesis of Graphene-Mesoporous Germanium (Gr-MP-Ge) nanomaterials was carried out through the following three-step process: 1. Anodization of the Ge wafer using Bipolar Electrochemical Etching (BEE) on bulk Ge wafers, 2. Acetylene infiltration and 3. Graphene formation within the porous structure through thermal treatment. The combination of the last two steps is identified as Chemical Vapor Infiltration (CVI).

**Bipolar Electrochemical Etching (BEE):** For the anodization step, a one side polished p-type Gallium doped Ge wafer was used with the following characteristics: resistivity of 0.01-0.02  $\Omega$ .cm, monocrystalline with (100) crystalline orientation and 6-degree miscut.

To conduct the etching of the Ge, a custom-made electrochemical cell with the Ge wafer as the working electrode was employed. The electrochemical cell was made of Teflon, with a copper electrode as the backside wafer contact (isolated from the electrolyte) and a platinum counter-electrode. The electrolyte consisted of hydrofluoric acid (49%) and anhydrous acetic alcohol (99.9%) with a ratio of 5:1 (v/v). The current density used was 1.5 mA/cm<sup>2</sup> for the etching and passivation pulses. The duration of pulses was 1 s for etching (positive current) and 2 s for passivation (negative current).

**Chemical Vapor Infiltration (CVI):** To achieve nanographene coating within the MP-Ge, CVI was carried out using a tubular furnace (Carbolite Gero Limited, United Kingdom). In this furnace, the tube and the sample holder boat (MTI corporation, California, USA) are made of quartz. Dihydrogen and acetylene were employed as precursors with argon as the vector gas. The samples were placed vertically during the deposition process. The ratio of acetylene flow to the flow of other gases was 0.89 % (i.e. acetylene flow/dihydrogen + argon flow) and the temperature was controlled with a E1320 controller.

**Raman spectroscopy:** The Raman measurements were conducted using an AIST-NT OmegaScope system. This system exploits a thermoelectrically cooled Andor CCD detector and a Nanofinder 30 Raman spectrometer. A 0.7 N.A. 100 $\times$  Mitutoyo MPlan Apo objective was employed to focus a 532.1 nm laser beam (solid state Cobolt 04-01 series laser source) onto the sample surface.

**X-ray Photoelectron Spectroscopy (XPS):** X-ray photoelectron spectrometry (XPS) measurements were performed with a Kratos Axis Ultra XPS DLD. The machine is equipped of an X-ray source of Al monochromatic with an energy of 1486.69 eV with applied power of 225 W. A constant pass energy (PE) mode was used for the analyzer (PE = 160 eV for the survey scan and Epass = 20 eV for the high-resolution scans). The calibration was done on a metallic Au sample. The binding energy was calibrated for the 4f<sup>7/2</sup> of metallic Au at 83.96 eV. The dispersion of the spectrometer was adjusted to a binding energy of 932.63 eV for the 2p<sup>3/2</sup> of metallic copper. To compensate the charging effect, the samples were electrically connected to the ground and a charge neutralizer was used. The analyzed area was an oval-shaped spot of 300  $\mu$ m x 700  $\mu$ m surface area. The data was analyzed with the CasaXPS software (version 2.3.18). The experimental Relative Sensitivity Factor (RSF) data as given by Kratos Analytical for their machines applied to quantify

the XPS spectra. Moreover, a Shirley background was used on all spectra. The charge effect was corrected on the Ge 3d peak at 29.3 eV. This was done on Ge, but not on carbon.

**Transmission Electron Microscopy (TEM):** The sample was cleaved in half and the two pieces were glued together with the top surfaces facing each other using epoxy resin. The “sandwich” sample was then glued to a metal puck to be polished. Polishing was done with sandpaper ranging from 400 grit to 4000 grit to reach a mirror-like finish. The sample was polished to attain 100  $\mu\text{m}$  – 200  $\mu\text{m}$  thickness. Then two 3 mm disks were cut from it using an ultrasonic disk cutter. The glue line was in the center of the disk. The samples were thinned further down to 80  $\mu\text{m}$  – 100  $\mu\text{m}$ . The samples were then attached to a molybdenum ring to provide support. The samples were dimpled ground to 30  $\mu\text{m}$  thickness at the center. Afterwards the samples were ion milled using a Gatan PIPS until a small hole appeared in the center of the samples. The milling parameters were 4.0 kV, 4.0 mA, 6 – 7 degree milling angle, milling time of 4 – 5 hours. The microscope is FEI Tecnai at 300 keV and magnification of 410 Kx.

**Molecular dynamics modeling:** Molecular dynamics simulation was performed with Large-Scale Atomic/Molecular Massively Parallel Simulator (LAMMPS) and the results were visualized with Visual Molecular Dynamics (VMD) from University of Illinois at Urbana-Champaign.<sup>31–34</sup>

**Figure 1:** Schematic representation of the three main steps for the synthesis of a Gr-MP-Ge nanomaterial. Step 1. Nanostructuring of (100) germanium substrate using BEE (anodization). Current density was 1.5 mA/cm<sup>2</sup>, wafer resistivity was 0.01-0.02  $\Omega\cdot\text{cm}$ , electrolyte was made of hydrofluoric acid and ethanol with a ratio of 5:1 (v/v). Step 2. Acetylene infiltration at 110  $^{\circ}\text{C}$  in a tubular furnace with argon and hydrogen at atmosphere pressure. Step 3. Graphene coating with tubular furnace at carbonization temperature, which was varied in this study.

### 3. Results and discussion

#### Synthesis of the Gr-MP-Ge: Goal and synthesis steps

The ultimate material that is expected is a crystalline MP-Ge substrate coated with a thin layer of nanographene, encapsulating all the porous structure. Therefore, the crystalline structure and nanostructuring of fabricated MP-Ge should be maintained during the rest of the process, especially after the carbon coating deposition. Here, the proposed synthesis method consists of three major steps as shown in figure 1. The first step was devised to create the mesoporous structure of Ge using bipolar electrochemical etching (BEE) technique, which can be extended to the full-size wafers for large-scale production of such type of nanomaterial.<sup>35</sup> It has been demonstrated that the thickness and density of mesoporous layer could be well controlled by the process parameters, such as current density and pulse duration.<sup>24–26</sup> This step was realized on a (100), single side polished, gallium p-doped Ge wafer with a resistivity of 0.01 – 0.02  $\Omega\cdot\text{cm}$ . Electrolyte was made of hydrofluoric acid and ethanol with a ratio of 5:1 (v/v). Then the nanographene coating was carried out through acetylene infiltration in the pores of the Ge substrate, at atmosphere pressure. This step was performed in a tubular furnace with argon and dihydrogen atmosphere at initial temperature of 110 °C. Dihydrogen ( $\text{H}_2$ ) is a reductant specie and allows to reduce the native oxide present and avoid the formation of new oxide on the sample during the synthesis and the cooling down. Furthermore, presence of  $\text{H}_2$  in vapor allows to regenerate hydrogenated surface of germanium.<sup>36,37</sup> Once acetylene was infiltrated in the mesoporous structure, the temperature was raised in order to transform the acetylene molecules into carbon atoms.

Since the carbonization temperature has a direct effect on the quality of the carbon layer, multiple Gr-MP-Ge nanomaterials were synthesized at different carbonization temperature of 400 °C – 920 °C (See experimental section for details).<sup>37</sup>

Despite, the two last steps are performed in the same reactor, they represent two critical steps in the synthesis process. First, graphene formation is the direct consequence of the acetylene infiltration which is critical to ensure uniformity in depth of the deposition. Second, temperature treatment is critical to control the quality of the deposition. Therefore, the deposition is highly dependent on the good infiltration but temperature plays also a critical role discussed in the Raman section of this work.

**Figure 2** Typical Raman spectra, using  $\lambda_L=532$  nm, of MP-Ge (red and top line) and Gr-MP-Ge nanomaterial (blue and bottom line) treated at 500 °C for 10 min, respectively.

### Nature, quality and domain size of the carbon coating: Raman spectroscopy

Figure 2 Typical Raman spectra, using  $\lambda_L=532$  nm, of MP-Ge (red and top line) and Gr-MP-Ge nanomaterial (blue and bottom line) treated at 500 °C for 10 min, respectively.

For all samples, treated at 400 °C – 920 °C, the Raman spectra were collected with a Raman spectrometer using an excitation laser of 532.1 nm (See figure S1 in the Supporting Information). Figure 2 depicts the typical Raman spectra acquired on MP-Ge (red line) and Gr-MP-Ge nanomaterials (blue line) treated at 500 °C.

The peak observed at 300  $\text{cm}^{-1}$  corresponds to the  $T_{2g}$  Raman mode of the diamond-type for Ge crystal. Besides, the D and G peaks located at 1350  $\text{cm}^{-1}$  and 1588  $\text{cm}^{-1}$  – 1602  $\text{cm}^{-1}$ , respectively, can be considered as a signature of carbon.<sup>38</sup> Normally, the Raman spectrum of disordered graphite contains two peaks, i.e., the G peak around 1580  $\text{cm}^{-1}$  – 1600  $\text{cm}^{-1}$  and the D peak around 1350  $\text{cm}^{-1}$ .<sup>39</sup> The presence of disorder and defects inside the  $\text{sp}^2$  film are likely responsible for D peak. Additionally, the 2D peak region has a low intensity and important broadness for the sample treated at 500°C. The shape is modified with higher temperature treatment (Figure S1b) with appearance of marked 2D and D+D' peaks. These changes are due to the decrease of disorder with the increasing temperature.<sup>40</sup> The  $\{I(D)/I(G)\}$  ratio allows to extract information about the nature of the materials such as the domain size within the coating layer. Based on the work of Ferrari and Robertson<sup>39</sup>, the  $\{I(D)/I(G)\}$  ratio increased with the carbonization temperature and the G peak position shifted towards 1600  $\text{cm}^{-1}$  that indicates the transition from graphite towards nano-graphite (stage 1), with the presence of only  $\text{sp}^2$  hybridization for carbon-carbon bonding. Furthermore, as

noticed on similar material as mesoporous silicon, the number of layer is estimated at 2-3 layers and the growth is self-limiting catalytic reaction.<sup>15,41</sup> Considering all these information, we call the carbon coating studied here, nanographene.

In stage 1, the relation of Tuinstra and Koenig is applicable. This relation explains that the ratio of intensities of D and G peaks is inversely proportional to the domain size,  $L_a$ , as follows:<sup>38,39,42</sup>

$$\frac{I(D)}{I(G)} = \frac{C(\lambda)}{L_a} \quad (1)$$

where  $C(\lambda = 532 \text{ nm})$  is  $\sim 49.6 \text{ \AA}$  according to the equation  $C(\lambda) \approx C_0 + \lambda_L C_1$ , in which  $C_0$  and  $C_1$  are estimated to be  $-126 \text{ \AA}$  and  $0.033$  respectively.<sup>43</sup>

Figure 3 displays  $\{I(D)/I(G)\}$  ratio variations as well as the evolution of the domain size  $L_a$ , calculated using equation (1), versus the carbonization temperature. As it can be seen, the domain size,  $L_a$ , was changing from  $\sim 8$  to  $3 \text{ nm}$  for samples that were carbon coated at  $400$  to  $920 \text{ }^\circ\text{C}$ , respectively. Therefore,  $L_a$  decreases with increasing the carbonization temperature suggesting that higher temperature favored creation of more nucleation sites leading to more grain boundaries.

The combination of the observations of the  $I(D)/I(G)$  and the 2D peak shape indicates that the domains of graphene are becoming smaller but with a higher crystalline quality with increasing treatment temperature.

The most important deduction is the tunability of the domain size by a factor of 2. Evidently, lower carbonization temperature resulted in lower  $I(D)/I(G)$  ratio, which is desired for synthesis of less grain boundary nanographene layer. In contrast, Raman spectra of the sample that was treated at  $400 \text{ }^\circ\text{C}$  (see Figure S1 in the Supporting Information) attested the presence of carbon and suggested such a temperature is the limitation for the growth and the thermal cracking of the acetylene precursor. Therefore, a carbonization temperature higher will be chosen for the next. Consequently,  $500 \text{ }^\circ\text{C}$  is very close to the optimal condition for large domain size and maintaining the porosity of the substrate. Furthermore, molecular dynamic modeling will show later in the paper, the good reactivity at this temperature.

**Figure 3** Evolution of the I(D)/I(G) ratio and domain size, La, of graphene coating as a function of carbonization temperature.

**Figure 4** (a) HR-TEM image of a cross-section of Gr-MP-Ge nanomaterial with an electron beam set at 300 keV and magnification of 410 Kx, (b) diffraction image obtained by FFT, (c) IFFT image of diffraction image present in (a) using a mask to keep only the spot for (-111) and (1-11), here the solid blue line denotes the physical location of obtained profile (d) Profile of the distance between the planes for {111}.

### MP-Ge with crystalline structure: TEM

To characterize the crystallinity of the proposed nanomaterial, TEM measurements were carried out with an electron beam at 300 keV. For this purpose, only the porous part is observed in cross-section.

Figure 4a presents the High-Resolution TEM (HR-TEM) image exhibiting germanium crystal planes taken from a Gr-MP-Ge synthesized at 500 °C. Figure 4a is the direct observation using TEM for Gr-MP-Ge sample and allows to extract the diffraction image presenting in figure 4b. The different shades of gray are related to the difference in the thickness of the sample. The diffraction image in figure 4b was obtained by applying Fast Fourier Transform (FFT) on the HR-TEM image, shown in figure 4a.<sup>44</sup> As can be seen in figure 4b, diffraction image contains spots with a well-defined periodic pattern. Each spot represents an atomic plane of Ge and the distance between the central spot, marked with (000) and the spot marked (-11-1), is 3.47 Å.

For a cubic crystal, the relation between the lattice constant  $a_0$ , the Miller indices (h, k, l) and the lattice spacing  $d$  is defined based on the Bragg's law as follows:

$$d = \frac{a_0}{\sqrt{h^2+k^2+l^2}} \quad (2)$$

Based on the equation (2), the lattice constant  $a_0$  is found to be 5.9 Å corresponding to the lattice parameter of Ge.

Figure 4c displays the Inverse Fast Fourier Transform (IFFT) of the diffraction image presented in figure 4b. Prior to applying the IFFT, a mask was applied on the image for selecting only the two spots representing (-111) and (1-11) planes. In figure 4c, the planes of Ge corresponding to the lattice plane family of {111} can be clearly identified. Figure 4d illustrates the profile of pixels in the image shown in figure 4c. Here, intensity of the observed peaks is arbitrary and it depends on the image contrast. However, the distance between these peaks corresponds to the distance between the planes of Ge.

TEM data confirmed that the single-crystallinity of Ge was preserved after porosification and carbon coating. Furthermore, the aim is to keep the high surface area in maintaining the morphology of the porous material after graphene growth which is confirmed with SEM observations (see figure S2). SEM observations highlights a change in the distribution of size of the crystallites due to the temperature treatment (re-densification of the crystallites increasing their size). In spite of that the morphology of the porous structure is keeping mesoporous with a thickness of around 500 nm and a high specific surface area. It is the aim of our process to preserve the mesoporous structure on a sufficient thickness to have a large specific surface area in comparison with the bulk. Although the

TEM characterization confirmed the crystalline structure of Ge, the carbon component could not be studied using this technique. In fact, during the sample preparation for TEM imaging, an epoxy made of carbon material was utilized. Consequently, distinguishing the two materials in diffraction images and other measurements was not possible.

TEM measurements and Raman spectroscopy data showed that the crystallinity of Ge was preserved, while the carbon coating resulted in the formation of nanographene with disorder mostly related to the grain boundaries. Then, in order to characterize the bonding nature between MP-Ge and nanographene, XPS measurements were conducted.

### Bonding of carbon to MP-Ge: XPS

**Figure 5** Survey XPS spectra, with an Al monochromatic source (1486.69 eV). Spectra were taken from MP-Ge and Gr-MP-Ge nanomaterial after Ar ions bombardment, to determine which elements were present. Offset on spectra are done in order to enhance the quality of reading.

**Figure 6** (a) XPS spectra of Ge 3d core energy for Gr-MP-Ge after Ar ions bombardment, (b) XPS spectra of C 1s core energy for Gr-MP-Ge after Ar ions bombardment. (A color version of this figure can be viewed online.)

Figure 5 compares the XPS survey spectra obtained from MP-Ge and Gr-MP-Ge nanomaterial. According to these spectra, the main chemical elements are Ge, oxygen and carbon. The MP-Ge spectrum contains two peaks corresponding to the oxygen, O1s at 531.14 eV and OKLL at 976 eV. Whereas XPS spectrum of the Gr-MP-Ge nanomaterial has only the O1s peak, which is shifted to 533.00 eV; besides, it is less intense and less sharp compared to the XPS spectrum of MP-Ge. This may suggest that the graphene slightly passivated the Ge surface and partially prevented oxide formation. Furthermore, the survey spectra for both samples show the presence of Ge peaks at 1218 eV, 1251 eV, 29.3 eV related to, respectively, Ge2p<sup>1/2</sup>, Ge2p<sup>3/2</sup> and Ge 3d. Moreover, XPS peaks related to Ge3p and Ge3s are presented at 122.2 eV and 181.1 eV, respectively. The peak related to carbon C1s at 283.2 eV is only present for Gr-MP-Ge. In order to determine the bonding condition between the Ge and carbon, high-resolution XPS scans on these two specific elements were collected.

Figure 6 shows high-resolution XPS scans of the Ge3d at 29.5 eV and C1s at 283.5 eV, taken after 630 s argon ion etching (Ar<sup>+</sup> sputtering) of the samples. Argon ions etching allows to remove a part of the surface and investigate material properties located at deeper distance from the surface. It also allows removing the adventitious carbon contaminations from the XPS chamber and at the surface of samples. The Lorentzian asymmetric (LA) function fitting of the Ge3d in high-resolution XPS spectrum gives two peaks corresponding to Ge element. A Gaussian/Lorentzian product lineshape is used with a 30 % Lorentzian component for fitting the germanium oxide at 30.8 eV as shown in figure 6a.<sup>45</sup> The XPS peaks at binding energies of 29.3 eV and 29.9 eV correspond to Ge elementary 3d<sup>5/2</sup> and 3d<sup>3/2</sup>, respectively. The small peak at 30.8 eV represents the  $\sigma$  bonding between Ge and oxygen (GeO). The intensity of this peak is also very low, which points out toward small quantity of this bonding. Similarly, the Lorentzian asymmetric (LA) function fitting C1s curve provided two peaks, as shown in figure 6b. The first peak is located at 284.0 eV and it represents the sp<sup>2</sup> carbon-carbon bonding. The second peak is located at 283.1 eV and corresponds to fullerenic carbon.<sup>46,47</sup> Grieco *et al.* suggested that the sp<sup>2</sup>-bonded carbon atoms in pentagonal and hexagonal rings give a cage-like polyhedral geometry to fullerenic carbon.<sup>48</sup> The intensity of this peak linearly increased with the etching time (Figure S3) indicating that the ion bombardment might induce defects.<sup>47</sup> Indeed, in order to investigate the uniformity of the deposition in depth into the porous structure, XPS high-resolution spectra for Ge3d and C1s are taken at different time of etching with Ar ions bombardment (see figure S3). Before etching, C1s presents only one peak at 284.1 eV, after 30s of etching, two peaks are present, the first one at 284.2 eV and the second at 283.1 eV. This second peak appears only after etching and its intensity linearly increases with the time of etching. We

conclude that this peaks is related to defects created during the bombardment for the etching of the surface. At 6640 s of etching, carbon is no longer present and the Ge3d peak is perfectly similar to the one obtained on germanium monocrystalline substrate. It is assumed that the entire porous layer was etched and the germanium substrate is reached. As a result of this, carbon is present in all the depth of the porous layer. It is worth noting that no peak related to  $sp^3$  bonding and Ge-C bonding were observed. Thus, the XPS data indicate that there is no covalent bond between Ge and carbon. In fact, the dominant bonds are Ge-Ge as well as  $sp^2$  C-C.

### Molecular Dynamics Modeling

To further study the mechanism of carbon coating growth, molecular dynamics simulations were conducted.<sup>49,50</sup> In this modeling the initial substrate was a crystalline bulk Ge with (100) orientation rather than MP-Ge substrate. Despite morphological differences with the mesoporous structure, the chemical interaction between the Ge and carbon remains unchanged. As a first attempt, all the precursors were carbon atoms (Figure S4). In the next step, two kind of calculations are brought off, first with acetylene molecules ( $C_2H_2$ ) and the second one with  $C_2H$  radicals, in order to study conditions closer to those of real experimental conditions and to identify the decomposition leading to the deposition. Temperature variations were studied in order to determine the optimal conditions for improving quality of the growing graphene as well as efficient temperature for cracking of acetylene. Therefore, various temperatures, close to those of the experimental conditions, were simulated; specifically, 200, 500, 700, 900 °C. The Ge-Ge and Ge-C interactions were described based on the Tersoff potential. In addition, the Tersoff mixing rules were used for Ge-C interactions as a first attempt.<sup>51</sup> Then, Ge-H interactions were added based on the non-bonded interactions of Universal Force Field (UFF) leading to the Lennard-Jones potential  $V_{Ge-H}(r)$ , as follows:<sup>52</sup>

$$V_{Ge-H}(r) = 4\epsilon \left[ \left( \frac{\sigma}{r} \right)^6 - \left( \frac{\sigma}{r} \right)^{12} \right] \quad (3)$$

where  $\sigma = 3.62 \text{ \AA}$  and  $\epsilon = 0.0546 \text{ eV}$ . Besides, C-C and C-H interactions were described using Reactive Empirical Bond-Order (REBO) potential for  $C_2H$  and  $C_2H_2$  precursors of deposition simulations.<sup>53</sup>

Three runs of molecular dynamics simulations were carried out with, respectively, 1000 carbon atoms, 500  $C_2H_2$  molecules, and 500  $C_2H$  radicals. Molecules were introduced one after each other towards the Ge (100) periodic slab ( $5a_0 \times 5a_0 \times 3a_0$ ,  $a_0 = 5.66 \text{ \AA}$ ) every 2000-time step (dt). Hence, the same number of carbon atoms was released toward the surface. For C deposition,  $dt = 1 \text{ fs}$ ,

whereas for  $C_2H$  and  $C_2H_2$   $dt = 0.1$  fs, considering fast motion of the carbon bonded hydrogen. During molecular modeling, a Langevin thermostat maintained temperature of vapor and Ge substrate, for mimicking equilibrium thermal CVI.<sup>54</sup>

**Figure 7** Profile view (a) and top view (b) obtained with the molecular modeling using Tersoff potentials of growth with only acetylene molecules as carbon precursors at 500 °C, Profile view (c) and top view (d) of Graphene growth at 500 °C with addition of  $C_2H$  radicals as carbon precursors.

Germanium substrate is not represented for snapshots (d) and (f) for further clarity; thus, only carbon-carbon and hydrogen-carbon bonds are represented.

(A color version of this figure can be viewed online, yellow spheres are Ge atoms, blue ticks are C-C bonds and blue-white ticks are C-H bonds)

Figure 7 shows the snapshots of the simulation at 500 °C, for two precursors, which were 500  $C_2H_2$  molecules and then 500  $C_2H$  radicals. Figure 7a and 7b present results of the molecular modeling at 500 °C with acetylene molecules as precursors. Figure 7c and 7d represent the results for the case in which  $C_2H$  radicals were used as precursors, at 500 °C. Since we were interested in bond formation of C on Ge surface, the snapshots only show the atomic arrangements of Ge atoms and all the covalent bonds of carbon atoms. The covalent bonds in blue are between carbon atoms (C-C) and white ones are between carbon and hydrogen atoms (C-H). The C-C and C-H bonds are represented without the atoms, for clearly highlighting carbon ring domains.

Based on figure 7c and 7d, clearly, C<sub>2</sub>H deposition led to growth, while C<sub>2</sub>H<sub>2</sub> molecules did not react, as can be seen in figure 7a and 7b. Moreover, figure 7c and 7d present organized rings carbon which are pentagon and hexagon and rarely heptagon. Finally, in the case of acetylene molecules as precursors and growth temperature of 500 °C, molecules are adsorbed without reactivity on the surface. Nevertheless, consistent with XPS data, no covalent bonds between the Ge and the carbon atoms, has been observed.

In the case of the C<sub>2</sub>H vapor, graphene domains are formed indicating that the presence of radical is required for nucleation and growth of the graphenic coating. Even if it is not perfectly flat and organized, the deposition is not amorphous carbon as Raman spectroscopy and XPS measurements previously depicted attested. Amorphous carbon corresponds to stage 2 in ref. 39 with a downshift of the G peak and a proportion of almost 20 % of sp<sup>3</sup> hybridization.<sup>39</sup>

In order to evaluate the organization of the deposition, Radical Pair Distribution Function (g(r)) (RPDF) is used to analysis calculations done at different temperature and with C<sub>2</sub>H radical precursors. First, a perfect layer of graphene obtained with modeling dynamic modeling is taken as reference and RPDF is applied. For graphene, the number of first neighbor is 3 atoms and that of second neighbor is 9 atoms. The distance between one atom of carbon and the first neighbor is 1.425 Å and 2.475 Å for the second one. The same analysis, achieved on the simulations at 200, 500, 700 and 900 °C with C<sub>2</sub>H precursors, gave the same distances between the close neighbor. It means that coating shows a structure close from the graphene one. The number of neighbor is also pointed out. In average, the number of first neighbor is 2.5 atoms which attested the presence of defects in the form of pentagon, aliphatic chain or incomplete ring.

The molecular dynamic modeling, in good agreement with the experimental findings, elucidated some underlying mechanisms responsible for growth of nanographene on MP-Ge substrate during the CVI process. First, it showed that there was no diffusion of carbon atoms inside Ge substrate. Second, evidently, acetylene molecules alone cannot react directly with the Ge surface, even at high temperature and growth of graphene on Ge surface (100) requires the existence of radicals. This means radicals, such as C<sub>2</sub>H, must appeared. Calculations performed with C<sub>2</sub>H<sub>2</sub> and H<sub>2</sub> at 500 °C exhibited radicals in vapor phase far from the surface attesting the formation in the vapor phase (see figure S6). However, a competitive reaction involving Ge radicals, as suggested by Share et al. in the case of silicon, cannot be discarded.<sup>15</sup> Moreover, the further decomposition of C<sub>2</sub>H radicals occurring at the surface of Ge certainly involved such mechanism. Germanium radicals on the top of the surface could participate in this decomposition and form carbon atoms which reorganise through thermally stimulated processes, to form the graphene film.<sup>37</sup> Germanium surface

reorganizes it in dimers to reduce the number of dangling bonds. This reorganization impacts drastically the reactivity of the surface toward gas-phase reactants.<sup>17,55</sup> Our assumption is that the carbon precursors are decomposed in the vapor phase and then are captured by the vacancies of germanium dimers before reorganize them through thermally stimulation processes to form graphene film. Third, as was shown with Raman spectroscopy data, modeling outcomes confirmed formation of nanographene structure, while in good correlation with XPS data, modeling indicated that C-Ge covalent bonding was not created.

#### **4. Conclusions**

We developed a new Graphene Mesoporous-Germanium nanomaterial that integrates directly graphene into the mesoporous structure. As a result, 2D graphene became 3D graphene by conforming to the porous structure. First, a study of the D and G peaks that appeared in the Raman spectra indicates the temperature dependency of the nanographene coating quality. Decreasing carbonization temperature improved the domain size of nanographene signifying less grain boundaries. Moreover, the nanographene coating is composed of  $sp^2$  C-C covalent bonding and did not have any observable Ge-C covalent bonding demonstrating that the graphene integrity and related properties are preserved. Therefore, the domain size of the carbon coating is tunable with the carbonization temperature, which allows adjusting properties such as electrical and thermal conductivity.

The synthesis mechanism at work was investigated by molecular dynamics modeling showing that only  $C_2H$  radicals react with Ge surface and that acetylene molecules could not directly react with Ge. In an excellent agreement with experimental data, modeling data showed that graphene film could be obtained at 500 °C with radicals, and, no covalent bonds would be formed between Ge and C.

Finally, mesoporous Ge shows a high degree of crystallinity even after all the process.

The successful synthesis of this nanostructured material opens opportunities in a broad range of applications such as epitaxial growth of material, energy storage systems, health, thermoelectric devices or microelectronics.<sup>1,56</sup> Indeed, in order to combine the respective advantages of semiconductors and graphene, hybrid or composite materials were developed with the aim of directly applying it to a Complementary Metal-Oxide-Semiconductor (CMOS) based manufacturing process.<sup>3,57</sup> Therefore, direct growth of graphene on semiconductors needs to be developed with the objective of integrating the method within the CMOS industry, which is incompatible with the use of metal.<sup>57</sup> Recently, some important breakthrough in this area has been

achieved.<sup>37,58</sup> These achievements offer the opportunity to incorporate the remarkable properties of graphene for notable enhancement of semiconductor-based devices, possibly beyond the limits set by their nature or fabrication processes. As a matter of fact, the next decades will be dedicated to the introduction of graphene in semiconductor fabrication lines for direct integration on devices.<sup>3,57</sup> The limitation of 2D graphene is exceeded with the incorporation of graphene in 3D.<sup>59,60</sup> CMOS are not the only application possible, possible applications for this kind of material are wide and numerous and could be analogous to similar materials, such as the graphene-mesoporous silicon, with demonstrated applications like compliant substrates for heteroepitaxy, supercapacitors, drug delivery, sensor applications.<sup>61–63</sup>
