**Running head:** Parasite adaptive response to olive cultivation

1  
2  
3 ABSTRACT: Cultivated plants usually differ from their wild progenitors in several  
4 morphological and/or physiological traits. Their microbe communities might also differ ~~in~~  
5 ~~particular due to~~because of adaptation to new conditions related to cultivation. To test this  
6  
7 hypothesis, we ~~here~~-investigated d morphological traits in a parthenogenetic root-knot nematode  
8  
9 (*Meloidogyne javanica*) from natural and agricultural environments. Seventeen populations of  
10  
11 *M. javanica* were sampled on cultivated ~~or~~and wild olives in Morocco, and then maintained in  
12  
13 control conditions for a "common garden" experiment. We estimated the genetic variation on  
14  
15 three traits (stylet size, neck width, and body width) by a quantitative genetic design - ten  
16  
17 families per population and nine individuals per family were measured - while molecular  
18  
19 variation was investigated with a mitochondrial marker to identify the genetic lineages of  
20  
21 nematode isolates sampled from wild and cultivated olives. Significant morphological  
22  
23 differences were detected between individuals from wild *vs.* cultivated host for the three traits,  
24  
25 while no phylogenetic clustering was observed among isolates collected on those two hosts.  
26  
27 Our results thus ~~sustain~~suggest an adaptive response of the ~~studied~~-asexual parasite, ~~likely for~~  
28  
29 ~~dealing with~~possibly related to the deep modification of soil nematode ~~community~~communities  
30  
31 between natural olive stands and orchards.

## INTRODUCTION

The evolution of traits depends upon genetic variation on which natural selection can act to produce adaptations in response to the environment (Fabian & Flatt, 2012). Environmental variation modulates organismal development and substantially contributes to phenotypic variation within and among populations. Understanding how environmental and genotypic variations interact to generate phenotypic variation is thus a central challenge in biology, especially for deciphering how organisms adapt to anthropogenic disturbance (e.g. Braendle & Teotonio, 2015; Cook, 2018; Grishkan *et al.*, 2018; Ringot *et al.*, 2018). Domesticated organisms are appropriate models for the study of such evolutionary processes due to their recent evolution under selection (< 12,000 years ago for most crops), and good archaeological or historical records on their human-mediated diffusion and subsequent diversification (Meyer & Purugganan, 2013). Besides, novel environmental conditions (e.g. related to animal breeding or plant cultivation) may also have ecological and evolutionary consequences on the interacting biota. For instance, parasites and endophytes associated to plants or animals should have also adapted to their host after their domestication (e.g. Stukenbrock *et al.*, 2007; Gladieux *et al.*, 2010).

The olive tree (*Olea europaea* L.) is the iconic Mediterranean crop that accompanied the emergence of first civilizations in the Middle East (Kaniewski *et al.*, 2012). Archaeological evidences supports an early olive exploitation during the Neolithic, but its domestication (characterized by the establishment of orchards, and the vegetative multiplication of individuals with interesting agronomical traits, such as bigger fruits and adaptation to anthropogenic habitats) is considered to start in the Levant at the Chalcolithic period, at least 6000 years ago (for a review see Kaniewski *et al.*, 2012). The cultivated olive origins are complex and multiple, with the human-mediated diffusion of cultivars, first from the northern Levant, followed by recurrent admixtures with local wild olives (commonly referred to oleasters) or (pre-

1  
2  
3 )domesticated forms in various parts of the Mediterranean Basin (Díez *et al.*, 2015; Besnard &  
4 Rubio de Casas, 2016). The structure of microbiome communities associated to the olive still  
5  
6 needs to be better investigated to assess the impact of olive domestication and cultivation  
7  
8 practices on their diversity (Besnard *et al.*, 2018). Recent studies on nematodes (Palomares-  
9  
10 Rius *et al.*, 2012, 2015; Ali *et al.*, 2017; Archidona-Yuste *et al.*, 2018, 2020a) and fungi  
11  
12 (Montes-Borrego *et al.*, 2014; Abdelfattah *et al.*, 2015) associated to the cultivated and/or wild  
13  
14 olives indicate that such communities are influenced by environmental factors (e.g. soil  
15  
16 parameters, cultivation methods) but also the genotype of the host. In particular, Ali *et al.*  
17  
18 (2017) reported higher species richness for plant parasitic nematodes (PPNs) in wild olive  
19  
20 stands, while their abundance was higher in olive orchards.  
21  
22  
23  
24  
25

26  
27 The mitotic parthenogenetic *Meloidogyne javanica* (Treub) Chitwood is one of the  
28  
29 nematode species parasiting the olive (Ali *et al.*, 2014). Like all PPNs impacting the roots,  
30  
31 *Meloidogyne* species prevent proper water and nutriments absorption. By consequence, the  
32  
33 impact on growth and yield of olive can be important (Lamberti & Lownsbery, 1968; Lamberti  
34  
35 & Baines, 1969; Sasanelli *et al.*, 1997, 2002), notably in nurseries (Nico *et al.*, 2002). While  
36  
37 few studies have been carried out on the intra-population genetic variability or the genetic  
38  
39 dispersal between populations in plant parasitic nematodes (Plantard & Porte, 2004), root-knot  
40  
41 nematodes (or RKNs; *Meloidogyne* spp.) have been relatively well studied. A particular  
42  
43 attention was given to RKNs because they are widely distributed and are endoparasites of nearly  
44  
45 every species of higher plants (Moens *et al.*, 2009) causing significant yield crop losses  
46  
47 worldwide. A huge morphological and genetic variability have been reported between  
48  
49 *Meloidogyne* species and between populations from the same species (Netscher, 1978; Hesar  
50  
51 *et al.*, 2011; da Silva *et al.*, 2014; Medina *et al.*, 2017; Tatu-Nyaku *et al.*, 2018). This diversity  
52  
53 has been described based on various biological traits such as the morphology but it can also be  
54  
55 studied through the ability of parasitism or the adaptation to environmental conditions (Jepson,  
56  
57  
58  
59  
60

1  
2  
3 1987; Eisenback & Triantaphyllou, 1991). In addition, the selection of virulent strains of RKNs  
4  
5 on resistant plants may result in a co-evolution between the parasitic nematode and its host  
6  
7 (Castagnone-Sereno, 2006).  
8  
9

10 The aim of this study was to evaluate the effect of crop cultivation on trait variation in  
11  
12 one RKN species parasiting olive roots. We conducted a common garden experiment in order  
13  
14 to measure the differentiation of three quantitative traits between 17 Moroccan populations of  
15  
16 *M. javanica* collected in both cultivated and natural *O. europaea* stands. We also characterized  
17  
18 genetic lineages of those RKNs using a mitochondrial marker, to control for their relatedness  
19  
20 and assess lineage diversity within and among populations.  
21

## 26 MATERIAL AND METHODS

### 27 BIOLOGICAL MATERIAL AND FIELD SAMPLING

28  
29  
30  
31  
32 In this study, we worked on the 17 Moroccan populations of the nematode *Meloidogyne*  
33  
34 *javanica* that were sampled in olive stands by Ali *et al.* (2016, 2017). Even if this species is  
35  
36 parasiting the roots, we collected soil in the upper rhizosphere (the 20–30 cm deep) with a small  
37  
38 spade (Ali *et al.*, 2016, 2017), because *M. javanica* spend almost all of their life cycle in the  
39  
40 soil (Cadet & Thioulouse, 1998). This nematode survey was carried out from March to April  
41  
42 2012. Population locations (with GPS coordinates) are given in Fig. S1. We reused the same  
43  
44 population labels as described in Ali *et al.* (2017). Those populations were either collected on  
45  
46 cultivated olives or oleasters, to which we will then refer as "Cultivated" and "Wild" habitat,  
47  
48 respectively [see Ali *et al.* (2017) for more details on sampling locations]. Cultivated olives  
49  
50 from the agricultural sites correspond to the 'Picholine Marocaine' cultivar (Ali *et al.*, 2017),  
51  
52 that is largely spread in Morocco (Khadari *et al.*, 2008), but we did not have any information  
53  
54 about rootstock genotypes. All cultivated olives were conducted in traditional (7 locations) and  
55  
56  
57  
58  
59  
60

1  
2  
3 high density orchards (5 locations; Ali *et al.*, 2017). The soil sample was brought back in the  
4 quarantine laboratory at the Center for Biology and Management of populations (UMR CBGP,  
5 France). The species identification was first made morphologically (for the genera) and then  
6 was confirmed by esterase phenotype analysis (Ali *et al.*, 2016). *Meloidogyne javanica*  
7 populations were then reared and maintained on tomato. For nematode inoculation, tomato  
8 plants (*Lycopersicon esculentum* Mill. cv. Roma) were prepared in 50-ml plastic corning tubes  
9 (35-mm diameter) containing a mixture of compost, sand and sodium polyacrylamide crystals.

#### CHARACTERIZATION OF MATERNAL LINEAGES WITH A MITOCHONDRIAL DNA SEQUENCE

20  
21 We first controlled for the relatedness and lineage diversity within and among *M. javanica*  
22 populations. For this purpose, we collected individuals of *M. javanica* reared on tomatoes (Fig.  
23 1) just after field collection as explained above. An individual second stage juvenile (J2) was  
24 isolated from fifteen egg masses per population and then conserved in 6  $\mu$ L of distilled water  
25 at -20°C. DNA was then extracted from each J2 using the DNeasy Blood & Tissue kit (Qiagen  
26 Inc.). Because a small amount of living material was used, DNA extracts were poorly  
27 concentrated (< 1 ng/ $\mu$ L).  
28

30  
31  
32  
33  
34  
35  
36  
37  
38

39 Considering the lack of suitable genetic markers for *Meloidogyne*, knowledge of their  
40 population genetic structure and colonization process remains poor. Given the asexual  
41 reproductive mode of *M. javanica* and its relatives (i.e. obligate parthenogenesis; Castagnone-  
42 Sereno, 2006), we expect that clonal reproduction led to no sexual recombination and an overall  
43 low genomic variation between isolates, as recently reported in a close relative (*M. incognita*;  
44 Koutsovoulos *et al.*, 2020). Mitogenome (mtDNA) polymorphisms allowing distinguishing  
45 species and lineages among parthenogenetic RKNs of the *M. incognita* group (MIG group;  
46 Janssen *et al.*, 2016), we developed an mtDNA marker based on a highly variable minisatellite.  
47 A non-coding region containing 63-bp tandem repeats, named 63R in *M. javanica* (Okimoto *et*  
48 *al.*, 1991; Besnard *et al.*, 2014), was thus sequenced. The use of an mtDNA locus also had the  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 advantage of an easier PCR amplification (compared to nuclear single-copy regions) due to  
4 multiple copies in the cell. Such a locus is thus a marker of choice when dealing with poorly  
5 concentrated DNA extracts. Although the mitogenome is supposedly non recombinant,  
6 heteroplasmy (i.e. mix of mtDNA variants within individuals) has however been reported in  
7 *Meloidogyne* (especially in the 63R minisatellite, but not only; Okimoto *et al.*, 1991; Besnard  
8 *et al.*, 2019). Beforehand, such intra-individual variation needs to be carefully considered  
9 because it may limit the usefulness of mtDNA polymorphisms for population genetics (Lunt *et*  
10 *al.*, 1998).

11  
12  
13  
14  
15  
16  
17  
18  
19  
20  
21  
22 The 63R fragment was amplified by PCR with the following primers: 63R-For1  
23 (TTGAAATTGCTTTATTGTTACTAAGAAG) and 63R-Rev (ACCTTAGAAATATGAAWCCTAWAGA). PCR  
24 reaction assays were carried out in a 20- $\mu$ L final volume containing 2  $\mu$ L PCR buffer 10x  
25 (Qiagen), 1  $\mu$ L of each primer (initial concentration at 10  $\mu$ M), 12  $\mu$ L of UV treated distilled  
26 water and 4  $\mu$ L of genomic DNA. The thermocycler was programmed for 15 min at 95°C  
27 followed by 40 cycles of 30 s at 94°C, 1 min, 30 s at 55°C and 1 min 30 at 72°C and then 10 min  
28 at 72°C. PCR products were purified and sequenced in both directions using the same  
29 amplification primers referred above by Eurofins MWG (Germany). When necessary (i.e.  
30 fragment size > 800 bp), a third sequencing reaction was performed with an internal primer  
31 (63R-For2: GAATCCATAAATCAGAAAATTGAGG). In total, we successfully analyzed 119  
32 individuals from both natural (37 individuals) and agricultural locations (82 individuals; Table  
33 S1).

34  
35  
36  
37  
38  
39  
40

42  
43  
44  
45  
46  
47  
48  
49  
50 Sequences were manually edited with the BioEdit software (Hall, 1999). We noticed  
51 cases of heteroplasmy when a mix of distinct length or single nucleotide variants was observed  
52 in the chromatogram. In such cases (ca. 10% of isolates), the heteroplasmic pattern was  
53 carefully annotated and the most abundant sequence was considered (see results). Sequences  
54 were finally aligned in MEGA v.6 (Tamura *et al.*, 2013). Mitotype networks were reconstructed  
55  
56  
57  
58  
59  
60

1  
2  
3 with the reduced median method implemented in NETWORK v.10 (Bandelt *et al.*, 1999)  
4 considering only single nucleotide polymorphisms (that allowed identifying 'haplogroups').  
5  
6 Mitotypes of two closely related species [*M. arenaria* (*Ma*; LS974734) and *M. incognita* (*Mi*;  
7 KJ476151)] were used as outgroups. Length polymorphisms due to variable number of repeats  
8 in the minisatellite (that allowed identifying 'haplotypes') were secondarily considered, but as  
9 this repeated motif shows a relatively high level of heteroplasmy, it was interpreted with caution  
10 (see results).  
11  
12  
13  
14  
15  
16  
17  
18  
19

20 Population structure was analyzed using hierarchical  $F$ -statistics, estimated from variance  
21 components of gene frequencies (Weir & Cockerham, 1984).  $F_{ST}$  is a metric of population  
22 differentiation at neutral genetic markers (Weir & Cockerham, 1984) and here was calculated  
23 between habitats (populations are nested within habitat i.e. cultivated vs. wild, and individuals  
24 are nested within population) with the package HIERFSTAT (Goudet, 2005) for the statistical  
25 software R (R Development Core Team, 2019). For each population, we also estimated an index  
26 of mtDNA diversity as  $D = 1 - \sum p_i^2$ , where  $p_i$  is the frequency of haplogroup or haplotype  $i$  in  
27 the population. This parameter was thus calculated for both mtDNA haplogroups ( $D_{haplogroups}$ )  
28 and haplotypes ( $D_{haplotypes}$ ).

#### 42 EXPERIMENTAL DESIGN CONSTRUCTION

43 For each *M. javanica* population, egg masses were randomly selected from ten mothers (after  
44 molecular characterization, which was done on different individuals; Fig. 1) and put  
45 individually to hatch in distilled water in Petri dishes (5-cm diameter). This species reproduces  
46 by obligatory mitotic parthenogenesis, i.e. females reproduce without the involvement of males  
47 or sperm (Van der Beek *et al.*, 1998). This means that all individuals coming from the same  
48 mother are expected genetically identical between them and also to their mother. Each egg mass  
49 is considered as progeny (i.e. family). Ten egg masses (i.e. ten families) were thus formed per  
50 population. From each egg mass, 50-60 infective juveniles (J2) were withdrawn by a pipette  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 and used to inoculate a one-month-old tomato plant. The inoculum suspension was injected in  
4 several holes onto the soil surface around the stem base. The plants were maintained in a climate  
5 chamber with 12 hours light at 23°C and 12 hours dark at 20°C.  
6  
7  
8

9  
10 Four to six weeks after inoculation, egg masses of each family were isolated from each  
11 tomato plant (Fig. 1). Three egg masses per plant were collected representing three replicates  
12 per family. Egg masses were individually put to hatch in Petri dishes (5-cm diameter), and three  
13 individuals per egg mass were then randomly chosen for further phenotypic measurements (see  
14 below). The dishes were controlled every day in order to take individuals for morphological  
15 measurements at the same age. This was necessary to avoid a spurious relationship between the  
16 morphological variability among individuals with their stage of development. Fixing was thus  
17 done when individuals were ten-days old (after hatching). Freshly hatched second-stage  
18 juveniles (J2s) were randomly picked from each dish and placed in a drop of water. J2s were  
19 temporarily conserved in the fridge and then fixed and killed in the glycerol previously heated  
20 at 40°C (De Grisse, 1969).

#### 37 TRAITS MEASUREMENTS AND ANALYSES

38  
39 For the morphometric measures, three J2s per egg mass were collected and deposited in a drop  
40 of 15 µL of fixing solution on a slide with paraffin wax. The slide was then covered with a glass  
41 cover slip and then placed for a few seconds on a hot plate to ensure that the paraffin melts and  
42 then left to cool to keep the J2s trapped in the fixing solution. More than 1530 individuals were  
43 measured as described in Fig. 1. Several photos were performed on each J2. All observations  
44 were carried out under an optical microscope (Leica DMRD) attached to a camera (Leica DMF  
45 20). Measurements were then done on photos using the LAS (Leica® Application Suite) applied  
46 software v.2.5.0 R1. On each J2, the following morphological traits were measured (Fig. 2): (i)  
47 maximum body width; (ii) width of the body at the median bulb (hereafter neck width); and  
48 (iii) stylet length. Measures of these traits are frequently used in the morphological

2  
3 characterization of RKNs, and an intraspecific quantitative variation has been reported (Jepson,  
4 1987; Siddiqi, 2000; Hesar *et al.*, 2011). The observations were made under magnification of  
5  
6 10× or 20× for the entire size of the individual, and under 100× for the two others characters.  
7  
8  
9 A Spearman test (Hall, 2015) was used to assess the correlation between the three traits.  
10  
11

12 We considered traditional and high-density orchards together as “cultivated” locations.  
13  
14 We tested the values of traits between habitats ('Cultivated' or 'Wild') using a hierarchical  
15 analysis of variance (ANOVA) using the statistical software R (R Development Core Team,  
16 2019). Populations were thus nested into habitat, families into population, and individuals into  
17 families. By this way, we estimated the variance components between habitats ( $\sigma^2_{\text{Hab}}$ ), between  
18 populations within habitats ( $\sigma^2_{\text{Pop}}$ ), between families within populations ( $\sigma^2_{\text{Fam}}$ ) and between  
19 individuals within families ( $\sigma^2_{\text{Ind}}$ ) with the method of restricted maximum likelihood (REML;  
20 Lynch & Walsh 1998). Individuals are thus nested within a family, which is nested within a  
21 population, which is nested within a habitat. REML estimates were obtained using the package  
22 NLME for R (Pinheiro *et al.*, 2019). These components of variance allowed us to estimate  
23 broad-sense heritability ( $H^2$ ) for each phenotypic trait.  $H^2$  represents the amount of the genetic  
24 part in the phenotypic variation of a given trait. Heritability scores range from 0 to 1; when  $H^2$   
25 = 1, then all variation in a population is due to differences or variation between genotypes (i.e.  
26 there is no environmentally caused variation); at the opposite, when  $H^2 = 0$ , all variation in the  
27 population comes from the environment experienced by individuals. Although there can be a  
28 range depending on the methodology used, heritability values less than 0.20 are usually  
29 considered low, between 0.21 and 0.40 are moderate, and above 0.40 are high (Lynch & Walsh,  
30 1998). Broad-sense heritabilities were calculated as  $H^2 = V_G / V_P$ , with  $V_G$  and  $V_P$  the population  
31 genetic and phenotypic variances, respectively (Falconer, 1989). Since individuals reproduced  
32 by parthenogenesis, offspring are considered genetically identical to their mother. Thus, genetic  
33 variation ( $V_G$ ) was estimated as the between-family variance ( $\sigma^2_{\text{Fam}}$ ), and  $V_E$  was estimated by

1  
2  
3 the between-individuals variance ( $\sigma^2_{\text{Ind}}$ ).  $V_P$  is the result of the genetic plus the environmental  
4 variances. Barton & Turelli (1989) argued that common garden experiments like here can  
5 overestimate heritabilities because the environmental variance is greatly reduced. In order to  
6 investigate genetic variation without any environmental variance, Houle (1992) suggested  
7 using the coefficient of genetic variation ( $CV_G$ ):  $CV_G = (\sigma^2_{\text{Fam}})^{0.5} / m$ , where  $m$  is the population  
8 phenotypic mean.  
9

10  
11  
12  $Q_{\text{ST}}$  is the analog of  $F_{\text{ST}}$  but for quantitative trait. It measures differentiation at a  
13 quantitative trait (Spitze, 1993; Whitlock, 2008). We thus estimated quantitative trait  
14 differentiation among habitats for each trait as the quantitative variance between habitats over  
15 the total [i.e.  $\sigma^2_{\text{Hab}} / (\sigma^2_{\text{Hab}} + \sigma^2_{\text{Pop}} + \sigma^2_{\text{Fam}})$ ].  
16

17  
18 A Mantel test was also used to evaluate if the morphological variability between  
19 populations is correlated with the geographical distance between populations. We computed  
20 this test using the library `vegan` (Dixon, 2003) in R.  
21  
22

23  
24 At last, we tested a possible correlation between molecular diversity ( $D$ ) and the  
25 quantitative diversity for each population (considering either  $\sigma^2_{\text{Fam}}$ ,  $H^2$  or  $CV_G$ ). In particular,  
26 we tested that a population with high molecular diversity could also show a high quantitative  
27 diversity. Correlations between diversity indexes ( $D_{\text{haplogroups}}$  or  $D_{\text{haplotypes}}$ ) and quantitative  
28 diversity parameters were estimated using the Pearson method (Hall, 2015) in R. However, as  
29 we tested multiple correlations for three traits, the problem of multiplicity occurs. Indeed, the  
30 more hypotheses we check, the higher the probability of finding a significant  $p$ -value by chance  
31 arises. We thus « corrected » those  $p$ -values by the « Bonferroni correction » in which the  $p$ -  
32 values are multiplied by the number of comparisons.

3 In this study, we collected 17 *M. javanica* populations in Morocco: 12 from cultivated  
4 conditions and five from natural conditions (Fig. S1). Populations belonging to the same habitat  
5 ('Cultivated' vs. 'Wild') are not significantly closer to one another than populations belonging  
6 to different habitats (Mantel test :  $R = 0.10$  and  $p = 0.16$ ). In other words, there is no correlation  
7 between the habitat type and the geographical distance.

#### 16 MOLECULAR VARIATION

17  
18 An mtDNA fragment (63R region) of 900 to 1400 bp was generated on 119 individuals.  
19 Sequencing revealed variation in the number of repeats in the minisatellite 63R region plus five  
20 additional single nucleotide polymorphisms (SNPs) located in regions flanking the 63R. A  
21 careful examination of these SNPs showed one case of heteroplasmy on individual '253-M6'  
22 that combined two types of sequences [referred to *Mj* I-7 (the most abundant; above 80%) and  
23 *Mj* IV-7; Table S1]. Other accessions did not show such patterns of intra-individual  
24 polymorphisms on SNPs, indicating that these polymorphisms may be potentially informative  
25 to distinguish divergent evolutionary lineages of *M. javanica*. These five SNPs allowed the  
26 distinction of four mitochondrial haplogroups (Fig. 3). Haplogroup *Mj* III was only found at  
27 location P-285, and is relatively divergent from the others (distinguished by three or four SNPs).  
28 Individuals collected on wild and cultivated olives shared the two most frequent related  
29 haplogroups *Mj* I and *Mj* II (> 40%; Table 1), while two minor haplogroups (< 10%) were only  
30 found in two cultivated locations (P-253 and P-285; Fig. 3). No clear distinction between  
31 isolates collected on wild and cultivated olives was thus observed based on SNPs.

49  
50

51 When considering the number of repeats within the 63R minisatellite, a higher variation  
52 was observed (Figs S2, S3). The number of repeats varied from 7 to 14. By combining SNPs  
53 and length variation, 19 haplotypes were distinguished (Tables S1 and S2; GenBank nos:  
54 LS974735 to LS974753) but a relatively high level of heteroplasmy was also observed (13/119  
55 isolates; Table S1). In addition, the haplotype network was mostly unresolved (Fig. S2)  
56  
57  
58  
59  
60

1  
2  
3 indicating a high level of homoplasy in the data. For these reasons, their interpretation has to  
4  
5 be done with caution. Overall, the relatively high intra-population diversity (Fig. S3) coupled  
6  
7 to the fact that many close locations did not share any haplotypes nevertheless suggest a  
8  
9 complex pattern of isolation and migration between locations, but this needs to be investigated  
10  
11 with more reliable DNA markers on a larger population sampling. Yet, isolates from wild and  
12  
13 cultivated olives again shared numerous haplotypes indicating they do not represent old  
14  
15 diverging evolutionary lineages.  
16  
17  
18

19  
20 We found no genetic structure between habitats ( $F_{ST} = -0.044$  and  $-0.017$ , for haplogroups  
21  
22 and haplotypes, respectively), while a relatively high structure was detected between  
23  
24 populations within habitat ( $F_{ST} = 0.516$  and  $0.464$ , using haplogroups and haplotypes,  
25  
26 respectively).  
27  
28  
29

#### 30 PHENOTYPIC VARIATION

31  
32 The mean trait values per population are reported in Table 2, and are similar to those previously  
33  
34 reported on *M. javanica* (e.g. Hesar *et al.*, 2011). One weak correlation was found between neck  
35  
36 and body widths ( $R = 0.10$ ,  $p < 0.05$ ). Individuals belonging to populations parasiting cultivated  
37  
38 olive trees tend to be smaller. They exhibit a smaller body width, a smaller neck and a smaller  
39  
40 stylet (Table 2). They all show a significant difference between the 'Cultivated' and 'Wild'  
41  
42 conditions (Table 2). Between habitats, mean broad-sense heritabilities are varying across traits,  
43  
44 ranging from 0.13 to 0.30 (Table 3). Mean  $CV_G$  values between habitats are low and range from  
45  
46 0.01 to 0.02. Values per population are given in Table S3.  
47  
48  
49

50  
51  $Q_{ST}$  values were estimated between habitats for the three traits (Table 4). They range from  
52  
53 0.04 to 0.48, suggesting a structure in phenotypic traits between habitats, i.e. wild vs. cultivated  
54  
55 hosts.  $Q_{ST}$  values were relatively high for the neck and body widths (0.31 and 0.48,  
56  
57 respectively), in contrast to the size of the stylet, for which the measured  $Q_{ST}$  was very low  
58  
59  
60

(0.04). No significant correlation between molecular diversity and quantitative values per population for all traits was detected (Table S3; Figs S4, S5).

Because our sample design was unbalanced (i.e. 12 and five populations respectively sampled on cultivated and wild olives), some of our comparisons could be biased. We thus chose to compare the five populations sampled on high-density cultivated olives against the five populations sampled on oleasters. The results are shown in supplementary material (Tables S4, S5, S6) and exhibit very similar results suggesting that our results based on the whole sample are reliable for molecular and quantitative data.

## DISCUSSION

In this study, molecular and morphological variation was observed among isolates of a plant-parasitic nematode of the olive tree. We first checked that there is no genetic isolation between populations sampled in "Cultivated" and "Wild" habitats. After growing in controlled conditions, we found that populations collected from olive orchards are smaller (for stylet size, body and neck widths) than in oleaster stands. We then quantified the genetic basis of such phenotypic differences. A selective process was suggested by our observations despite the clonal reproductive mode of *M. javanica*. Our results ~~sustain~~ suggest an adaptive response of ~~this~~ the root parasite for dealing with environmental changes between natural olive stands and orchards.

ON THE *M. JAVANICA* ASEXUAL EVOLUTION AND POPULATION DIFFERENTIATION

While low intraspecific genetic variation has been previously reported in *Meloidogyne* species (Castagnone-Sereno, 2002; Castagnone-Sereno *et al.*, 2019; Besnard *et al.*, 2019), a full nuclear genome analysis recently brought strong insights for clonal evolution in the parthenogenetic *M. incognita* (Koutsovoulos *et al.*, 2020). Yet, this species kept a high adaptive potential despite its clonal mode of reproduction, and a similar pattern may be expected in *M. javanica* that also belongs to the MIG group (Tigano *et al.*, 2005). Such asexual evolution is not common in animals and may have deep consequences on adaptive responses.

In our study, we were able to distinguish four main mtDNA haplogroups in *M. javanica* (and a total of 19 haplotypes when considering minisatellite variation; Table S2). We thus confirm the utility of the mitogenome for distinguishing lineages among the MIG group, even at the species level (Janssen *et al.*, 2016). Heteroplasmy was also detected (notably based on SNPs on one isolate). Such a mix of mitochondrial variants within some individuals may either result from the accumulation of mutations and maintenance of DNA polymorphisms over time, or some exchange of genetic material between individuals (possibly via horizontal gene transfers, demonstrated between distantly related species, but that could also happen between congeners; Danchin, 2011; Dunning & Christin, 2020). Whatever its origin, heteroplasmy has to be considered with caution, and we thus put more emphasize on SNPs, for which heteroplasmy was rare (< 1%). SNPs first allowed us to demonstrate that populations sampled on cultivated or wild olives are not differentiated. This means that *M. javanica* populations may exchange individuals between habitats. In contrast, we however showed a relatively high differentiation between populations within habitats, suggesting patterns of rapid isolation at the local scale, probably due to very stochastic events of extinction and dispersal via infected plant, soil or water [e.g. close populations 261 and 262 from the "Cultivated" habitat do not share any mitochondrial haplogroups (Fig. 3), while many haplotypes are specific to some populations

(Fig. S3)]. Despite the supposed clonal evolution in *M. javanica*, an unexpected high mtDNA variation was thus observed within and among populations in both natural and cultivated habitats (Fig. 3). Distinct nematode lineages therefore co-occur within both habitats, which may maintain an evolutionary potential for adapting to variable conditions.

#### DIVERGING SELECTION BETWEEN HABITATS

In parallel, significant phenotypic difference was observed between habitats strongly suggesting local adaptation of *M. javanica* to "Cultivated" or "Wild" conditions. Here, low to moderate heritability and  $CV_G$  values reveal a genetic basis to this variation. However, while such morphological difference can be explained by selection, drift could also be responsible for this pattern. In this context, comparisons of population differentiation at quantitative traits ( $Q_{ST}$ ) with population differentiation at genetic markers ( $F_{ST}$ ) can provide a powerful tool (Merilä & Crnokrak, 2001; McKay & Latta, 2002; Leinonen *et al.*, 2008; Whitlock, 2008). Selection is expected to affect regions at or close to the quantitative trait loci underlying the phenotypic trait, while neutral processes should have equal chance to affect any genomic region. To be short, a phenotypic differentiation exceeding neutral differentiation (i.e.  $Q_{ST} > F_{ST}$ ) is a sign of directional selection (Merilä & Crnokrak, 2001). Here, we found no phylogenetic clustering among isolates collected in cultivated and natural conditions with a null  $F_{ST}$  value between habitats, while  $Q_{ST}$  values for the weakly correlated neck and body widths were relatively high (0.31 and 0.48, respectively). This pattern ( $Q_{ST} > F_{ST}$ ) thus supports a selective effect on morphological divergence not due to drift alone. In contrast, we surprisingly did not detect a local adaptation signal between habitats for the size of the stylet, which is yet an important appendix for nematode nutrition. Environmental and genetic variances were however higher within the cultivated habitat than in the natural habitat. This absence of signal is possibly a consequence of a limited sampling in the wild, but another explanation could be the relaxation of selection on the stylet length due to a reduced inter-specific competition in the cultivated

1  
2  
3 habitat where the nematode communities are less diverse compared to the natural habitat (Ali  
4 *et al.*, 2017). We should thus investigate how this trait behaves during intra- and inter-specific  
5 competition. In addition, we cannot exclude that the stylet size  $Q_{ST}$  is also influenced by non-  
6 additive components due to dominance and epistasis (Goudet & Büchi, 2006).  
7  
8  
9

10  
11  
12 With its cultivation by humans, the environment of the olive has been considerably  
13 modified (via various cultural practices, including weed removal, nutrition and the use of  
14 pesticides), indirectly affecting phenotypes and community composition of microbes associated  
15 to the species (e.g. Ali *et al.*, 2017). There is accumulating evidence on the ability of soil  
16 microbe communities to deal with such anthropogenic disturbances (e.g. Grishkan *et al.*, 2018;  
17 Holterman *et al.*, 2019), but this needs to be better documented to evaluate their role in the  
18 domestication process (Milla *et al.*, 2015). A different composition of nematode communities  
19 was recently reported between cultivated and natural habitats of the olive tree in Morocco and  
20 Spain (Ali *et al.*, 2017; Archidona-Yuste *et al.*, 2020a). While cultivated conditions affect  
21 nematode richness and diversity, this can be due to many factors such as soil composition,  
22 cultural practices or the cultivated genotype. For instance, resistance to *M. javanica* has been  
23 reported in some olive genotypes (Palomares-Rius *et al.*, 2019; Archidona-Yuste *et al.*, 2020b),  
24 while crop intensification and grafting practices may have deep consequences on soil nematode  
25 communities (e.g. Warschefsky *et al.*, 2016; Ali *et al.*, 2017; Barazani *et al.*, 2017). In the 17  
26 locations here studied, Ali *et al.* (2017) showed a slightly lower phytoparasitic nematode (PPN)  
27 richness in cultivated stands than in the wild habitat (mean: 6.0 vs. 6.4 genera/dm<sup>3</sup>), while, in  
28 contrast, the total PPN abundance increased (mean: 3977 vs. 3448 individuals/dm<sup>3</sup>). This trend  
29 is in accordance with the general pattern reported in the study on 94 sites. The size reduction  
30 of *M. javanica* in cultivated conditions could thus be related to higher PPN density in this  
31 habitat. To deepen this hypothesis, measuring traits on several cohabiting nematode species  
32 would surely give insights on the structure and adaptive response of these communities in

#### 16 WHAT DETERMINES AN ADAPTIVE RESPONSE IN AN ASEXUAL NEMATODE?

17  
18 Finally, our study highlighted an adaptive response in an asexual parasite. This ~~could be~~ might  
19 be unexpected since clonal reproduction should lead to limited genomic recombination.  
20  
21 Nevertheless, genomic plasticity of RKNs should produce some diversity that is essential for  
22 their evolutionary response (Castagnone-Sereno & Danchin, 2014). This may be promoted via  
23 lateral gene transfers and large genomic rearrangements (Danchin, 2011; Koutsovoulos *et al.*,  
24 2020). An epigenetic response should be also investigated because this could be responsible for  
25 heritable variation in gene expression (e.g. Mirouze & Paszkowski, 2011). Such exhaustive  
26 phenotypic and genomic characterization of *M. javanica* populations parasiting olives may be  
27 very informative to test these hypotheses, but as shown in our study, its implementation at large  
28 scale still remains a technical challenge (i.e. both for settling controlled experiments and  
29 generating genomic data).

7 *Meloidogyne javanica* sampled in high-density cultivated or wild olive stands.

8  
9 **Table S6.** REML variance components for three quantitative traits measured on  
10 *Meloidogyne javanica* populations sampled in high-density cultivated and wild olive habitats.

11  
12 **Figure S1.** Distribution of *Meloidogyne javanica* populations sampled in Morocco.

13  
14 **Figure S2.** Mitochondrial haplotype reduced-median network.

15  
16 **Figure S3.** Geographic distribution of mitochondrial haplotypes of *Meloidogyne javanica* in  
17 wild and cultivated olive habitats in Morocco.

18  
19 **Figure S4.** Correlation plot between haplogroup diversity and quantitative phenotypic diversity  
20 calculated for the stylet size, neck width and body width.

21  
22 **Figure S5.** Correlation plot between haplotype diversity and quantitative phenotypic diversity  
23 calculated for the stylet size, neck width and body width.

**Table 1.** Mitochondrial haplogroup frequency in individuals isolated from cultivated and wild olives. Mitochondrial haplogroups were defined based on five SNPs (Fig. 3).

<b>Mitotype</b>	<b>Cultivated</b>	<b>Wild</b>
<i>Mj I</i>	45.1%	58.3%
<i>Mj II</i>	43.9%	41.7%
<i>Mj III</i>	8.6%	-
<i>Mj IV</i>	2.5%	-

**Table 2.** Mean values of three life-history traits (measured in  $\mu\text{m}$ ) studied on *Meloidogyne javanica* individuals from Cultivated (C) and Wild (W) olive stands (definition in text; locations given in Fig. S1). Standard deviation of each value is given in parentheses. The effects of habitat (Cultivated or Wild), population, and family (nested within population) were tested by hierarchical ANOVA.  $p$ -values are considered significant when inferior to 0.05, and coded as follow: \*\*\* for  $p < 0.001$ , \*\* for  $p < 0.01$ , \* for  $p < 0.05$ .

Trait	C	W	Habitat	Population	Family
Stylet size	12.85 (0.61)	13.05 (0.52)	***	***	*
Neck width	11.67 (0.38)	11.86 (0.33)	***	***	***
Body width	13.08 (0.71)	13.51 (0.61)	***	*	***

**Table 3.** Quantitative components of variance for three phenotypic traits (stylet size, neck width and body width). These parameters ( $\sigma^2_{\text{Fam}}$ ,  $\sigma^2_{\text{Ind}}$ ,  $H^2$ ,  $CV_G$ ) were estimated per population and then used for calculating means by habitat (C = Cultivated; W = Wild) and on all samples (All).

Trait	Habitat	$\sigma^2_{\text{Fam}}$	$\sigma^2_{\text{Ind}}$	$H^2$	$CV_G$
Style size	C	0.0820	0.2031	0.2789	0.0199
	W	0.0680	0.0932	0.3280	0.0168
	All	0.0778	0.1708	0.2933	0.0190
Neck width	C	0.0140	0.1014	0.1373	0.0093
	W	0.0147	0.1034	0.1102	0.0095
	All	0.0142	0.1019	0.1305	0.0093
Body width	C	0.0867	0.4279	0.1846	0.0205
	W	0.0352	0.3179	0.0939	0.0131
	All	0.0716	0.3955	0.1579	0.0183

**Table 4.** REML variance component for quantitative traits between habitats. For each trait, we report the variance between habitats ( $\sigma^2_{\text{Hab}}$ ), between populations within habitat ( $\sigma^2_{\text{Pop}}$ ), between families within populations ( $\sigma^2_{\text{Fam}}$ ) and between individuals within families ( $\sigma^2_{\text{Ind}}$ ). We also assessed the quantitative differentiation between habitats ( $Q_{\text{ST}}$ ) of each trait (details in text).

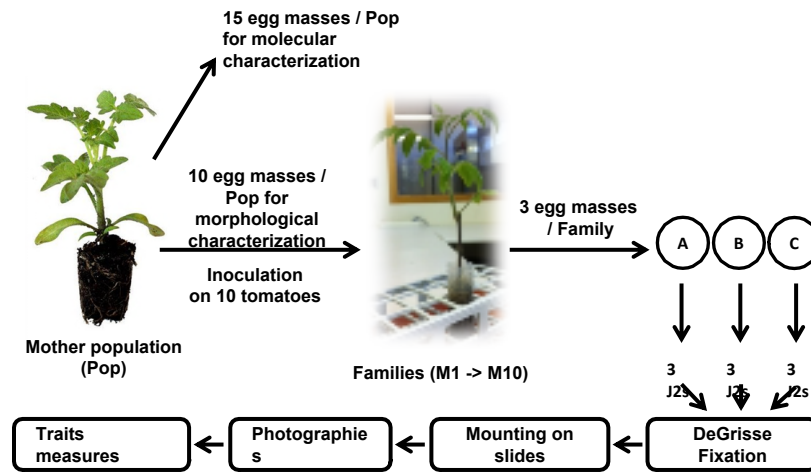

Trait	$\sigma^2_{\text{Hab}}$	$\sigma^2_{\text{Pop}}$	$\sigma^2_{\text{Fam}}$	$\sigma^2_{\text{Ind}}$	$Q_{\text{ST}}$
Stylet size	0.008	0.110	0.080	0.171	0.040
Neck width	0.014	0.019	0.014	0.103	0.310
Body width	0.085	0.012	0.085	0.379	0.479

## LEGENDS OF FIGURES

**Figure 1.** Experimental design for molecular characterization and trait measurements of *M. javanica* populations. For each population, fifteen egg masses (one individual per egg mass) were randomly chosen for molecular measures, while ten egg masses were collected (families), and reared on tomatoes for the morphological measures. Then, for each family in every population, three individuals per egg-mass were randomly sampled and measured after photography (details on traits in the text). As we worked on 17 populations, ten families per population and nine individuals (on average) per family, 1530 nematodes were measured for three traits.

**Figure 2.** Photography of a nematode (under microscope; 100×) indicating the three traits measured and their morphological significance.

**Figure 3.** Mitochondrial DNA variation among *Meloidogyne javanica* isolates sampled on wild and cultivated olives in Morocco. Mitochondrial haplogroups were defined based on five single nucleotide polymorphisms (SNPs) in regions flanking the 63R minisatellite. **a)** Mitochondrial haplogroup reduced-median network (Bandelt *et al.*, 1999). Mitotypes of two closely related species [*M. arenaria* (*Ma*; LS974734) and *M. incognita* (*Mi*; KJ476151)] were used as outgroups (small black circles). Four haplogroups were distinguished among *M. javanica* isolates collected on cultivated olives, with the most two frequent ones (*Mj* I and *Mj* II) also observed on wild olive isolates (W). Size of pie charts is proportional to the relative frequency of each mitotype. **b)** Geographic distribution of haplogroups among the 17 provenances (between five and ten isolates were analyzed per location). Size of pie charts is proportional to the number of isolates analyzed per location. For mtDNA haplotypes defined on both SNPs and minisatellite length variation, see Figs S2 and S3.

## SUPPORTING INFORMATION

**Adaptive response to olive cultivation of a generalist  
parasitic nematode (*Meloidogyne javanica*)**

ELODIE CHAPUIS, NADEEN ALI, CAMILLE NOUS &amp; GUILLAUME BESNARD

Supporting Information contains:

**Table S1.** List of the 119 isolates characterized with the 63R region

**Table S2.** Mitotype occurrence in individuals isolated from cultivated and wild olives

**Table S3.** Quantitative components of variance for three phenotypic traits

**Table S4.**  $F_{ST}$  values among habitats and between populations of *Meloidogyne javanica* when considering only high-density cultivated and wild olive populations

**Table S5.** Effect of habitat, population, and family on three life-history traits of *Meloidogyne javanica* sampled in high-density cultivated or wild olive stands

**Table S6.** REML variance components for three quantitative traits measured on *Meloidogyne javanica* populations sampled in high-density cultivated and wild olive habitats

**Figure S1.** Distribution of *Meloidogyne javanica* populations sampled in Morocco

**Figure S2.** Mitochondrial haplotype reduced-median network

**Figure S3.** Geographic distribution of mitochondrial haplotypes of *Meloidogyne javanica* in wild and cultivated olive habitats in Morocco

**Figure S4.** Correlation plot between haplogroup diversity and quantitative phenotypic diversity calculated for the stylet size, neck width and body width

**Figure S5.** Correlation plot between haplotype diversity and quantitative phenotypic diversity calculated for the stylet size, neck width and body width

**Table S1.** List of the 119 isolates characterized with the 63R region. SNPs allow us to distinguish four mitochondrial haplogroups, namely *Mj I*, *Mj II*, *Mj III* and *Mj IV*. Then, the number of repeats (from 7 to 14) in the 63R minisatellite is also given, allowing defining a mitochondrial haplotype. For 13 individuals with heteroplasmy (mix of at least two types of sequence), the main mitotype is defined as the most abundant sequence in the chromatogram. In these cases, minor sequences are also indicated in parenthesis.

Population ID	Habitat	Isolate	63R type
252	Cultivated	252M1	<i>Mj II</i> -11
252	Cultivated	252M2	<i>Mj II</i> -10
252	Cultivated	252M3	<i>Mj II</i> -10(11)

**Table S4.**  $F_{ST}$  values among habitats and between populations of *Meloidogyne javanica* when considering only high-density cultivated and wild populations (2 x 5 populations). This analysis was done either with mtDNA haplotypes or haplogroups.

<b>mtDNA data</b>	<b>Between habitats</b>	<b>Between populations</b>
Haplogroups	-0.0143	0.4703
Haplotypes	-0.0205	0.4237

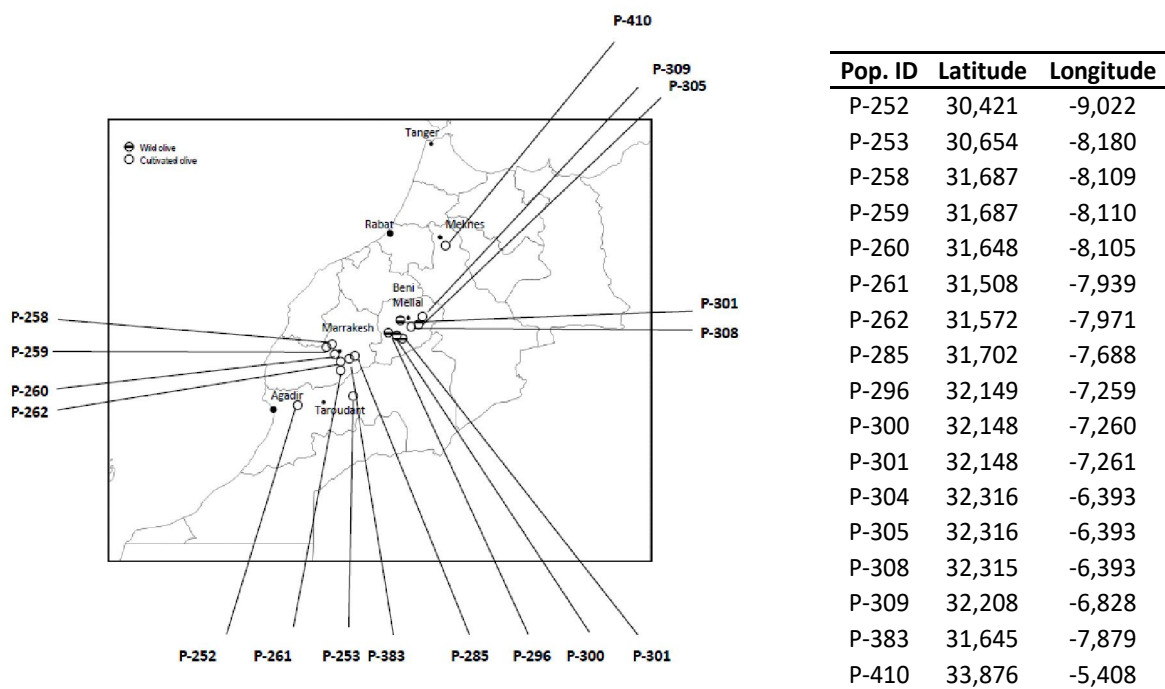

For Peer Review

**Table S5.** Effect of habitat (cultivated or wild), population, and family (nested within population) on three life-history traits of *Meloidogyne javanica* sampled in high-density cultivated (C) or wild (W) olive stands. Standard deviation of each value is given in parentheses. Significance of effects was tested by a hierarchical ANOVA:  $p$ -values are coded as follow: \*\*\*  $p < 0.001$ , \*\*  $p < 0.01$ , \*  $p < 0.05$ , and NS means non-significant ( $p > 0.05$ ). (An effect of 'Family' on stylet size was marginally significant;  $p = 0.06$ ).

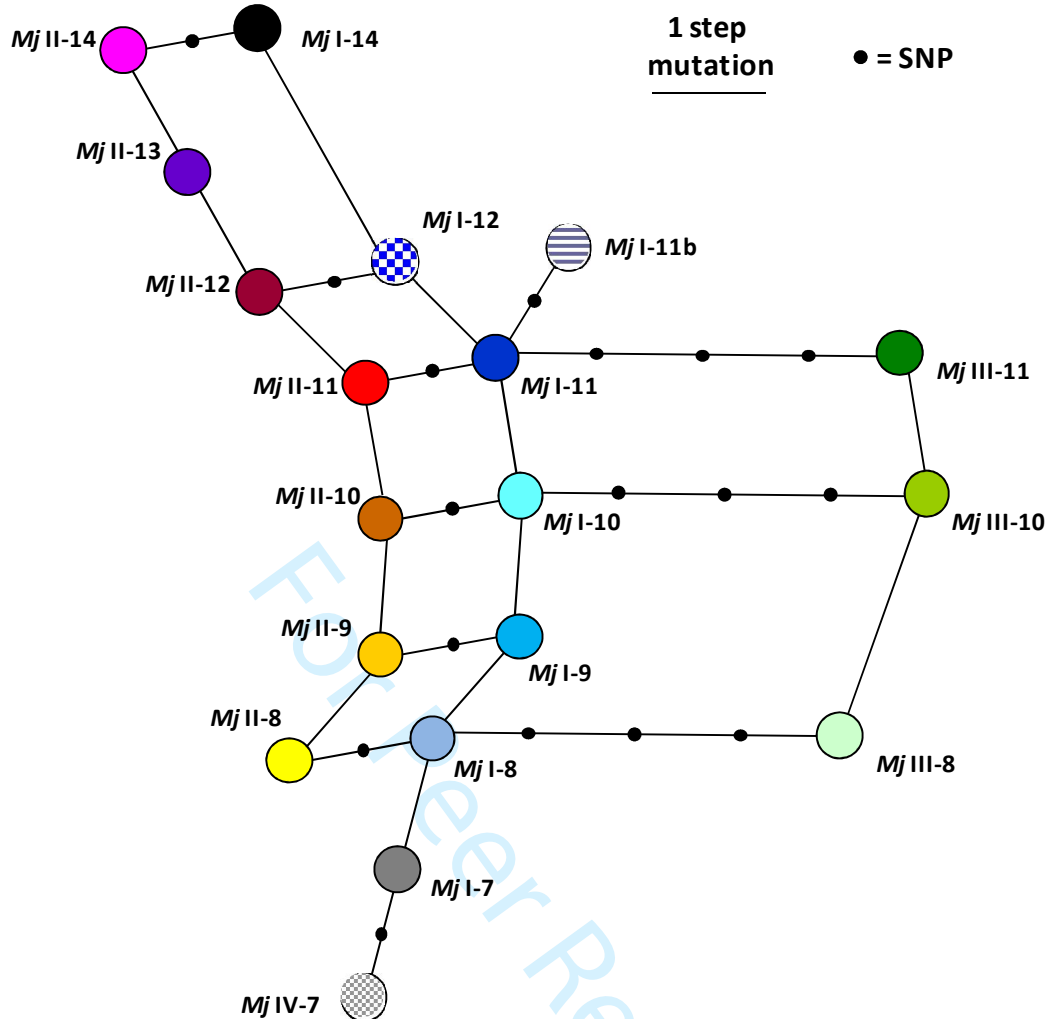

Trait	C	W	Habitat	Population	Family
Stylet size	13.07 (0.52)	13.05 (0.52)	NS	**	NS
Neck width	11.72 (0.37)	11.86 (0.33)	***	***	***
Body width	13.12(0.74)	13.51 (0.61)	***	*	***

**Table S6.** REML variance components for three quantitative traits measured on *Meloidogyne javanica* populations sampled in high-density cultivated and wild habitats. For each trait, we report the variance between habitats ( $\sigma^2_{\text{Hab}}$ ), between populations within habitat ( $\sigma^2_{\text{Pop}}$ ), between families within populations ( $\sigma^2_{\text{Fam}}$ ) and between individuals within families ( $\sigma^2_{\text{Ind}}$ ). We also assessed the quantitative differentiation between habitats ( $Q_{\text{ST}}$ ) of each trait.

Trait	$\sigma^2_{\text{Hab}}$	$\sigma^2_{\text{Pop}}$	$\sigma^2_{\text{Fam}}$	$\sigma^2_{\text{Ind}}$	$Q_{\text{ST}}$
Stylet size	8E-09	0.069	0.074	0.133	0.000
Neck width	0.011	0.018	0.014	0.100	0.268
Body width	0.069	0.012	0.070	0.380	0.456

**Figure S1.** Distribution of *Meloidogyne javanica* populations sampled in Morocco (for more details, see Ali *et al.*, 2017. *BMC Ecol.* **17**: 4). Seventeen locations were sampled in 2012. Cultivated and wild stands are represented by white and striped circles, respectively. GPS coordinates of populations are given on the right.

**Figure S2.** Mitochondrial haplotype reduced-median network (Bandelt *et al.*, 1999. *Mol. Biol. Evol.* **16**: 37-48). Haplotypes were defined based on five single nucleotide polymorphisms (SNPs) and the number of repeats in a minisatellite in the 63R locus. Nineteen haplotypes were distinguished among isolates (Table S2). The number of minisatellite repeats was coded (from 7 to 14) as a single multi-state character (considering a stepwise mutation model). The unresolved topology (reticulation) of this network has to be interpreted with caution, but it likely results from homoplasy at the minisatellite motif [i.e., the 63R variants are mostly shared among the three most frequent lineages (defined on SNPs; Fig. 3)].

**Figure S3.** Geographic distribution of mitochondrial haplotypes of *Meloidogyne javanica* in wild and cultivated olive habitats in Morocco (17 populations with five to ten isolates per location). Size of pie charts is proportional to the number of isolates analyzed per location.

**Figure S4.** Correlation plot between haplogroup diversity ( $D_{haplogroup}$ ) and quantitative phenotypic diversity calculated for the stylet size (A), neck width (B) and body width (C). Each phenotypic parameter [coefficient of genetic variation ( $CV_G$ ); heritability ( $H^2$ ); and family genetic variance ( $\sigma^2_{Fam}$ )] is presented on a line. Each point represents a population. For each graph, the Pearson correlation coefficient (R) is given, as well as the  $p$ -value associated corrected for multiple comparisons (9) using the Bonferroni method.

**Figure S5.** Correlation plot between haplotype diversity ( $D_{haplotype}$ ) and quantitative phenotypic diversity calculated for the stylet size (A), neck width (B) and body width (C). Each phenotypic parameter [coefficient of genetic variation ( $CV_G$ ); heritability ( $H^2$ ); and family genetic variance ( $\sigma^2_{Fam}$ )] is presented on a line. Each point represents a population. For each graph, the Pearson correlation coefficient (R) is given, as well as the  $p$ -value associated corrected for multiple comparisons (9) using the Bonferroni method.
