Two acoustic bubbles may attract or repel due to the secondary radiation force acting on them. We use here a dual-frequency levitation chamber in order to trap two oscillating microbubbles at close, fixed distance, and to perform measurements of the interaction force. We successfully compare our measurements to a commonly used theoretical model that assumes linear spherical oscillations, and disregards attenuation and multiple scattering between bubbles. The deviation from the model arises when nonspherical surface oscillations are triggered, leading to an additional hydrodynamic force induced by second-order liquid flow.

DOI: [10.1103/PhysRevE.00.001100](https://doi.org/10.1103/PhysRevE.00.001100)

Introduction. The acoustic radiation force is generated from the transfer of momentum flux from an imposed, external, oscillatory pressure field to a gas bubble. The force for which the incoming field comes from a driving ultrasound field is called primary radiation force. When coming from the radiated pressure of a nearby oscillating bubble, this force is called secondary radiation force. These radiation forces have been intensively used to control bubble motion in an ultrasound field, either to trap them by using their ability to resist to buoyancy and turbulence [1] or to propel gas bubbles for microswimming applications [2]. The secondary radiation force, named secondary Bjerknes force [3], can be either attractive or repulsive, depending on the bubbles characteristics. If the oscillations are in phase, the bubbles attract each other; if not, they repel each other [4]. While many theoretical studies extended the original theory to provide estimations of secondary radiation forces in a standing-wave field [5], by taking into account nonlinearity of bubble oscillations [6,7], and later multiple scattering between two interacting closely spaced bubbles [8], only few experimental results provided quantitative estimations of this force. The main experimental difficulty relies in the quantification of small amplitudes forces (typically in the range of nanonewtons) for a couple of closely spaced bubbles (interbubble distance less than ten times the bubble radius). For this reason many authors assess the interacting force from observation of their attractive motion when insonified. A pioneer study by Crum [5] measured the interaction force from the translational velocities of two attracting bubbles in a low-frequency (\sim hertz) standing-wave field. This technique have been overhauled by other authors [9,10], for higher driving frequencies (\sim kilohertz) and smaller bubbles (\sim micrometers). Lanoy *et al.* [11] observed repulsive forces between a bubble pair, each of them located at the opposite side of the interface between water (freely moving bubble) and a yield-stress fluid (fixed bubble). The trajectory of the free bubble allows assessing secondary Bjerknes force, recovering attraction and repulsion features, and

highlighting the importance of taking into account multiple scattering. For biomedical applications (megahertz frequencies for micrometer-diameter bubbles), Garbin *et al.* [12] measured the interaction forces between two free, optically trapped bubbles. Similarly to therapeutic ultrasound applications, short acoustic burst and coated bubbles were used, and secondary radiation forces were assessed from mutual attractive motion.

We report here an experimental method to assess simultaneously the bubble interface dynamics and the secondary Bjerknes force for free (nonattached), noncoated microbubbles at fixed interbubble distance. The influence of nonspherical bubble oscillations on the interaction force is also evidenced. Assessing interacting forces between stable oscillating bubbles is crucial as being a key mechanism in the self-organization of dispersed bubbles into structured clouds [13]. It is also worth noting that shape distortions between two interacting bubbles has only been observed in the case of strong coupling where one (or both) bubbles collapse and lead to breakup [14].

Experimental setup. We design a dual-frequency acoustic levitation chamber that enables the trapping of a bubble pair at a fixed distance while being acoustically excited. A schematic representation of the experimental setup is shown in Fig. 1(a). The experiments are conducted in an 8-cm-edge cubic tank filled with microfiltered and demineralized water (Carlo Erba, water for analysis). The microbubbles are generated at the tip of a thin capillary (inner diameter $20\ \mu\text{m}$) linked to a microfluidic pressure controller (Elveflow, OB1 MK3) supplied by an air compressor (Newport, ACWS). The capillary is located at the bottom of the water tank, generating an uprising, periodically spaced train of bubbles. The size of the microbubbles as well as the interbubble distance can be slightly influenced by tuning the input pressure using the controller. A bubble train of interdistance $\sim 1\ \text{mm}$ and mean radius $\sim 100\ \mu\text{m}$ is usually reached.

The bubble train is acoustically trapped within a standing-wave field generated by a high-frequency (HF) transducer (Sofranel IDMF018, 1 MHz nominal frequency) slightly immersed at the top side of the water tank. This HF field induces

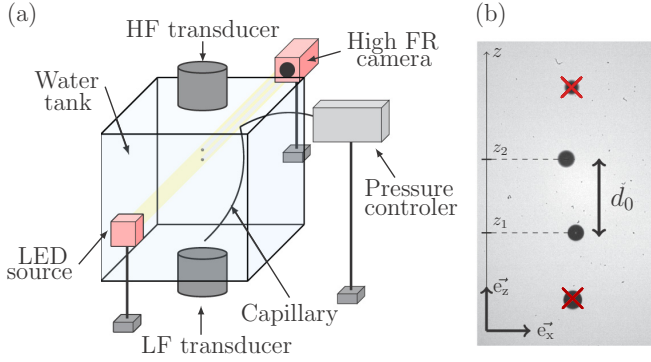

FIG. 1. (a) Schematic representation of the experimental setup used to assess secondary Bjerknes forces. (b) Photograph of a four-bubble train before bubble pair selection.

a primary radiation force that allows trapping the bubbles at successive pressure nodes, as the investigated bubbles (of radii ranging from 70 to 130 μm) are significantly greater than the resonant radius $R_{\text{res}}^{\text{HF}} \sim 3.3 \mu\text{m}$ [13]. Due to the large contrast between the bubble size and the HF resonant radius, bubbles are trapped at rest in the wave field, meaning without experiencing radial oscillations. The interbubble distance is $\sim 750 \mu\text{m}$, corresponding to roughly six to ten bubble equilibrium radii, at rest. Figure 1(b) shows an example of a train of trapped bubbles that are, at this stage, not perfectly aligned vertically. Because the present study focuses on the interaction between a bubble pair, only two of them are kept. The selected pair of bubbles is such that the interbubble distance equals half a HF wavelength and their respective radii cover a broad range of radii distribution.

Once stabilized in the HF trapping field, the bubble oscillations are induced by a low-frequency (LF) Langevin transducer (RESON, 31 kHz nominal frequency) located at the bottom of the tank and emitting a 31.9 kHz continuous, sinusoidal waveform. We noticed no LF cavity resonance and negligible primary radiation force as the bubbles remain close to their trapping locations. The LF wavelength ($\sim 5 \text{ cm}$) is large compared to the radii of the bubbles and the interbubble distance. The bubble pair is therefore assumed to be driven at a uniform local pressure field. The dynamics of the bubble pair oscillations is captured with a CMOS camera (Vision Research V12.1) equipped with a $12\times$ objective lens (Navitar). A backlight illumination is ensured by a continuous light-emitting diode (3 W LED). The recordings are performed with a frame size of 128×256 pixels, allowing a 130 kfps frame rate (opening time $1 \mu\text{s}$). This frame rate allows quantifying the bubble interface dynamics (approximately four samples per acoustic period) in addition to the interbubble distance.

Characteristics of the HF trapping field. When a single bubble pair is trapped within the HF acoustic field, each bubble (of equilibrium radius $R_{0,i}$, $i = 1, 2$) experiences a force balance between the HF primary radiation force $\mathbf{F}_{B1,i}$ and the buoyancy force $\mathbf{B}_i = -(\rho_l - \rho_g)V_i\mathbf{g}$, where ρ_l and ρ_g refer to the density of fluid and inner gas, respectively, V_i is the volume of the i th bubble, and $\mathbf{g} = -g\mathbf{e}_z$ is the geocentric gravitational acceleration. The periodically spaced, trapped, bubble train allows assuming a unidimensional plane-wave feature of the

HF field $p_{\text{HF}}(z, t) = P_{\text{HF}} \sin(2\pi z/\lambda_{\text{HF}}) \sin(2\pi f_{\text{HF}}t)$, where P_{HF} is the acoustic pressure, λ_{HF} is the HF wavelength, and f_{HF} is the HF frequency. Thus the HF primary radiation force is written as

$$\mathbf{F}_{B1} = \beta(R_{0,i}, f_{\text{HF}}, P_{\text{HF}}) \sin\left(4\pi \frac{z_i}{\lambda_{\text{HF}}}\right) \mathbf{e}_z, \quad (1)$$

where β is a constant which depends on the bubble equilibrium radius $R_{0,i}$ and the acoustic field characteristics, and z_i is the location of the i th bubble center [5]. According to the bubble size contrast in comparison to the HF resonant radius $R_{0,i} \geq R_{\text{res}}^{\text{HF}}$, bubbles are acoustically trapped at successive pressure nodes $z_n^* = n\lambda_{\text{HF}}/2$, $n = 0, 1, \dots$. Due to the buoyancy force, each bubble is in fact located above the theoretical pressure node of the HF standing-wave field (see Fig. 3).

Above the trapping pressure threshold $P_{\text{HF}}^{\text{th}}$ (for which $\|F_{B1,i}\| > \|B_i\|$), each bubble center location is experimentally measured during a step-by-step increase of the pressure P_{HF} . The vertical displacement of the bubble centers follows the spatial waveform of the primary radiation force given by Eq. (1), for which the locations z_i and radii $R_{0,i}$ are assessed. This allows estimating the trapping acoustic amplitude P_{HF} . Once the calibration curve of the trapping pressure is performed, the amplitude of the HF field is kept constant (typical value $\sim 50 \text{ kPa}$) and results in an initial, interbubble vertical distance d_0 .

Measurement of the secondary radiation force. Switching on the LF acoustic field induces bubble oscillations around their equilibrium radius $R_{0,i}$. The radiated acoustic pressure emitted by each bubble on the other is responsible for the generation of a local gradient of pressure leading to the secondary radiation force. Each bubble is therefore trapped at a

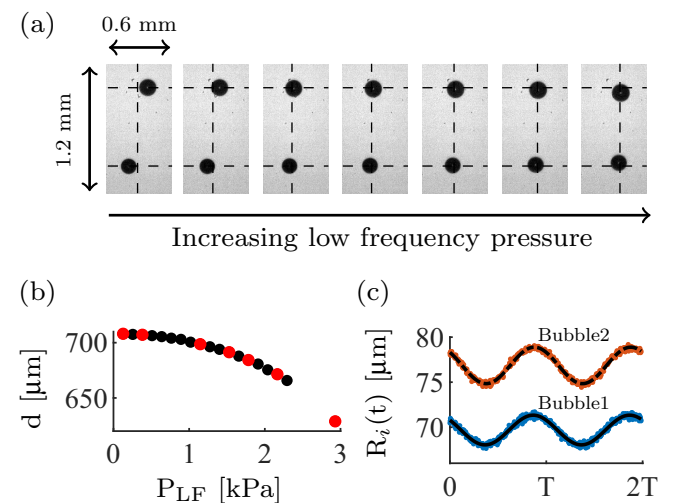

FIG. 2. (a) Extracts of two interacting bubbles for increasing LF field. (b) Evolution of the vertical interbubble distance as a function of the LF acoustic pressure P_{LF} . Each red dot corresponds to a snapshot photograph of (a). (c) Temporal evolution of the bubble radii, with respect to two acoustic periods, for the highest applied LF pressure.

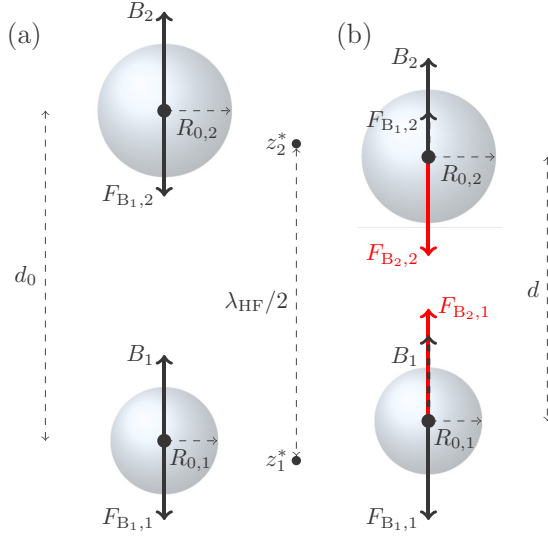

FIG. 3. (a) After acoustic trapping, each bubble experiences a force balance between buoyancy \mathbf{B}_i and the primary HF radiation force $\mathbf{F}_{B1,i}$. (b) A secondary interaction force $\mathbf{F}_{B2,i}$ acts when the LF field is on, resulting in vertical attraction and repulsion of the bubble centers. z_n^* refers to the HF theoretical pressure nodes separated by half a wavelength, setting $n = 1$ for the lowest one (bubble 1).

164 new equilibrium location resulting from the force balance

$$\mathbf{F}_{B1,i} + \mathbf{F}_{B2,i} + \mathbf{B}_i = \mathbf{O}. \quad (2)$$

165 As shown in Fig. 2(a), the bubbles tend to align in the vertical
 166 direction. This evidences a predominant trapping force in the
 167 vertical direction compared to the one on the horizontal
 168 plane. As sketched in Fig. 3, the bubble centers may pass
 169 through the theoretical pressure nodes z_n^* if bubbles attract or
 170 even repel. When attraction occurs, bubbles will coalesce if
 171 one of the bubble centers location crosses half the distance to
 172 the next pressure antinode (i.e., where the primary Bjerknes
 173 force is maximum). This limits the achievable interbubble distance
 174 to $d_{\text{limit}} = \lambda_{\text{HF}}/4$, that is as small as 3.5 times the mean
 175 equilibrium radius for the largest investigated bubbles. The
 176 knowledge of the HF pressure P_{HF} allows fully determining
 177 the amplitude of the secondary radiation force $\mathbf{F}_{B2,i}$, whose
 178 magnitude is theoretically identical for each bubble. All investigated
 179 bubble pairs are summarized in the $(R_{0,1}, R_{0,2})$
 180 diagram in Fig. 4(a). Depending on the size of the bubble
 181 equilibrium radius relative to the LF resonant radius $R_{\text{res}}^{\text{LF}} \sim$
 182 $103 \mu\text{m}$, a bubble pair may experience attraction or repulsion.
 183 Cases of repulsive forces have been observed but are no longer
 184 analyzed as bubbles were rapidly repelled away from each
 185 other, out of the camera field and of its focal plane. All
 186 attractive bubble pairs exhibit purely spherical oscillations,
 187 except one couple [asterisk marker in Fig. 4(a)] for which one
 188 axisymmetric nonspherical mode was triggered. This case is
 189 discussed later.

190 The absolute value of the secondary radiation force for an
 191 attractive bubble pair $(R_{0,1}, R_{0,2}) = (97, 78) \mu\text{m}$ trapped in a
 192 78 kPa HF field is shown in Fig. 4(b). The forces measured
 193 on each bubble are nearly identical and exhibit the same trend
 194 for decreasing interbubble distance. The measured secondary
 195 radiation force is shown to be in remarkable agreement with

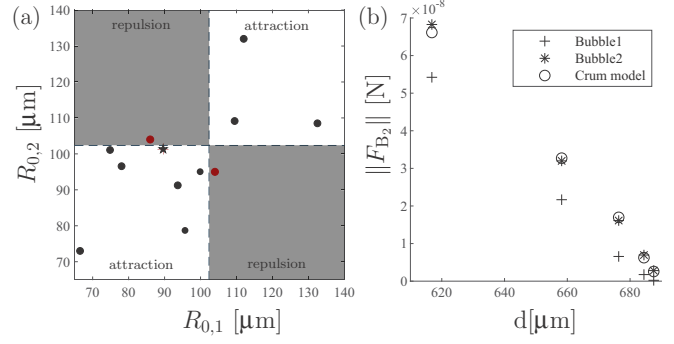

FIG. 4. (a) Bubble pairs radii distribution. Dashed lines correspond to the value of the LF resonant radius. (b) One series of experimentally assessed secondary Bjerknes forces.

the linearized model proposed by Crum [5]:

$$\mathbf{F}_{B2,i} = -2\pi\rho\omega_{\text{LF}}^2 \frac{R_{0,1}^2\epsilon_1 R_{0,2}^2\epsilon_2}{d^2} \cos(\Delta\phi) \mathbf{u}_{r,i}, \quad (3)$$

197 where ω_{LF} is LF angular frequency, ϵ_i is the bubble expansion
 198 relative to the equilibrium radius, $\Delta\phi$ is the phase shift
 199 between bubble oscillations, and $\mathbf{u}_{r,i}$ is the unit vector along
 200 the axis passing through the centers of the bubble pair. To
 201 assess the coefficient ϵ_i , we notice that each bubble inter-
 202 face displays purely, almost linear, spherical oscillations [as
 203 those in Fig. 2(c)] ruled by $R_i(t) = R_{0,i}[1 + \epsilon_i \cos(\omega_{\text{LF}}t)]$. The
 204 Crum model assumes linear oscillations, distant bubbles, and
 205 disregards attenuation effects, such as the phase shift $\Delta\phi$
 206 can only take the values 0 (bubble attraction) or π (bubble
 207 repulsion). At first sight, the secondary radiation forces cannot
 208 be compared for the whole experimental sets of bubble pair
 209 due to the variety of bubble equilibrium radii $R_{0,i}$ and trapping
 210 pressure P_{HF} . Therefore, a commensurable interaction force
 211 $\|F_{B2}\|R_m/P_{\text{HF}}^2$ is investigated as a function of the normalized
 212 distance d/d_0 in Fig. 5. Here $R_m = (R_{0,1} + R_{0,2})/2$ is the
 213 mean bubble radius and $\|F_{B2}\|$ is the mean value of the in-

FIG. 5. Commensurable secondary Bjerknes forces $\|F_{B2}\|R_m/P_{\text{HF}}^2$ for the whole set of attractive bubble pairs as a function of the normalized distance d/d_0 .

FIG. 6. (a) Secondary radiation force measured for each bubble as a function of the interbubble distance. The gray area indicates the onset of an axisymmetric shape mode on bubble 1. (b) Snapshot of the spherical and nonspherical interfaces of the bubble pair corresponding to (a). Expected streamlines are superimposed. (c) Extreme interbubble distances were observed when both bubbles exhibit nonspherical modes (bubble 1, undefined shape mode and bubble 2, axisymmetric sixth mode).

214 teraction force measured on each bubble. The factor R_m/P_{HF}^2
 215 is found from the derivation of the interaction force between
 216 a bubble pair of similar sizes and close to their theoretical
 217 equilibrium location $z_i \sim z_i^*$. The agreement of the whole data
 218 sets along the linear relationship in Fig. 5 provides reliability
 219 in the proposed experimental method to assess the secondary
 220 Bjerknes force. In addition, the Crum model is validated for
 221 the whole set of investigated bubble pairs, even for the case
 222 $d/d_0 \sim 0.7$, meaning interbubble distances as close as ~ 3.5
 223 bubble radius.

224 *About bubble-induced hydrodynamic forces.* It is known
 225 that a single free, spherically oscillating, microbubble does
 226 not induce second-order liquid flow due to the spherosymme-
 227 try of the resulting linearized acoustic velocity field [15]. Even
 228 if the theoretical investigation of the liquid flows generated by
 229 two oscillating bubbles have not yet been proposed, it may be
 230 suggested that symmetry breaking due to the presence of an
 231 in-vicinity oscillating bubble would lead to a supplementary
 232 hydrodynamic force. The results obtained for two spherically
 233 oscillating bubbles [Figs. 4(b) and 5] coupled to the agreement
 234 with the Crum model indicate that, if this hydrodynamic force
 235 exists, it is negligible in our experiment. However, significant
 236 vortical flows are produced when bubble oscillations include
 237 a translational [16] or nonspherical mode [17,18]. We recall
 238 that, for a bubble of equilibrium radius R_0 driven at the
 239 acoustic angular frequency ω , nonspherical instability arises
 240 above a particular pressure threshold [19]. This threshold
 241 has been reached for a bubble of equilibrium radius $R_{0,1} =$
 242 $102 \mu\text{m}$, while the other one ($R_{0,2} = 88 \mu\text{m}$) remains spheri-
 243 cal [Figs. 6(a) and 6(b)]. Below the onset of nonspherical
 244 oscillations, bubbles attract each other and the measured in-
 245 teraction force follows the same trend as previously observed.
 246 Once a surface mode is triggered, the secondary radiation
 247 force significantly deviates from its linear monotonous evolu-

248 tion. Recordings of the interface behavior of bubble 1 indicate
 249 the predominance of a subharmonic axisymmetric mode 5.
 250 Its bubble contour $r_1(\theta, t)$ can hence be written $r_1(\theta, t) =$
 251 $R_{0,1} + a_{0,1} \cos(\omega_{\text{LF}} t) + a_{5,1} P_5(\cos \theta) \cos(\omega_{\text{LF}} t/2)$, where we
 252 extract the modal coefficient $a_{0,1} \sim 4 \mu\text{m}$, $a_{5,1} \sim 3 \mu\text{m}$, and
 253 $P_5(\cos \theta)$ is the Legendre polynomial of degree $n = 5$.

254 Regarding that second-order streaming arises from the
 255 interaction of two modes oscillating at the same angular
 256 frequency ω [15], the only contribution of bubble 1 to the
 257 streaming flow is the self-interaction of the mode 5 with
 258 itself [20]. This self-interaction results in a crosslike pattern
 259 at large distance with lobelike vortices in the vicinity of the
 260 bubble interface. Figure 6(b) illustrates the expected pattern.
 261 Depending on the orientation of the nonspherical mode 5
 262 in the $(\mathbf{e}_x, \mathbf{e}_z)$ plane, the branches of the crosslike pattern
 263 would present inward (leading to bubble 2 attraction) or
 264 outward (bubble 2 repelling) velocity vector field. The shift
 265 of the measured secondary radiation force from the linear
 266 relationship expected for purely spherical oscillations reveals
 267 that bubble 2 gets closer to bubble 1 due to the liquid flow.
 268 This suggests inward velocity field in the direction $2 \rightarrow 1$ on
 269 this cross branch. Injecting the value $a_{5,1}$ of the shape mode
 270 amplitude, the LF angular frequency, fluid properties, and
 271 the bubble equilibrium radius into the self-interacting shape
 272 mode-induced streaming [20] provides the order of magnitude
 273 of the radial velocity at the location of bubble 2, which is
 274 $v_{\text{fl}} \sim 10 \mu\text{m s}^{-1}$. This results in a drag force applied on bubble
 275 2 of the order of magnitude of \sim piconewtons. We recall that
 276 bubble 1 would experience a net force if it oscillates nonspheri-
 277 cally with two nonzero adjacent modes $(a_{n,1}, a_{n+1,1})$ [21].
 278 However, the modal analysis performed on bubble 1 only
 279 reveals odd nonspherical modes. No propulsive force is
 280 therefore expected. We experimentally estimate the net force
 281 experienced by each bubble to ~ 100 nN, obtained from
 282 Fig. 6(a) when computing the shift of secondary radiation
 283 force from the expected linear behavior. This suggests that the
 284 streaming pattern induced by two, closely spaced, oscillating
 285 bubbles may be significantly different from the one obtained
 286 in the single bubble case. Indeed multiple scattering of the
 287 linear acoustic field emitted by each bubble would lead to the
 288 broadening of mode interaction between the bubble pair, ex-
 289 pected for extremely small interbubble distances, as small as
 290 $d \sim 400 \mu\text{m}$, or equivalently $d/d_0 \sim 0.5$ [Fig. 6(c)], obtained
 291 when both bubbles oscillate nonspherically. The modeling of
 292 such multibubble-induced streaming field is still challenging.

293 *Conclusions and perspectives.* Measurements of secondary
 294 radiation force between trapped, free, interacting acoustic
 295 bubbles have been performed by means of a dual-frequency
 296 levitation chamber. In contrast to prior work where secondary
 297 Bjerknes force is extracted using the bubble translational
 298 motion, here two closely spaced bubbles are trapped at fixed
 299 distance. Our measurements evidence the agreement with the
 300 Crum model for forces ranging over two orders of magnitude
 301 in the nanonewton scale, and allow investigating two interact-
 302 ing bubbles exhibiting nonspherical oscillations. Future work
 303 will aim at investigating the coupled nonspherical oscillations
 304 of a bubble pair, as well as the second-order liquid flows
 305 induced by two closely spaced bubbles, paving the way to
 306 the understanding of acoustofluidic interaction into a bubble
 307 cloud.
