**Abstract**— We fabricated junctionless and inversion-mode monocrystalline nanowire nMOSFETs down to  $L=18\text{nm}$  gate length and  $W=20\text{nm}$  width. We demonstrate record performance of nanowire junctionless transistors for analog applications:  $A_{VT}=1.4\text{mV}\cdot\mu\text{m}$  matching,  $A_{v0}=62\text{dB}$  gain ( $L=200\text{nm}$ ),  $f_T=126\text{GHz}$  cut-off frequency and  $f_{MAX}=182\text{GHz}$  maximum operating frequency ( $L=35\text{nm}$ ). Junctionless transistor performances even exceed those of inversion-mode ones in terms of back-bias capability, low-frequency noise, hot-carrier degradation and  $f_{MAX}$ . This is explained by junctionless physics: channel length modulation, bulk conduction and high channel-depth sensitivity to back bias.

## I. INTRODUCTION

Recent years have seen renewed interest for junctionless CMOS transistors because of the relative simplicity of its process integration and its potential fabrication at low temperature as a Back-End-Of-Line transistor for a 3D-sequential integration [1]. On the one hand, polycrystalline silicon or germanium junctionless channels, whose doping is activated by a laser anneal, are a promising solution for low-cost and extremely-low-temperature fabrication [2, 3]. On the other hand, monocrystalline Si junctionless channels have already been demonstrated on either planar Silicon-On-Insulator (SOI) [4], FinFET [5] or nanowire architectures [6,7].

## II. DEVICE PROCESS FLOW

We fabricated Inversion-Mode (IM) and JunctionLess nanowire nMOSFETs down to  $W=20\text{nm}$  channel width and  $L=18\text{nm}$  gate length. The channel thickness is  $11\text{nm}$ . The junctionless devices are made by epitaxially growing a  $7\text{nm}$  thick *in-situ* phosphorous (P) doped Si film on a  $4\text{nm}$  undoped SOI layer. Excellent crystalline quality is obtained (Fig.1). After full process integration the final channel doping level is uniform and equal to  $8.10^{18}\text{ at/cm}^3$ . Such channel doping and thickness are suitable even for the largest devices. The fabrication process is outlined in Fig.2. All the devices feature the same gate stack with  $\text{HfO}_2$  dielectrics (equivalent oxide thickness  $EOT=1\text{nm}$ ),  $\text{TiN}$  + poly-Si and identical  $8\text{nm}$  thick spacer.

Junctionless transistors (named JL) have been fabricated. In order to optimize their Source/Drain resistance and to dope only the JL-RSD, a  $5\text{keV}$  P implantation was carried out in the  $17\text{nm}$  thick Raised Source/Drain (RSD) followed by a Solid Phase Epitaxy Regrowth (SPER) annealing at  $525^\circ\text{C}$  30 min (see Kinetic Monte-Carlo profile on Fig.2). Note that no lateral dopant diffusion occurs, leading to a small doping concentration under the spacer. This process module is suitable for a  $525^\circ\text{C}$  3D-sequential integration process [8]. Moreover, in order to decorrelate the impact of the channel doping and the source/drain resistance, we also fabricated so-called Junctionless Accumulation Mode (JAM) transistors with the same channel doping and RSD thickness as the JL devices but with HDD+LDD implantation +  $1050^\circ\text{C}$  anneal, as for IM MOSFETs.

## III. DEVICE ELECTRICAL CHARACTERIZATION

The **Digital**  $I_{ON}-I_{OFF}$  figure of merit (Fig. 3) shows no significant difference between JAM and IM FET for  $L=35\text{nm}$ . Also, the parasitic gate to SD capacitance  $C_{GDS}$  suggests a similar direct overlap controlled by the SD implant (Fig. 4). On the other hand, the JL FET has a  $0.06\text{fF}/\mu\text{m}$  lower  $C_{GDS}$  vs. JAM/IM, which cannot be explained by the fringe components but rather by a depletion region extending below the spacers in JL transistors (Fig.5). Nevertheless JL devices suffers from

lower performance due to higher access resistance ( $R_0$ ) and non-optimized junctions (Fig. 3).

**Local variability:** matching coefficient  $A_{VT}$  is higher for JL/JAM devices than IM ( $1.7/1.4$  vs.  $1.0\text{ mV}\cdot\mu\text{m}$ , Fig. 6). This degradation with the channel doping is attributed to Random Dopant Fluctuation [9].

**Analog:** we consider a nominal analog transistor width of  $W=0.24\mu\text{m}$ , (planar SOI configuration instead of a trigate nanowire structure). The JL/JAM subthreshold slope (SS) is  $SS=64\text{mV}/\text{dec}$  vs.  $61\text{mV}/\text{dec}$  for the IM device (Fig. 7). However, **back-bias** can be leveraged in order to adjust the threshold voltage and tune performance [10]. Indeed, back-bias is more effective for wider than for narrower devices and it is more effective on JL/JAM than on IM transistors (Fig.8). Markedly, a negative back-bias applied on JAM moves the bulk conduction channel upwards towards the gate, which results in an improvement of the electrostatic control (SS,  $g_d$ ) and, therefore, improving  $g_m/I_d$  and  $g_m/g_d$  (Figs 9-10). As a result, JAM FETs reach analog performances that are slightly better than IM devices, up to an  $A_{v0}=20\log(g_m/g_d)=68\text{dB}$  gain.

**Reliability:** we have performed Positive Bias Temperature Instability (PBTI) and Hot Carrier Injection (HCI) (Figs. 11-12). We demonstrate similar PBTI (88 years lifetime at  $V_{DD}=0.8\text{V}$ ) for JL and JAM devices, demonstrating a negligible impact of the channel doping. However the JL threshold voltage shift is not sufficient for Time-To-Failure extrapolation. We speculate it may be due to the thermal budget difference, mainly due to the  $1050^\circ\text{C}$  spike annealing absence. Better HCI is measured for JL as compared to IM. It can be explain by a lower and shifted to the drain (not underneath the gate dielectric as for IM/JAM) peak electric field.

**Low-frequency drain current noise** measurements (Fig.13) show a 31-die average  $1/f$  signature and a slightly lower input-referred gate voltage noise level ( $S_{Vg}$ ) for JAM. Using the Carrier number fluctuations with Correlated Mobility Fluctuations model [11] and taking into account the series resistance noise ( $S_{Rsd}$ ), we fitted the normalized drain current noise at  $f=10\text{ Hz}$  (Fig.28) to extract the volumetric oxide effective trap density  $N_T$ , and the remote Coulomb scattering coefficient  $\alpha_{sc}$  for all wafers. We extracted a value of  $N_T \approx 7.5 \cdot 10^{17}\text{ eV}/\text{cm}^3$  for all cases, reflecting a similar interface quality, independently of the conduction mode. This value is also very close to state-of-the-art  $N_T$  values of high-k-metal-gate CMOS technologies [12]. Concerning  $\alpha_{sc}$ , a very similar value ( $\approx 4 \times 10^3\text{ Vs/C}$ ) is extracted for all wafers, showing that the remote Coulomb scattering is not affected by the different conduction modes. Finally,  $S_{Rsd}$  has a significant impact only for JL, which can be linked to non-optimized source/drain doping [13].

Mobility differences, due to channel doping (see  $g_{mMAX}$  in Fig.7), are also translated into a cut-off frequency shift, measured at  $F_T=130\text{ GHz}$  for JAM vs.  $136\text{ GHz}$  for IM. But JAM exceeds IM devices in terms of  $F_{MAX}$  because of lower gate capacitances  $C_{GDS}$ . We demonstrate a record  $F_{max}=182\text{GHz}$  for JAM nMOS (Fig. 15).

## IV. CONCLUSION

Finally, our Junctionless Accumulation Mode devices feature record performance among previously published junctionless nMOSFETs (Fig.16). Thanks to process technology variants, electrical characterizations and TCAD simulations, we demonstrated that such a technology offers a good tradeoff for mixed analog/digital applications.
