11 **Abstract**

12 The safety assessment of the geological disposal of nuclear waste glasses requires a thorough
13 understanding of the vapor hydration mechanisms of these glasses. In this context, the effect of
14 temperature and relative humidity on vapor hydration of the AVM6 glass, which is the most reactive
15 among the studied French AVM glasses, was investigated in the present study. Polished glass monoliths
16 were vapor hydrated for 1 year (i) at 97% relative humidity (RH), at temperatures 70°C and 90°C to study
17 the effect of temperature and (ii) at 50°C and 50% RH, 76% RH, 88% RH and 97% RH to study the effect
18 of RH. The altered glass samples were characterized by SEM, XRD and ToF-SIMS. The results were
19 compared with published results of AVM6 glass vapor hydrated at 50°C and 95% RH. The nature of the
20 secondary phases that precipitate varied with both temperature and relative humidity, leading to
21 variation in the behavior of elements in the altered layer (gel) but the altered layer morphology is similar
22 at all temperatures studied. The Arrhenius law for temperature dependence is respected between the
23 temperature range 50-90°C and the activation energy suggests that network-hydrolysis is the
24 predominant rate controlling mechanism at these temperatures and duration. The secondary phases
25 that incorporate transition metals and rare-earth elements are identified by XRD only in experiments
26 conducted at lower RH values.

27 **Keywords:** Vapor hydration, glasses, gel layer, secondary phases, mechanisms

28 1. Introduction

29 Glass is generally considered to be a stable matrix that can remain chemically durable for
30 hundreds of thousands of years, based on geological and archeological evidence [1], [2]. It can also be
31 versatile in terms of composition, due to its capability to incorporate a wide variety of elements in its
32 structure. Due to these properties, it is the chosen matrix for isolation and disposal of highly radioactive
33 waste elements in a deep geological repository. Although considered chemically durable, depending on
34 intrinsic glass properties and environmental conditions, glass gets corroded by water, whether in
35 immersed conditions (aqueous medium) or exposed to humidity (vapor phase). According to the
36 scenario projected for the deep geological waste disposal of nuclear waste glass packages in France [3], it
37 is predicted that the nuclear waste glasses could be exposed to unsaturated medium for tens of
38 thousands of years before subsequent aqueous alteration. Therefore, studies on the vapor phase
39 hydration of the French nuclear waste glasses have been published fairly recently [4]–[9]. Vapor
40 hydration of nuclear waste glasses was also a possibility in the scenario projected by the Yucca mountain
41 project for the American nuclear waste disposal [10]. Therefore, many studies that focus on vapor
42 hydration of American nuclear waste glasses have also been published [10], [11], [20], [12]–[19][21].
43 Vapor hydration studies have also been conducted on archeological or volcanic glasses with a goal to
44 either study the phenomenon of Obsidian hydration dating [22]–[26] or to draw analogies between long-
45 term vapor hydration of nuclear glasses and atmospheric corrosion of natural glasses [27]–[29].
46 Atmospheric alteration of medieval, historic glasses, stained-glass windows of Cathedrals and glass
47 artefacts in museums have been studied in order to understand the phenomenon and preserve these
48 glasses from further degradation [30]–[36]. These studies have helped to estimate vapor hydration rates
49 for different glass compositions, identify glass alteration products and secondary phases. Basic glass-
50 water reaction mechanisms such as molecular water diffusion, inter-diffusion with some loss of
51 alkali/alkaline-earth elements and network hydrolysis have been identified through these studies.
52 Nevertheless, a general trend of evolution of vapor hydration mechanisms over time has not yet been
53 established. While some studies identify network-hydrolysis as the predominant vapor hydration
54 mechanism for the studied duration [8], [33], certain alkali-rich glasses only show evidence of inter-
55 diffusion reactions within the hydrated glass [36]. It has also been suggested that the predominant vapor
56 hydration mechanism could change with increase in the duration of alteration from network-hydrolysis
57 to diffusion of species through the gel layer formed [8]. Some studies have also shown an inflexion by a
58 factor of 2 to 15 in vapor hydration rates in certain glass compositions [7], [8], [37]. The period around
59 which this inflexion occurs is dependent on temperature, relative humidity and possibly glass

60 composition. An inflexion or acceleration of vapor hydration rate may also be triggered by the formation
61 of secondary phases [16].

62 The effects of temperature and relative humidity on vapor hydration of glasses have been
63 studied on different glass compositions [4], [7], [12], [15], [16], [23], [27], [37], [5], [17], [36]. In general,
64 glass hydration rate increases both with temperature and relative humidity. Glass hydration rate may
65 follow an Arrhenius law for temperature dependence and the diffusion rate of water can increase either
66 linearly or exponentially with increasing relative humidity. Nevertheless, these studies have shown that
67 glass response to these parameters can vary depending on the glass composition. It has also been
68 established that vapor hydration mechanisms may not be the same at low (35-90°C) and high
69 temperatures (90-200°C) [4], [7]. Apart from that, the activation energies vary across a wide range for
70 different glass compositions and different studies. In short, the literature survey has shown the diversity
71 and unpredictability associated with glass behavior in unsaturated medium and a unified model has not
72 yet been established to predict vapor hydration rates at different environmental conditions. Adding to
73 this, is the fact that the number of studies conducted on the vapor hydration of glasses is far lesser than
74 the number of studies conducted on aqueous alteration of glasses. This highlights the necessity to
75 extensively study vapor hydration of nuclear waste glasses to be able to carry-out the safety assessment
76 of their geological disposal.

77 Therefore, this work was conducted within the framework of studying the behavior of the AVM
78 (*Atelier de Vitrification de Marcoule*) nuclear waste glass behavior in unsaturated medium [8]. AVM
79 glasses are complex borosilicate glasses made of more than 20 oxides and incorporate fission products
80 from the UNGG (*Uranium Naturel Graphite-Gaz*) reactor at the Marcoule nuclear facility. For practical
81 reasons, the glass studied here is an inactive simulant. The effects of temperature and relative humidity
82 were investigated specifically on the AVM6 glass, since the previous study in this framework showed that
83 among the different AVM glass compositions, AVM6 altered at the fastest rate in vapor phase at 50°C
84 and 95% relative humidity [8].

85 2. Materials and methods

86 The composition of AVM6 glass in mole percent of oxides is provided in table 1. The synthesis of this
87 glass has been described previously [38]. The glass samples used in this study and the cited study
88 published earlier [8] were retrieved from the same batch.

89 2.1 Experiments

90 The section below describes the two sets of experiments that were performed, and the experiments are
91 recapitulated in table 2. It is to be noted that in section 4, the results of the experiments described below
92 are compared with the results of the study published earlier [8] since the glass samples were retrieved
93 from the same batch and the experimental conditions are similar. However, the protocol used for glass
94 alteration varies. This has also been addressed in section 4.

95 2.1.1 Effect of temperature

96 The AVM6 glass was altered in vapor phase at temperatures 70°C and 90°C and relative humidity
97 97% for a period of 1 year. The protocol used for glass alteration is based on literature [4]. Glass
98 monoliths of dimensions 2.5x2.5x0.1 cm³ were placed vertically in a Teflon walled stainless steel
99 autoclave above 5.25 wt.% NaCl solution, which imposes a relative humidity of 97% [39]. The autoclave is
100 placed inside an aluminum cylinder to prevent rapid heating and cooling cycles, which might induce
101 water condensation on the glass monoliths. The setup is then put in an oven at 70°C or 90°C for a period
102 of 1 year. At the end of the runs, the reactors were removed from the oven, allowed to cool down to
103 ambient temperature and then the monoliths were stored in ambient conditions until characterization.

104 2.1.2 Effect of relative humidity

105 AVM6 glass monoliths of dimensions 2.5x2.5x0.1 cm³ were altered in vapor phase at 50°C and
106 four different relative humidity values (50±10%, 76±1%, 88±6% and 97±3%) for 1 year. The vapor
107 hydration protocol used is different than the one used to study the effect of temperature and is
108 described in detail in the reference [36]. It consists of an air-tight container equipped with a perforated
109 shelf to hold samples and a tray below the shelf to contain the saturated salt solution, which will be used
110 to impose the relative humidity in the container. This container was then placed in an oven at 50°C. At
111 this temperature, saturated MgNO₃ solution was used to impose 50% RH, saturated NaCl solution was
112 used to impose 76% RH, saturated KNO₃ solution was used to impose 88% RH and saturated K₂SO₄
113 solution was used to impose 97% RH. The relative humidity was measured using a sensor and the
114 uncertainty in the relative humidity was measured from the standard deviation of the sensor
115 measurements as well as taking into account 2% error associated with the sensor measurements. Due to
116 some technical issues with the air-tight container, there was slight evaporation of the salt solution, which
117 required frequent verification and adjustments. This resulted in fluctuations in the RH value, especially in
118 the containers at 50% RH and 88% RH. At the end of one year of experiment, the samples were removed
119 from the containers and placed in a desiccator (14% RH) until characterization.

120 2.2 Characterization techniques

121 **SEM:** Morphological analysis of the altered samples were carried out using a field emission Scanning
122 Electron Microscope (SEM) Zeiss Gemini Supra 55, JEOL JSM 6330F with an Energy Dispersive
123 Spectroscopy (EDS) system. The gel layer is identified visually through density differences between
124 pristine glass and gel layer. The spatial resolution of the SEM does not permit to detect the presence of
125 gel layers lower than 100 nm in thickness. EDS analysis can be used to identify secondary precipitates
126 using compositional analysis, but the minimum specimen size required for EDS analysis is 1 to 2 μm
127 (laterally and perpendicularly) to avoid signals from surrounding material. All samples were cut and
128 observed directly (after metallization using carbon) by tilting the altered sample at an angle to observe
129 the altered surface and eventually the presence of an altered layer at the cross-section. Additionally, all
130 samples were enrobed in an epoxy resin, and polished to surface roughness $< 1 \mu\text{m}$ to be observed in
131 SEM for cross-section images.

132 **XRD:** The presence of crystalline secondary phases was analysed using a Philips X'Pert diffractometer X-
133 Ray Diffraction (XRD) apparatus equipped with a copper tube ($\lambda_{\text{CuK}\alpha 1}=1.542 \text{ \AA}$, voltage 40 kV and intensity
134 40 mA) and a goniometer ($4\text{-}80^\circ 2\theta$, step size 0.01744°). Each glass monolith was analyzed for 12 h on a
135 multiple purpose sample stage (MPSS). The resulting peaks (if present) in the XRD pattern were treated
136 with EVA software to identify the secondary phases corresponding to the peak [40].

137 **ToF-SIMS:** The behavior of elements in the altered layer was characterized using ToF-SIMS (SSIMS on
138 TOF 5 (IONTOF)). Depth profiles of secondary positive ions were obtained by alternating analysis and
139 abrasion cycles. 25 keV Bi_1^+ primary ions at 1.5 pA current were used for analysis cycles. 1 keV primary
140 O_2^+ ions at 300 nA current were used for the abrasion cycles. The eroded area was $200 \times 200 \mu\text{m}^2$. The
141 analyzed area was $50 \times 50 \mu\text{m}^2$. The surface charge was neutralized on the monoliths by a pulsed low-
142 energy ($< 20 \text{ keV}$) electron flux. The depth calibration was carried out using the abrasion rate and a
143 mechanical profilometer to measure the crater depth at the end of the analysis. It is to be noted that the
144 same abrasion rate was used for analyzing the gel layer and the pristine glass. This choice was justified by
145 the good correspondence between thickness of altered layer measured by SEM and ToF-SIMS in other
146 works [7].

147 Thus at the end of the analysis, we obtain the intensities of different elements as a function of the depth
148 of the sample analyzed (depth profiles). The profiles were normalized with respect to the intensity of
149 each element (C) in the pristine glass (denoted as PG) and with respect to the intensity of Si (C_{Si}) at
150 given depth as shown in the equation 2.2.1 below.

151 $Normalized\ intensity = \frac{\frac{C}{C_{Si}}}{\left(\frac{C}{C_{Si}}\right)_{PG}}$ Equation 2.2.1

152 $Altered\ layer\ depth = x_0\ at\ which\ \left(0.5 - \frac{\frac{C_B}{C_{Si}}}{\left(\frac{C_B}{C_{Si}}\right)_{PG}} = 0\right)$ Equation 2.2.2

153 In most of the vapor hydration studies, boron is the element that is the most depleted in the altered
 154 layer (in depth and in quantity), although it is surprising [4], [7], [8]. Retention of boron in the gel layer is
 155 often less than 10-20%. Therefore, it is used as a tracer to calculate the depth of the altered layer using
 156 equation 2.2.2. The depth of hydrogen penetration is compared to the thickness of boron depletion
 157 during vapor hydration. The hydrogen penetration depth is calculated from the ToF-SIMS profiles using
 158 equation 2.2.3 as shown below.

159 $Depth\ of\ hydrogen\ penetration = x\ at\ which\ (H\ intensity = \frac{\left(\frac{C_H}{C_{Si}}\right)_{(gel\ layer)^{+1}}}{\left(\frac{C_H}{C_{Si}}\right)_{PG}})$ Equation 2.2.3

160 Many factors regarding the nature of the sample contribute to the uncertainties associated with the
 161 measurement of altered layer thickness by ToF-SIMS method. These factors are: (i) the surface
 162 roughness of the samples due to the presence of secondary precipitates, (ii) same speed of abrasion that
 163 was used to analyze the precipitates, gel and the pristine glass and (iii) the irregular and discontinuous
 164 alteration zones in case of heterogeneously altered samples. Since these factors were not quantifiable in
 165 this study, error values cannot be calculated. Nevertheless, ToF-SIMS analysis of different samples is
 166 useful to uniformly compare the samples, since 50 x 50 μm² is a relatively larger zone of analysis. It is
 167 also extremely useful to study the behavior of elements in the altered layer.

168 3. Results

169 3.1 Effect of temperature

170 SEM images

171 The SEM images of the AVM6 glass altered at 97% RH and at 70°C and 90°C (experiments 1 and 2
 172 in table 2) are shown in figure 1. The surface of AVM6 glass altered at 70°C was covered with
 173 clusters/carpets of leafy secondary phases that were of an amoeboid shape. On the other hand, the
 174 surface of AVM6 glass altered at 90°C was covered entirely with a carpet of leafy secondary phases. The
 175 leafy precipitates on the surface of the sample altered at 90°C visually seems better developed than the

176 leafy precipitates on the surface of the sample altered at 70°C. The altered surface of both samples
177 seemed to contain holes of a few hundred nm in size. The AVM6 glass altered at 90°C seemed to have
178 more of these holes. The SEM image of the cross section of the AVM6 glass altered at 70°C shows a
179 homogeneous gel layer of 290-350 nm thickness (figure 1(e) and figure S1 (e and f) in supplementary
180 data). In the zone characterized by SEM, no holes were identified in the cross-sections. The SEM images
181 of cross-sections of the AVM6 sample altered at 90°C shows the presence of several mushroom shaped
182 holes that are a few μm deep and wide (also see figure S2 in supplementary data). Above these holes,
183 the surface was covered with a gel layer of homogeneous thickness of about 1 μm .

184 *XRD patterns*

185 The XRD patterns of the AVM6 glasses altered at 70°C and 90°C are provided in figure S3 in
186 supplementary data and the possible secondary phases identified through EVA software analysis of the
187 peak patterns is summarized in the end in table 6. Although the protocol used for vapor hydration at
188 70°C and 90°C used NaCl to impose relative humidity, no peaks to indicate the presence of NaCl were
189 identified. The sample altered at 90°C showed the presence of a small peak around 20° (2 θ) (around 4.5
190 Å in d-scale) and 24.5° (2 θ) (around 3.6 Å in d-scale) that indicates the presence of aluminosilicates
191 (possibly neosilicates or clay minerals). The AVM6 glass altered at 70°C did not show any peaks other
192 than RuO₂ (platinoids that did not get incorporated in the network during glass preparation). However,
193 the background subtracted XRD pattern seemed to contain peaks merged with the background noise
194 around the same region (20° and 24.5° (2 θ)) (see figure S4 in supplementary data).

195 *ToF-SIMS profiles*

196 The ToF-SIMS profiles of the AVM6 sample altered at 70°C and 90°C are provided in figures 2 and
197 3 respectively. The thicknesses of the altered layers measured by the depths of boron depletion
198 (equation 2.2.2) are provided in table 3.

199 The ToF-SIMS profiles of the AVM6 glass vapor hydrated at 70°C show that (figure 2), apart from
200 hydrogen penetration, formation of SiOH and boron depletion, the alkali and alkaline-earth elements are
201 very mobile in the gel layer. It seems that these elements have migrated towards the surface of the gel
202 layer probably to form secondary precipitates. From these profiles, it looks like the first 40-80 nm in the
203 ToF-SIMS profiles are secondary precipitates. The migration of alkali and alkaline-earth elements has
204 resulted in a depletion of these elements in the gel layer close to the gel-glass interface. The depletion of
205 rare-earth elements and transition metals towards the surface of the altered sample could be due to the
206 presence of a layer of precipitates close to the surface that does not incorporate these elements. (See

207 figure S5 in supplementary data for un-normalized ToF-SIMS profiles which also show this depletion).
208 This could mean that there is no real loss of rare-earth elements and transition metals. The migration of
209 alkali and alkaline-earth elements towards the surface could be either to form precipitates such as
210 carbonates or to play a charge balancing role in the phyllosilicates that were seen in the SEM images
211 (figure 1).

212 The ToF-SIMS profiles of all the elements in the gel layer of AVM6 glass altered at 90°C (figure 3)
213 resemble that of the AVM6 glass altered at 70°C, except, the thickness of the altered layer is 1 μm and
214 the thickness of the layer of secondary precipitates (based on the depth of depletion of rare-earth
215 elements and transition metals, and the mobility of alkali and alkaline-earth elements) is around 250 nm.

216

217 3.2 Effect of relative humidity

218 *SEM Images*

219 Figure 4 shows the SEM images of the AVM6 samples vapor hydrated at 50°C and 97% RH and
220 88% RH for 1 year (experiments 6 and 5 respectively in table 2). On the surface of the AVM6 sample
221 vapor hydrated at 97% RH, circular clusters of fibrous secondary precipitates of a few μm diameters are
222 present along with fewer shapeless clusters of fibrous phases (also see figure S6(a) in supplementary
223 data). The SEM image of the cross-section of the sample shows an altered layer of approximately 200 nm
224 thickness, which could be most likely a layer of fibrous secondary precipitates. In the section of the
225 sample analyzed, many irregularly altered zones could not be identified (in the cited reference [8], many
226 irregularly altered zones were identified on the same AVM6 glass altered at 50°C and 95% RH in the
227 climatic chamber for 6 months and 18 months).

228 The surface of the AVM6 sample vapor hydrated at 88% RH also seemed very similar to the
229 sample vapor hydrated at 97%. This sample could also contain some irregularly altered zones as shown in
230 figure 4(e).

231 Figure S7 in supplementary data shows the SEM images of the AVM6 samples vapor hydrated at
232 50°C and 76% RH and 50% RH for 1 year (experiments 4 and 3 respectively in table 2). Visually these
233 surfaces are different from each other and also are different from the surfaces of the samples altered at
234 the two higher RH values. The figures S7 (a) and (d) show the altered surfaces of AVM6 samples altered
235 at 76% RH and 50% RH respectively at the same magnification. The shapes of the secondary phases

236 formed on these surfaces are visually different. The sample altered at 50% RH seems to contain more
237 singular needle-like precipitates and there are circular spots on the altered surface that appear bulged.
238 No such bulged zones are visible on the sample altered at 76% RH. However, the surface looks scaled, as
239 though it could be a more advanced stage of the bulged zones that have peeled off. A few singular
240 needle-like precipitates were visible on the sample altered at 76% RH as well.

241 *XRD patterns*

242 Figure S8 in supplementary data shows the XRD patterns of the AVM6 glass altered in all four RH
243 values and the possible secondary phases identified through EVA software analysis of the peak patterns
244 is summarized in the end in table 6. At all 4 RH values, a peak around 6° (2θ) (or 15 \AA) is present
245 indicating the formation of an aluminosilicate containing Na, Mg and Fe. The intensity of the peak
246 increases with increasing relative humidity, suggesting that either a higher quantity of this phase had
247 precipitated with increasing relative humidity or that as the relative humidity increases, the crystallinity
248 of the precipitates improve. This peak was present on the same AVM6 samples altered at 50°C and 95%
249 RH for 6 months and 18 months in the cited reference as well [8] and the composition of the phase was
250 identified to be similar to that of montmorillonite, based on XRD and TEM analyses.

251 Only the AVM6 samples altered at lower RH values, 50% and 76% RH, contain peaks around 10°
252 and 19.2° (2θ) (around 9.2 and 4.6 \AA in d-scale), which could be $\text{Nd}_2(\text{CrO}_4)_3 \cdot 7\text{H}_2\text{O}$ or $\text{Pr}_2(\text{CrO}_4)_3 \cdot 7\text{H}_2\text{O}$ (see
253 figure S9 in supplementary data). Usually, Nd gets incorporated in phases such as powellite ((Ca,
254 Nd)MoO₄) or saponite (smectite clay mineral) [41], but these phases were not identified. These two
255 samples also contain a peak at 15° (2θ) (around 6 \AA in d-scale), which could hypothetically be attributed
256 to sodium aluminosilicate hydrates and a peak at 32° (2θ) (around 2.8 \AA in d-scale) which indicates the
257 presence of NaCl. While the presence of NaCl on the AVM6 sample altered at 76% RH was expected since
258 NaCl was used to impose relative humidity, its presence on the AVM6 sample altered at 50% RH is
259 puzzling since MgNO_3 was the salt used to impose relative humidity. One of the possible explanations
260 could be that the Cl was sourced from the tap water used to impose the relative humidity, although its
261 concentration was much lower than in the NaCl salt solution

262 For the AVM6 samples altered at 88% and 97% RH, in addition to the peak at 6° (2θ), there are
263 also peaks at 8° , 10° , 12° and 14° (2θ) (around 11 , 8.8 , 7.5 and 6.3 \AA in d-scale) that correspond to
264 sodium aluminosilicates, possibly zeolites such as mordenite and stellerite (see supplementary data
265 figure S10).

266 *ToF-SIMS profiles*

267 Table 4 provides the altered layer depths (boron depletion) and the depths of hydrogen
268 penetration through the surface of the AVM6 glasses altered in all 4 RH values calculated using equation
269 2.2.2 and 2.2.3. Figure 5 presents the ToF-SIMS profiles of the AVM6 sample altered at 50% RH and 50°C
270 for 1 year (experiment 3 in table 2). The thickness of boron depletion is around 27 nm in the gel layer,
271 which is a little higher than the boron depletion in a pristine AVM6 glass (14 nm (figure S11 in
272 supplementary data)). Transition metals and rare-earth elements are depleted in the first 10-20 nm of
273 the altered layer, which was the case in pristine samples as well (figure S11 in supplementary data). The
274 depletion of Ba, Sr and Li is slightly deeper than the depletion of boron in the AVM6 glass altered at 50%
275 RH. The retention of boron in the first 20 nm of the altered layer is only between 2-10%. It seems as
276 though the altered layer might be heterogeneous since the altered layer-glass interface of hydrogen
277 penetration is larger than the thickness of altered layer and according to the profile of boron, its
278 concentration is not uniform in the altered layer and the interface is also large. However, it cannot be
279 ascertained because large interfaces may also be caused by the presence of secondary precipitates on
280 the altered surface. The thickness of the layer is smaller than the resolution of SEM, so the assumed
281 heterogeneity of the altered layer cannot be verified.

282 Figure 6 shows the ToF-SIMS profiles of the AVM6 glass altered at 76% RH (experiment 4 in table
283 2). The altered layer depth is 190 nm and the thickness of hydrogen penetration is 200 nm. Similar to the
284 AVM6 glass altered at 50% RH, the retention of boron is around 2-10% in the altered layer. The retention
285 of Na in the altered layer is uniform and is around 40%. The other alkali and alkaline-earth elements are
286 depleted in the part of the altered layer that is close to the altered layer-glass interface and their
287 concentration increases towards the surface of the altered glass. Such a profile suggests that the
288 elements have migrated towards the surface probably to form secondary precipitates. Ba is the most
289 mobile alkaline-earth element, with only 1-4% retention in the altered layer close to the interface. The
290 retention factors of Ca, Sr and Li in this region are also only around 10%. The transition metals and the
291 rare-earth elements are depleted in the first 20-40 nm of the altered layer. Contrary to the behavior of
292 the other transition metals, the retention factor of Mn declines continually in the altered layer towards
293 the altered surface until it is only 2-3% retained and Cr is enriched in the altered layer and depleted only
294 towards the surface.

295 Figure 7 shows the normalized ToF-SIMS profiles of the elements for the AVM6 glass altered at
296 88% RH (experiment 5 in table 2). The altered layer thickness is around 124 nm and the thickness of

297 hydrogen penetration is around 129 nm. This thickness value is surprising since it is lower than the
298 altered layer thickness of the AVM6 glass altered at 76% RH for the same temperature and duration. As
299 seen from figure 4(e), the AVM6 glass altered at 88% RH has a heterogeneous altered layer. Therefore,
300 the reason for this unexpectedly lower altered layer thickness could be that the ToF-SIMS analysis might
301 have been done in a region with fewer irregularly altered zones or it could be associated with
302 uncertainties in the measurement. Apart from this discrepancy, the behavior of elements in the altered
303 layer is quite similar to that of the AVM6 glass altered at 76% RH in terms of shape of the profiles and the
304 retention factors of elements in the altered layer (except Mn). The Mn behavior in this glass is quite
305 similar to the behavior of other transition metals in the altered layer.

306 Figure 8 shows the normalized ToF-SIMS profiles of the AVM6 glass altered at 97% RH
307 (experiment 6 in table 2). The altered layer thickness is around 540 nm and the thickness of hydrogen
308 penetration is around 620 nm. Similar to the AVM6 glass altered at 50% RH, the altered layer-glass
309 interface is quite large. It seems that the altered layer could be heterogeneous in this case as well,
310 keeping in mind that the heterogeneity could also be caused by surface irregularities (presence of
311 secondary precipitates). The rare-earth elements and the transition metals are immobile in the altered
312 layer except the first 30-50 nm, where they seem to be slightly depleted probably due to the presence of
313 secondary precipitates in this region. Once again, the alkali and the alkaline-earth elements are very
314 mobile in the altered layer. They are depleted in the part of the altered layer close to the altered layer-
315 glass interface and their concentration increases towards the surface. Na seems to be enriched in the
316 first 250 nm of the altered layer (towards the surface).

317 4. Discussion

318 4.1 Effect of temperature

319 At the end of the experiment, the autoclaves in their aluminum over-container were removed
320 from the oven and cooled to ambient temperatures before they were opened to retrieve samples. There
321 is a risk that water may condense onto the samples during the cooling as a result of the reducing
322 temperature and the attainment of dew point. Consequently, some modifications may be made to the
323 altered surface such as dissolution of some alteration products and removal of some elements. However,
324 we did not find any markers to indicate explicitly that water had condensed onto the sample surfaces.
325 The ToF-SIMS profiles indicated the loss of boron from the altered layer. It was mentioned in the

326 previous study [8] that the loss of boron may be attributed to transportation in the vapor phase. The
327 mobility of the alkaline-earth elements may be controlled by the precipitation of clay minerals.

328 *Comparison of altered layer morphology:* In a previous study, the altered layer morphology of the vapor
329 hydrated AVM6 glass was already shown to be rather unusual [8]. It consisted of two types of alteration
330 layers on the same glass samples vapor hydrated at 50°C and 95% RH for 181 days and 557 days. The
331 altered surface contained a rather homogeneous continuous gel layer that was only a few tens of nm
332 thick in addition to intermittently present, irregularly shaped and highly porous altered zones.

333 In this study, the SEM images described in section 3.1 show that a similar morphology has been observed
334 on AVM6 samples vapor hydrated at 70°C and 90°C as well. The SEM images of the glass surface altered
335 at 70°C showed the presence of what seems to be holes beneath the carpet of phyllosilicates (figure 1
336 (c)), although present rather infrequently in comparison with the sample altered at 90°C. As can be seen
337 from figure S2(f) in supplementary data, these mushroom-shaped holes may not be completely empty,
338 but may be of very low density based on the contrast in electronic density. Based on the SEM
339 observations, figure 9 shows a schematic description of the possible altered layer morphology of AVM6
340 glass at different temperatures. The thickness of the homogeneous gel layer increases almost
341 exponentially with temperature. Similarly, at 50°C, what seemed to be highly porous irregular zones
342 might have developed into even more porous cup-shaped zones at 90°C, which seems to be a more
343 advanced stage of corrosion. This type of corrosion seems to resemble sub-surface pitting corrosion
344 commonly observed in steel or aluminum alloys due to slight inhomogeneity in the composition of the
345 initial matrix [42]. Although the mushroom type shape of these cups is rather interesting because,
346 dissimilarly, in pitting corrosion, usually oval holes with a pointy tip are observed. It was discussed in the
347 earlier work [8] that it seems that the homogeneous gel layer and the irregular pitting type alteration are
348 two separate processes occurring in parallel. The altered layer morphology is very similar at all the
349 studied temperatures since a homogeneous gel layer in addition to intermittently present irregular
350 altered zones are present in all three cases.

351 *Calculation of activation energies:* Next, the temperature dependence of vapor hydration rate on
352 Arrhenius law is verified, as this might provide some insights into vapor hydration mechanisms. Glass
353 alteration in aqueous medium is a thermally activated process. Several studies have shown that the
354 dependence of the overall glass dissolution rate (k) on temperature follows Arrhenius law ($k = A_0 e^{\frac{-E_a}{RT}}$)
355 [43], [44]. When the Arrhenius law is valid in a given temperature range, it means that glass alters by the

356 same mechanism in that range [43]. The term “overall glass dissolution rate” was used because all the
357 reactions resulting in glass alteration such as water diffusion, ion-exchange and network hydrolysis are
358 thermally activated. Therefore, it is difficult to identify the activation energy of individual reactions in the
359 glass alteration process. Nevertheless, the experiments in the literature have permitted to estimate that
360 an activation energy of around 65-75 KJ mol⁻¹ suggests that glass alteration occurs mostly by network
361 hydrolysis [44], [45]. An activation energy below 50 KJ mol⁻¹ suggests that inter-diffusion is the
362 predominant glass alteration mechanism [43]. It is usually considered that activation energies in-
363 between these two ranges indicate glass alteration by both network hydrolysis and inter-diffusion
364 mechanisms.

365 The vapor hydration of glasses is also a thermally activated process. Literature survey has shown
366 that the dependence of vapor hydration rate (r_h) on temperature in a given range follows Arrhenius law
367 only for certain glass compositions [36]. For example, in the study conducted on vapor hydration of
368 alkali/alkaline-earth-silicate glasses in the temperatures 20°C and 50°C in one case [36] and 40°C and
369 80°C in another case [46], the vapor hydration rate did not follow Arrhenius law for temperature
370 dependence. On the other hand, the vapor hydration rate of the SON68 glass follows Arrhenius law for
371 temperature dependence in range 125-200°C with an activation energy of 43-47 KJ mol⁻¹ [47] and an
372 activation energy of 34±4 KJ mol⁻¹ [7] in the temperature range 35-90°C. The difference in activation
373 energy between these two temperature ranges is not very high. The activation energy value suggests
374 that the mechanism which controls r_h is interdiffusion in both the temperature ranges for the studied
375 duration, but at higher temperatures, the importance of hydrolysis with respect to interdiffusion
376 increases. This is logical because, in general the activation energies are lower for interdiffusion reactions
377 than hydrolysis reactions. Activation energies measured in other studies in various conditions vary from
378 34 KJ mol⁻¹ to 137 KJ mol⁻¹ [16], [24], [48], [49].

379 *Calculation of activation energy between 70°C-90°C:* For experiments 1 and 2 in table 2, we calculate the
380 vapor hydration rate, first in m/day (by dividing the thickness of the homogeneous gel layers measured
381 using SEM images (table 3) by the duration of alteration) and multiply it by the glass density to obtain
382 the vapor hydration rate in g m⁻²day⁻¹ (r_h , which is considered equivalent to k in the equation given
383 above) after 1 year of alteration. While making this calculation, it is assumed that the vapor hydration
384 rate has been constant for the duration of the experiment (1 year). This can be justified since at 50°C and
385 95% RH, it was shown in earlier work that the vapor hydration rate of the AVM6 glass is constant up to
386 about 6 months approximately [8]. At 70°C and at 90°C, the vapor hydration rate must remain constant

387 for a longer duration since in literature it has been observed that at higher temperatures, the inflexion in
388 vapor hydration rate takes longer to occur [7], [37]. In the cited literature, the vapor hydration kinetics
389 was followed using FTIR spectroscopy for the SON68 glass; at 50°C, the vapor hydration rate was
390 constant until 200 days, whereas at 90°C, the vapor hydration rate remained constant until almost 600
391 days [7]. Using the vapor hydration rates measured at only these two temperatures (70°C and 90°C) and
392 the equation $\frac{d(\ln(V_H))}{dT} = \frac{E_a}{RT^2}$, we can calculate an activation energy of 62.3±12.5 KJ mol⁻¹ (see table 5 for
393 vapor hydration rates) for the AVM6 glass.

394 *Calculation of activation energy between 50°C-90°C:* We also have data on vapor hydration of AVM6
395 glass at 50°C and 97% RH, which can be included in the calculation of activation energies. However, the
396 data obtained in the current study at 50°C (table 4, thickness of the altered layer formed at 50°C and
397 97% RH for 1 year (experiment 6) measured using ToF-SIMS) cannot be used because the experiment
398 was conducted for 1 year and the previous study showed that the vapor hydration rate is definitely not
399 constant up to 1 year of alteration [8]. Additionally, analysis by TEM is required to study the morphology
400 of the altered layer and find out the presence and if so, the thickness of the homogeneous gel layer,
401 which seems to be only a few tens of nm at 50°C [8]. The ToF-SIMS data cannot be used to measure the
402 thickness of this homogeneous gel layer at 50°C This is due to the presence of the heterogeneous porous
403 altered zones, which interfere with the ToF-SIMS analysis carried out on a relatively large section of the
404 sample (50x50 μm²), contrary to TEM images. Therefore, the data from TEM images obtained in the
405 earlier study [8] on the same AVM6 glass altered at 50°C and 95% RH was used for the calculation of
406 activation energy. In this cited reference [8], the vapor hydration kinetics was followed using FTIR
407 spectroscopy. It showed that the vapor hydration rate was constant for the first 200 days approximately
408 and then the rate dropped by a factor of 5 and remained constant at the lower rate until 557 days. The
409 thickness of the homogeneous gel layer was around 50 nm after 181 days of vapor hydration, according
410 to TEM images [8]. Using the linear regression of the evolution of hydration kinetics up to 557 days
411 measured using FTIR spectroscopy [8], it was estimated that the thickness of the homogeneous gel layer
412 after 1 year is around 60 nm. Therefore, if we consider an average vapor hydration rate for 1 whole year
413 (0.46x10⁻³ g m⁻²day given in table 5), the activation energy calculated using the slope of evolution of ln(r_h)
414 vs 1/T (K⁻¹) from 50°C to 90°C is around 68.7±13.7 KJ mol⁻¹ (brown line in figure 10). On the other hand, if
415 we consider the vapor hydration rate until the first six months, up until which the vapor hydration rate
416 was constant (0.77x10⁻³ g/m²day), then the calculated activation energy is around 55.8±11.2 KJ mol⁻¹
417 (blue line in figure 10).

418 The calculated r_h values at 50°C (an average value calculated taking into account the inflexion of
419 the rate), 70°C and 90°C are provided in table 5. These vapor hydration rates were calculated only for the
420 thickness of the homogeneous gel layer formed on the surface and does not include the irregular
421 heterogeneously altered porous zones or the mushroom shaped holes that are intermittently present.

422 Figure 10 shows the evolution of $\ln(r_h)$ vs $1/T$ (K^{-1}) from 50°C to 90°C. The dependence of the rate
423 of vapor hydration (only the formation of gel layer, without including the 'pit' type irregular altered
424 porous zones) of the AVM6 glass follows Arrhenius law for temperature dependence with an activation
425 energy that may vary between 55-68 KJ mol^{-1} . This activation energy value suggests that the rate of
426 formation of the gel layer must be controlled predominantly by network hydrolysis reactions for the
427 studied duration in the temperature range 50°C to 90°C.

428 *Comparison of secondary phases:* Despite the similarity in the vapor hydration of AVM6 glass between
429 50°C and 90°C in terms of altered layer morphology and mechanism of formation of the gel layer, the
430 secondary phases that have precipitated are different, as can be seen from table 6. In previous work [8],
431 it was noted that the glass altered at 50°C and 95% RH during 6 months and 18 months had an intense
432 peak around 6° (15 \AA) that indicated the presence of a smectite (probably montmorillonite). The glasses
433 altered at 70°C and 90°C however did not have the same secondary phases precipitated on their
434 surfaces.

435 Based on the similarity in altered layer morphology and rate controlling gel-layer formation mechanism
436 and the difference in the precipitation of secondary phases at three different temperatures, the 'pitting'
437 type corrosion observed in AVM6 glass is most likely a property of the glass and not related to the
438 identity of the secondary phases that precipitate. Pristine AVM6 glass is slightly inhomogeneous due to
439 the presence of RuO_2 platinoids (figure S12 in supplementary data). However, as far as our analysis goes,
440 the local presence of platinoids could not be directly correlated to the presence of irregular porous
441 zones. Platinoids were also present in another simulated nuclear waste glass, but the vapor hydration of
442 this glass did not result in a similar irregular altered layer morphology as seen in AVM6 [37]. This too
443 supports the argument that the platinoids probably do not play a role in the rather particular altered
444 layer morphology of the AVM6 glass. Although the presence of these non-uniformly present altered
445 zones merit further analysis to link them to alteration conditions, glass property or composition, it could
446 not be carried out in the current study.

447

448 4.2 Effect of relative humidity

449 *Evolution of altered layer thickness as a function of RH:* As explained in the introduction, the choice of
450 AVM6 glass for studying the effect of relative humidity at 50°C was based on the fact that this glass
451 altered the fastest among the six glasses studied earlier [8]. However, at the time of launching the
452 experiment, it was unknown that the AVM6 glass alters in a heterogeneous manner. SEM images of the
453 samples altered at 88% RH and 97% RH seem to confirm the heterogeneous alteration of the AVM6
454 glass. However, TEM analysis was not carried out to verify if these altered samples had the same altered
455 layer morphology described in figure 9. Despite the possible heterogeneity of the altered layer and the
456 uncertainty associated with it, we use ToF-SIMS measurements to quantitatively study the effect of
457 relative humidity on the AVM6 glass samples that were analyzed in a more or less uniform manner.
458 These altered layer thicknesses and the thicknesses of hydrogen penetration into the sample include the
459 secondary precipitates, gel layer and possibly irregularly altered zones. They are plotted as a function of
460 the relative humidity in figure 11. From 50% RH to 97% RH, it can be seen that the altered layer thickness
461 increases more or less exponentially, except the discrepant value at 88% RH.

462
463 In literature, some studies have found that glass alteration rate evolves exponentially with
464 increasing relative humidity [16], [26], [36] and other studies have found that the evolution is linear [50],
465 [51][26]. A few studies have noted a threshold RH value below which glass alteration is negligible and
466 beyond which the alteration rate increases exponentially. This threshold value varies between 60% and
467 90%, depending on the study (glass composition, temperature) [16]. In our study too, there seems to be
468 a threshold value around 50-60%, below which glass alteration seems negligible.

469 Table 4 gives the depth of hydrogen penetration in the AVM6 glass samples altered at different
470 RH values. Considering this depth as a “diffusion thickness, e ”, a diffusion coefficient, D can be calculated
471 using the equation $e = 2\sqrt{\frac{Dt}{\pi}}$ based on Fick’s law. The diffusion coefficient (calculated in $\text{m}^2 \text{s}^{-1}$) (given in
472 table 4) also evolves exponentially with relative humidity (figure 11). A normalized diffusion rate called
473 relative rate has been calculated in order to compare with literature [51]. The cited reference has
474 regrouped a number of studies on the effect of relative humidity on vapor hydration of glasses (different
475 glass compositions and temperature). While comparing our data with the cited literature, it is clear that
476 the evolution of the diffusion rate in our study is very similar to the evolution of the diffusion rate of an
477 SRL131 glass, which is a borosilicate nuclear waste glass, altered in vapor phase at 202°C [16]. This shows

478 the effect of composition on a glass's response to change in relative humidity. Glass composition can
479 influence the quantity of water adsorbed on the glass surface. The release of alkali by initial ion exchange
480 reactions decreases the vapor pressure of water adsorbed on the surface of the glass and promotes
481 additional water vapor condensation [52]. The dependence of adsorbed water quantity on the alkali
482 content was demonstrated in the work done on an Obsidian glass and SRL165 glass as well [53]. Other
483 factors such as glass surface roughness may also influence the quantity of water adsorbed [54].

484 *Comparison of secondary phases:* The effect of relative humidity on secondary phase precipitation is also
485 noticeable from our results (as can be noted from table 6 which summarizes the secondary phases
486 precipitated in all 6 experiments). The samples altered at 88% and 97% RH have the same precipitates.
487 The peaks in the XRD pattern of AVM6 sample altered at 97% RH are more intense than those for the
488 sample altered at 88% RH. This is most likely related to the faster alteration of the sample at 97% RH,
489 due to the higher availability of water molecules. Some of the peaks are only present on the patterns of
490 the AVM6 samples altered at 50% RH and 76% RH. These peaks indicate the presence of NaCl and
491 hydrated oxides of rare-earth and transition elements. These precipitates have been identified despite
492 the relatively low alteration of the AVM6 samples altered at 50% RH.

493 *Comparison of behavior of elements in the altered layer:* The ToF-SIMS profiles have not only revealed
494 increasing alteration rate with increasing humidity, but certain elements such as Na, Mg, Al, Zr and other
495 transition metals and rare-earth elements also show increased retention factor in the altered layer with
496 increasing relative humidity. In order to facilitate comparison of the mobility and the retention of
497 elements in altered layers of different thicknesses, a "percent altered layer" was used for normalization.
498 "Percent altered layer" is calculated as $\frac{x}{x_0} * 100$, where x is any given depth and x_0 is the altered layer
499 depth calculated from equation 2.2.2. Figure 12 shows the normalized intensity of Na, Mg, Zr, Al, Mn, Ni,
500 Fe, Nd and Ca as a function of the "percent altered layer" for all four RH values. These figures show a
501 clear influence of the relative humidity on the retention of different elements in the altered layer. This
502 effect is particularly marked for Na and Mg. At a low RH (50%), the first 40% of the altered layer retains
503 only 10-20% of Na and Mg, whereas at 97% RH, Na is enriched in the altered layer and retention of Mg is
504 100%. The enrichment of Na and Mg towards the surface in the altered layer formed at 97% RH must be
505 due to their incorporation in phyllosilicates formed at the surface, since it was seen from the XRD
506 patterns that the intensity of the peak attributed to phyllosilicates increased with increasing RH. When it
507 comes to the elements Zr and Al, they are almost 100% retained in most of the altered layer for all RH
508 values except at 50% RH, where Zr is depleted up to 80% and Al is depleted up to 50% in the altered

509 layer near to the surface. Similarly, Nd is also significantly depleted only in the altered layer formed at
510 50% RH. It was earlier discussed that the depletion of transition metals and rare-earth elements in the
511 sample altered at 50% RH was similar to the depletion of these elements in the pristine samples (the first
512 10-20 nm). In case of Fe and Mn, they are depleted up to 90% in the altered layers formed at both 50%
513 RH and 76% RH, but almost fully retained in the altered layers formed at higher RH values. The behavior
514 of Ca is inverse to the all the other elements discussed above. In the altered layer formed at 50% RH, Ca
515 is almost 100% retained. In the altered layers formed at higher RH values, the retention of Ca is only
516 around 10% near the altered layer-glass interface but the enrichment increases towards the surface. The
517 normalized intensity is not 1 even at 100% of the altered layer, meaning that the depletion of Ca is more
518 profound than that of boron.

519 The reason for the influence of RH on the mobility of elements within the altered layer could be
520 related to the pH of the water film on the surface of glass exposed to relative humidity, since pH affects
521 the solubility of elements. The lower the RH, the lower the quantity of water adsorbed on glass surface
522 will be and consequently the pH may be higher. Here, hypotheses for migration mechanisms of these
523 elements have not been discussed. But one of the suggestions is that the migration of elements towards
524 surface may be facilitated by water condensation in gel porosity. It has already been discussed in earlier
525 work that it is very likely that water condenses in the pores of the altered layer formed in vapor phase as
526 well [8].

527 Looking at the possibility of variations in pH with changing relative humidity, it seems plausible
528 the rate-controlling mechanisms may also vary. However, at all four RH values, the $\text{pH}_{50^\circ\text{C}}$ values will still
529 be basic. Therefore, network-hydrolysis may still be the predominant rate-controlling mechanism at all
530 four RH values.

531 *Comparison of vapor hydration in different protocols*

532 The AVM6 sample in this study that was altered at 50°C and 97% RH for 1 year (experiment 6)
533 can be compared with the AVM6 samples that were altered at 50°C and 95% RH for 6 months and for 18
534 months which are described in the cited reference [8]. The AVM6 monolith samples were retrieved from
535 the same batch for both the studies. The difference between the study described in this work and the
536 study described in the reference is the alteration protocol (apart from the duration of alteration and the
537 slight variation in relative humidity). In this work, the AVM6 sample was vapor hydrated using a protocol
538 where the sample was placed in an air-tight container above a saturated K_2SO_4 solution to impose the
539 relative humidity. In the reference, the AVM6 sample was vapor hydrated in a WEISS WK64L climatic
540 chamber regulated at 50°C and 95% RH. Ideally, the glass alteration in both protocols must be similar

541 since the temperature and relative humidity are nearly the same. But, a few differences are noticeable
542 among the AVM6 samples altered in the two different protocols.

543 One of the remarkable differences lies in the ToF-SIMS profiles. In the ToF-SIMS profiles of the
544 two samples altered in the climatic chamber, a layer of phyllosilicates of 250-350 nm thickness is
545 distinguishable from the ToF-SIMS profiles through the behavior of all the elements including transition
546 metals and rare-earth elements in the AVM6 glass.

547 In case of the sample altered in this study, a phyllosilicate layer of around 200 nm can be
548 distinguished from the ToF-SIMS profiles through the profiles of the elements H, Na, Mg, Li and other
549 alkali and alkaline-earth elements. However, aluminum, transition metals and rare-earth elements do
550 not seem to be mobile at all. This could mean that the Si/X (where X is Al, a transition metal or rare-earth
551 element) ratio in the gel layer, phyllosilicate layer and the pristine glass is the same for the sample
552 altered in this study. The interface between the altered-layer and pristine glass is also different between
553 the two samples altered in the climatic chamber and the samples in this study. The thickness of the
554 altered layer measured using the boron ToF-SIMS profile in the sample altered in the climatic chamber
555 for 6 months is 1060 nm, whereas the thickness measured on the sample altered in this study for 1 year
556 is 541 nm. It is to be kept in mind that in both cases, the altered layer could be heterogeneous with more
557 irregularly altered zones in one case than the other, explaining this variation in the overall altered layer
558 thickness. The other factor that could have played a role is the fluctuation in the RH experienced in this
559 study. However, this shows the necessity of in-depth analysis of altered layer morphology in case of the
560 vapor hydrated samples.

561 The XRD patterns of all samples altered in two different protocols show the same peak at 6° (2θ),
562 indicating the presence of an aluminosilicate incorporating Na, Mg and Fe. But, the sample altered in this
563 study had some additional peaks at 8° , 10° , 12° and 14° (2θ) indicating the presence of other
564 aluminosilicates, which were absent in the sample altered for a longer duration in the climatic chamber.

565 The differences in the samples due the different vapor hydration protocols used are not drastic,
566 but seem to have affected the nature of some of the secondary precipitates (and thus, the element
567 behavior in the altered layer) and the overall thickness of the altered layer.

568 5. Conclusion

569 The effect of temperature between 70°C and 90°C at 97% RH and relative humidity between 50%
570 RH and 97% RH at 50°C on the vapor hydration of the AVM6 glass was studied. It was revealed that the
571 altered layer morphology was similar at all temperatures (continuous gel layer of homogeneous
572 thickness along with intermittently present irregularly altered zones). However, the nature/identity of
573 the secondary phases and the behavior of the elements in the gel layer varied with temperature.
574 Therefore, it is likely that the rather particular altered layer morphology of the AVM6 glass is dependent
575 on the glass properties (could be inhomogeneity in glass composition) and not the nature of the
576 secondary phases. The rate of formation of the homogeneous gel layer seems to follow Arrhenius law for
577 temperature dependence in the ranges 50°C to 90°C. The value of the activation energy suggested that
578 network hydrolysis was the predominant rate-controlling mechanism in the studied range for the studied
579 duration, likely due to high pH values of the water film. Similar to the temperature effect, changing
580 relative humidity too resulted in differences in some of the precipitated secondary phases and the
581 nature of the altered layer. XRD patterns suggest that secondary phases incorporating rare-earth
582 elements and transition metals (which are inactive simulants for radioactive actinides and fission
583 products in nuclear waste) precipitate at the sample surface only at low RH experiments. Their mobility
584 in the gel layer was also revealed to be high only at low RH experiments. This is rather a positive
585 information from the point of view of geological disposal scenario since the RH values expected in the
586 repository are close to saturation.

587 The results presented in this study show a few perspectives for future research. It is important
588 from the point of view of safety assessment of geological waste disposal to carry-out in-depth
589 characterization and stability/solubility studies of the radionuclide incorporating secondary phases that
590 may form under expected repository conditions. Since it seems that pH may play a crucial role in
591 determining the mobility of different elements in the altered layer, development of surface pH
592 measurement protocols using advanced techniques need to be envisaged. It would also be useful in
593 developing geochemical models to predict vapor hydration rates of different glass compositions. Vapor
594 hydration experiments as a function of time need to be carried out to verify that vapor hydration rate is
595 constant for the calculation of activation energy. Finally, the importance of comprehensive
596 morphological analysis of vapor hydrated glass surfaces needs to be emphasized.

597

598 **Acknowledgements**

599 We would like to thank Jean-Pierre Mestre (CEA) and Marie Fenart (CEA) for the SEM images, Myriam
600 Chartier (CEA) for XRD patterns, Laurent Dupuy and Elodie Chauvet (TESCAN Analytics) for the ToF-SIMS
601 profiles. This study was supported by CEA and EDF (Electricité de France). We would like to particularly
602 thank Florent Tocino and H el ene Schneider (EDF) for their support.

603 **Data Availability**

604 The SEM data supporting the findings are available within the article and the supplementary information.
605 The processed data of ToF-SIMS and XRD are also available within the article and supplementary
606 information. The raw data of the ToF-SIMS and XRD can be shared by the corresponding author upon
607 reasonable request.

Tables

Table 1

Table 1 Composition of AVM6 glass in mol% oxides

Oxides	mol%	Oxides	mol%	Oxides	mol%
SiO ₂	49.29	NiO	0.27	TeO ₂	0.01
Al ₂ O ₃	5.88	Cr ₂ O ₃	0.20	Cs ₂ O	0.03
B ₂ O ₃	18.64	P ₂ O ₅	0.00	BaO	0.03
Na ₂ O	16.65	SrO	0.03	La ₂ O ₃	0.02
CaO	0.24	Y ₂ O ₃	0.01	Ce ₂ O ₃	0.02
MgO	6.28	MoO ₃	0.13	Pr ₂ O ₃	0.01
Li ₂ O	0.89	MnO	0.05	Nd ₂ O ₃	0.04
ZrO ₂	0.10	Ag ₂ O	0.01	RuO ₂	0.08
Fe ₂ O ₃	0.79	CdO	0.26	PdO	0.05

Table 2

Table 2 Summary of experiments that were performed

Experiment No	Parameter studied	Temperature, °C	Relative humidity, %
1	Effect of Temperature	70	97
2		90	97
3	Effect of relative humidity	50	50±10
4		50	76±1
5		50	88±6
6		50	97±3

Table 3

Table 3 Thickness of the gel layer formed during vapor hydration of AVM6 glass at 70°C and 90°C at 97% RH for 1 year; (The ToF-SIMS thicknesses are based on the depth of boron depletion calculated from equation 2.2.2)

Experiment No		Thickness (SEM), nm	Thickness (ToF-SIMS), nm
1	AVM6- 70°C	300	390
2	AVM6- 90°C	1000	1050

Table 4

Table 4 Thickness of the diffusion of hydrogen into the surface of the altered glass, thickness of boron depletion (gel layer thickness) and the diffusion coefficient calculated from the thickness of hydrogen diffusion for the AVM6 glass altered in vapor phase at 50°C and x% relative humidity for 1 year . The given values are measured from ToF-SIMS profiles normalized with respect to pristine glass and Si intensity. The uncertainties associated cannot be calculated as explained in section 2.2

Experiment No	Relative humidity, %	Thickness (hydrogen), nm	Thickness (boron), nm	Diffusion coefficient, m ² /s
3	50	31	27	2.39x10 ⁻²³
4	76	200	190	9.96x10 ⁻²²
5	88	129	124	4.14x10 ⁻²²
6	97	620	541	9.57x10 ⁻²¹

Table 5

Table 5 Calculated vapor hydration rates (r_h) used to study if the temperature dependence of the vapor hydration rates follows Arrhenius law; The experiments were carried out for 1 year at 97%RH (for 70°C and 90°C) and 95%RH (for 50°C); (* calculated value)

Experiment No	Temperature, °C	Thickness of homogeneous gel layer after 1 year of vapor hydration, nm	Vapor hydration rate, g m ⁻² day (x10 ⁻³)
Data from literature [8]	50	60*	0.46
1	70	300	2.3
2	90	1000	7.67

Table 6

Table 6 Summary of secondary phases precipitated in all the six experiments based on the analysis by EVA software of the peaks in the XRD pattern

Experiment No	Peaks in XRD pattern (2theta)	Secondary phases
1	20°, 24.5° (?)	Alumino silicates/neosilicates/clay minerals (Chloritoid? Tosudite ?)
2	20°, 24.5°	Alumino silicates/neosilicates/clay minerals (Chloritoid? Tosudite ?)
3	6°	Aluminosilicate containing Na, Mg, Fe (Vermiculite? Montmorillonite?)
	10°, 19.2°	(Nd ₂ (CrO ₄) ₃ .7H ₂ O? or Pr ₂ (CrO ₄) ₃ .7H ₂ O?)
	15°	Sodium aluminosilicate hydrates?
	32°	NaCl
4	6°	Aluminosilicate containing Na, Mg, Fe (Vermiculite? Montmorillonite?)
	10°, 19.2°	(Nd ₂ (CrO ₄) ₃ .7H ₂ O? or Pr ₂ (CrO ₄) ₃ .7H ₂ O?)
	15°	Sodium aluminosilicate hydrates?
	32°	NaCl
5	6°	Aluminosilicate containing Na, Mg, Fe (Vermiculite? Montmorillonite?)
	8°, 10°, 12°, 14°	Sodium aluminosilicates / zeolites (Mordenite? Stellerite?)
6	6°	Aluminosilicate containing Na, Mg, Fe (Vermiculite? Montmorillonite?)
	8°, 10°, 12°, 14°	Sodium aluminosilicates / zeolites (Mordenite? Stellerite?)

Note for table 6: All AVM6 glasses contain peaks at approximately 28°, 35°, 40° and 54° due to the presence of platinumoids (RuO₂) in the pristine glass. The secondary phases have been identified by analysis of XRD patterns using EVA software. The question marks have been added to indicate that these are possibilities and a more thorough analysis would be required to confirm their presence. ^(?)The peaks seem to be present after background subtraction.

Figures

Figure 1

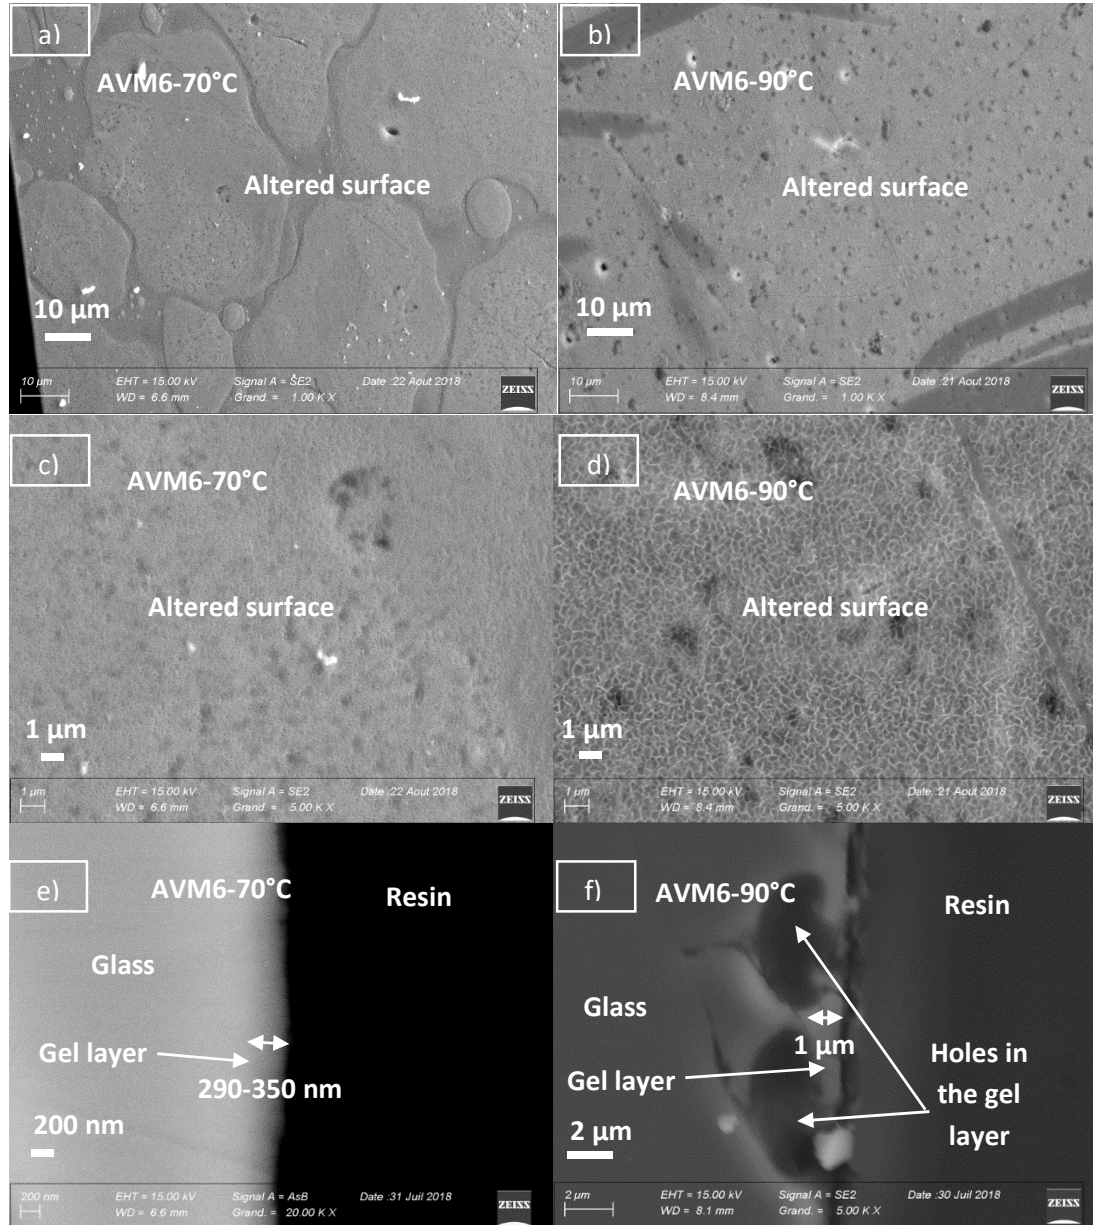

Figure 1 SEM images of AVM6 glass altered in vapor phase at 70°C (left- a, c, e) and 90°C (right- b, d, f) and 97% RH for 1 year. The top and middle images are direct observations of the altered surface while the bottom images show the cross-sections of the altered samples

Figure 2

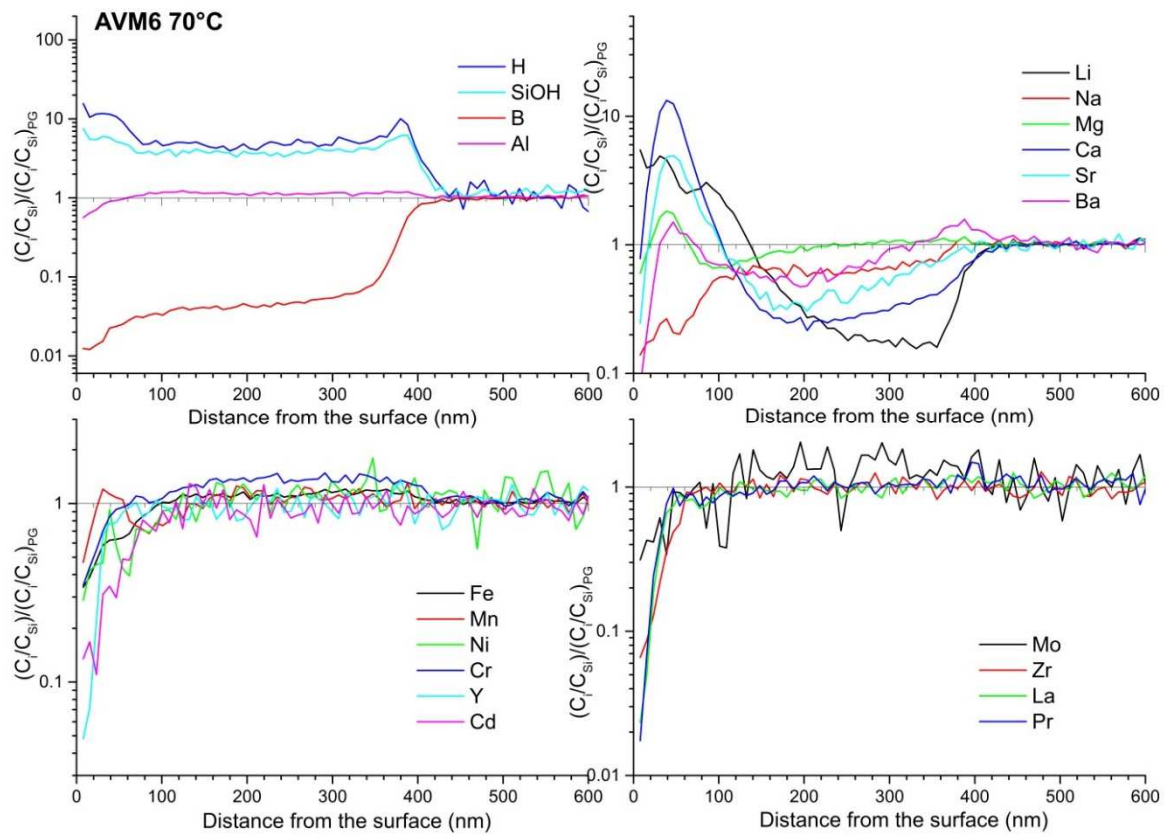

Figure 2 ToF-SIMS profiles (normalized with respect to the intensity of Si and pristine glass) for the glass AVM6 altered in vapor phase at 70°C and 97% RH for 1 year

Figure 3

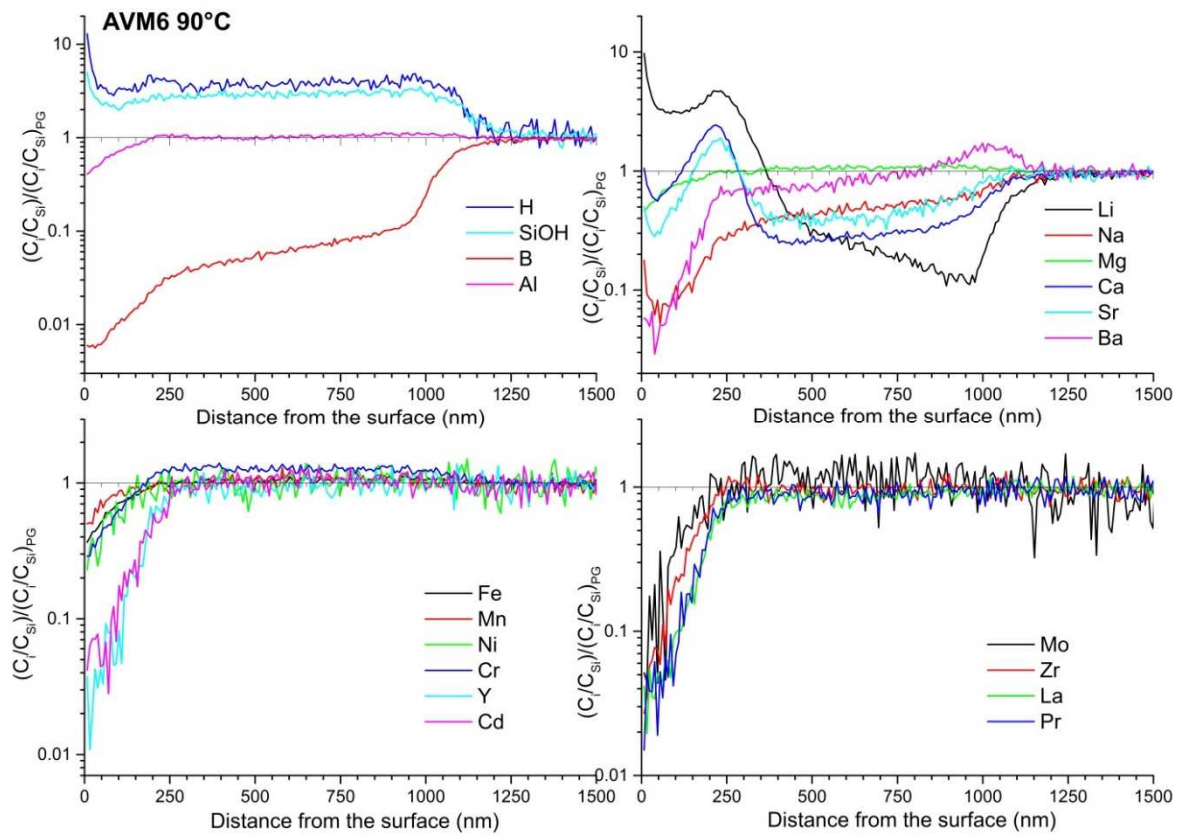

Figure 3 ToF-SIMS profiles (normalized with respect to the intensity of Si and pristine glass) for the glass AVM6 altered in vapor phase at 90°C and 97% RH for 1 year

Figure 4

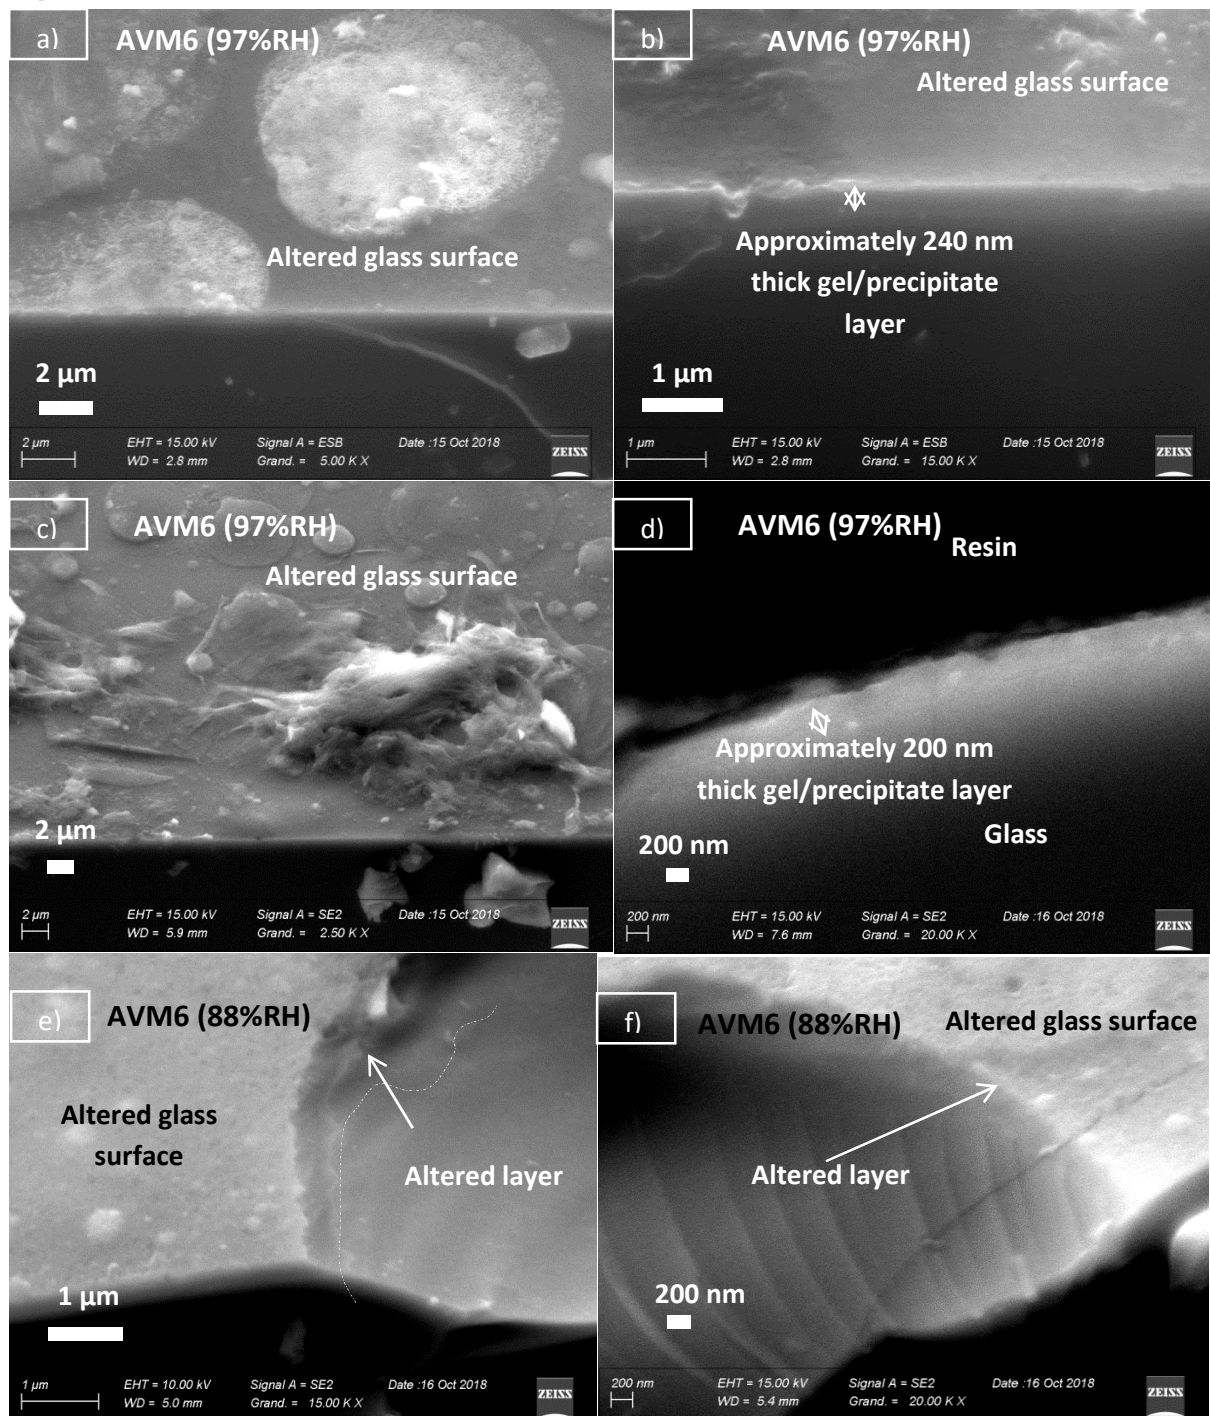

Figure 4 SEM images of AVM6 glass altered at 50°C and 97% RH (a, b, c and d) and 88% RH (e and f). The d image is a cross-section of the AVM6 sample altered at 97% RH. The remaining images are a direct observation of the altered sample

Figure 5

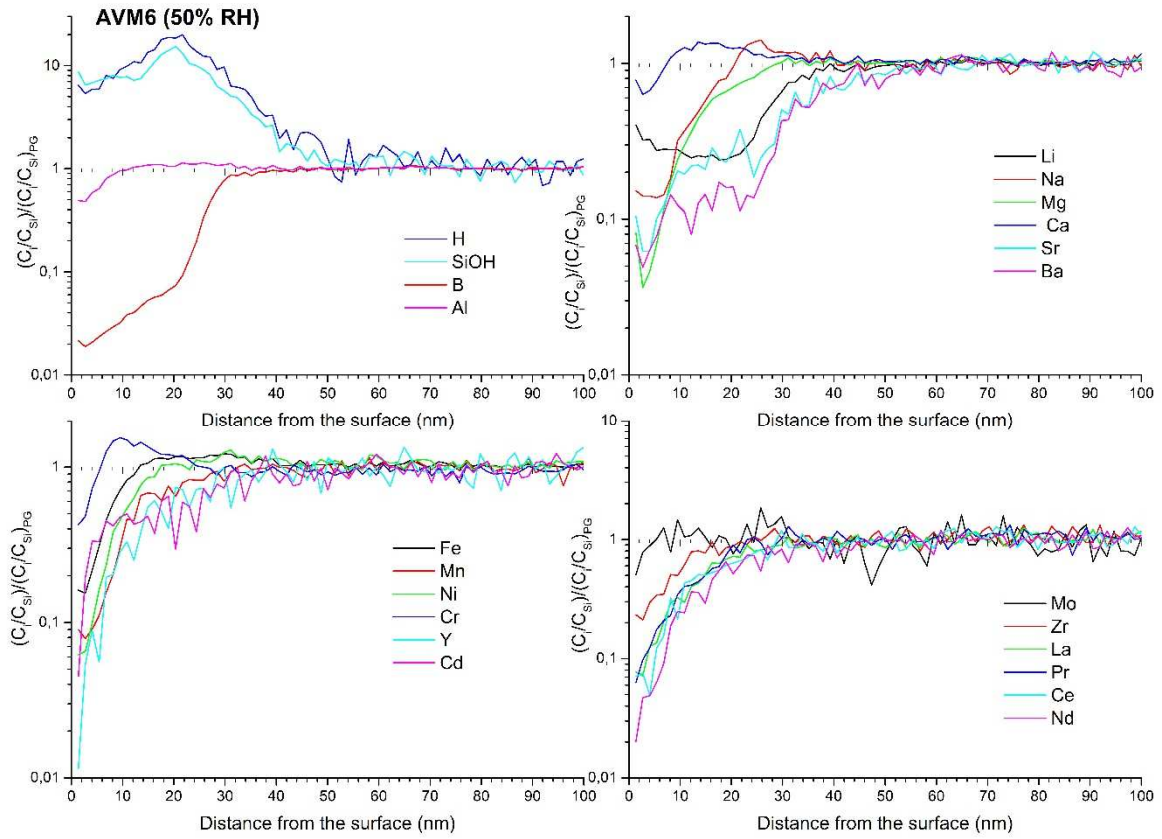

Figure 5 ToF-SIMS profiles (normalized with respect to the intensity of Si and pristine glass) for the glass AVM6 altered in vapor phase at 50°C and 50% RH for 1 year

Figure 6
