15 **Abstract**

16
17 Structural observations were carried out on particles obtained after hydrogenation cycling of
18 the Ti₂₅V₅₀Cr₂₅ and Ti₁₀V₇₅Cr₁₅ alloys processed by surface or bulk severe plastic deformation
19 using the surface mechanical attrition treatment (SMAT) and high-pressure torsion (HPT)
20 techniques, respectively. The produced particles differ in morphologies and fracture mode due
21 to the differences in hydrogen diffusion paths. The fracture mode for the SMAT-processed
22 samples with the gradient microstructure was mainly intragranular, whereas it was
23 intergranular for the nanograined HPT processed samples. Hydrogen diffusion, which
24 initiated at the grain boundaries on the surface, created Ti-rich and V-lean areas. The powders
25 contained mainly β -VH monohydride and partly γ -VH₂ dihydride, and an orientation
26 relationship of (100) _{β} // (110) _{γ} and [001] _{β} // [001] _{γ} with an angular deviation of $\sim 2.5^\circ$ was
27 observed between the two phases using the electron backscattered diffraction (EBSD)
28 analysis.

1 **1. Introduction**

2
3 The use of hydrogen as a fuel (associated with oxygen) represents a promising and
4 sustainable approach for energy production. However, its use remains challenging considering
5 its needs to be stored safely and compactly at room temperature. Nowadays, hydrogen is
6 employed rather as a gas, requiring special tanks under high pressure, or as liquid needing a
7 very low temperature storage (-252 °C), which is incompatible with an everyday use design
8 [1].

9 Another possible approach consists of storing hydrogen in solid matrices using
10 reversible reactions between solid metals and hydrogen through the formation of metal
11 hydrides [2,3]. Several materials like Mg-based [4,5] or TiFe [6,7] alloys have demonstrated
12 the feasibility of such an approach. Among these materials stand also the Ti-V-based alloys
13 [8–11] which present the advantages to have a high volumetric storage capacity [12,13]
14 associated with the ability to absorb and desorb the hydrogen at room temperature [12,14].
15 However, these alloys suffer from two main drawbacks: i) they require an initial high-
16 temperature thermal activation and ii) they present slow diffusion kinetics.

17 Different methods have been proposed to overcome these kinetic drawbacks like
18 matrix doping [15,16], alloying substitution [17,18] or microstructural lattice defect creation
19 [19,20]. The latter method involves the use of structural defects (grain boundaries,
20 dislocations, vacancies ...) as short circuits for the hydrogen diffusion. In a recent work, the
21 current authors [21] compared the effect of severe plastic deformation (SPD) carried out on i)
22 bulk sample by high-pressure torsion (HPT) method [22,23] and ii) the surface by surface
23 mechanical attrition treatment (SMAT) method [24,25] on the hydrogen storage kinetics of
24 $Ti_{10}V_{75}Cr_{15}$ and $Ti_{25}V_{50}Cr_{25}$ alloys. The results showed that both processing routes led to the
25 activation of the matrix at room temperature with a hydrogen absorption up to ~4 wt%.
26 However, the bulk nanostructured samples heavily deformed by HPT, which easily stored

1 hydrogen, did not show any desorption. Comparatively, the materials processed by SMAT
2 and having a gradient microstructure could reversibly absorb and desorb hydrogen. This
3 apparently surprising behaviour was rather consistent with the results of Couillaud et al. [26]
4 who have showed that the lattice defects can hinder the hydrogen desorption of a $\text{TiV}_{1.6}\text{Mn}_{0.4}$
5 alloy severely deformed by ball milling.

6 The reason for these opposite trends between the two types of materials processed by
7 HPT and SMAT was not clear and, in general, there is a wide lack of understanding on the
8 contributions of different structural defects on the i) hydrogen absorption/diffusion, and ii)
9 hydrogen trapping/releasing. Therefore, the aim of the present contribution is to carry out
10 post-mortem observations of the SMAT- and HPT-processed materials, after their
11 hydrogenation, in order to gain some new insights on the effect of different structural defects
12 on the hydrogen storage behaviours.

13

14 **2. Material and experimental techniques**

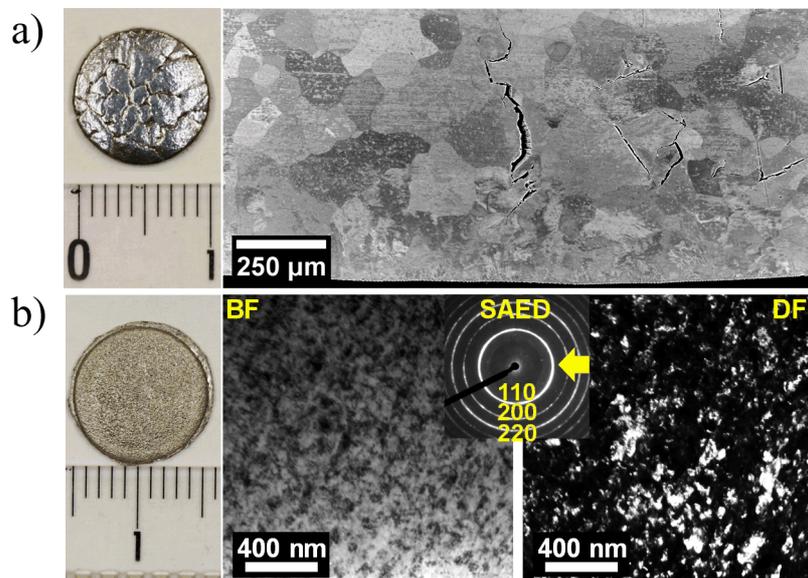

15

16 Two vanadium-based alloys were used in this study: $\text{Ti}_{10}\text{V}_{75}\text{Cr}_{15}$ and $\text{Ti}_{25}\text{V}_{50}\text{Cr}_{25}$. They
17 were prepared by arc melting under an argon inert atmosphere within a water-cooled copper
18 mold leading to a microstructure with a grain size in the range of 50-500 μm . No additional
19 heat treatment was applied on the elaborated ingots. Then, 10 mm diameter discs were cut by
20 electric discharge and mechanically polished to a thickness of 0.8 mm.

21 The microstructures were modified, in very different ways, by two different SPD
22 processing techniques. For the first type of modification, gradient microstructures were
23 produced by the SMAT process using 2 mm diameter AISI 52100 steel medias to shot-peened
24 the surface. The sample surfaces were treated during 480 s with a vibrating amplitude of 60
25 μm and a frequency of 20 kHz using a Stressonic device developed by Sonats [27]. For the

1 second modification, the bulk-nanograined samples were produced by HPT process using a
2 hydrostatic pressure of 6 GPa and 100 turns (rotation speed: 1 rpm) at room temperature.

3 These two processing techniques lead to different microstructures which are recalled in
4 Figure 1 (additional details can be found in [21]). TEM images were selected to describe the
5 HPT-processed sample due to its very fine nanostructure. The surface deformation induced by
6 the SMAT leads to the creation of a nanostructure along the first microns of the extreme
7 surface associated to a strain gradient towards the sample core [28] (Figure 1a). In addition
8 (as will be discussed afterwards), numerous cracks were generated due to the brittleness of the
9 V-based samples (see close-view). In comparison, the HPT bulk process generates a
10 nanostructure (Figure 1b) having grain sizes of 30-40 nm in the whole sample that was free
11 from any cracks (see close-view), thanks to the applied hydrostatic pressure during shear
12 deformation.

14 **Figure 1** $Ti_{10}V_{75}Cr_{15}$ macroscopic views and associated microstructures before
15 hydrogenation for a) the SMAT- (SEM) and b) HPT-processed (TEM) samples.
16

17 The materials after processing by SMAT and HPT were hydrogenated and
18 dehydrogenated for two cycles at 303 K and one cycle at 353 K to achieve pressure-
19 composition-temperature (PCT) isotherms, as described in details in an earlier paper [21]. The

1 materials after the third hydrogen storage cycle were in the form of pulverized particles.
 2 Indeed, because of the hydrogen storage cycles, the initially large samples fracture into
 3 powder particles. In order to make the reading more convenient, the particles produced by the
 4 repeated hydrogenation of the SMAT- and HPT-processed samples will be called in the
 5 following text "SMAT particles" and "HPT particles", respectively.

6 The characterization of morphological aspect of the cycled particles as well as their inner
 7 structure viewed on polished surfaces were both done on a Zeiss Supra 40 scanning electron
 8 microscope (SEM). A secondary electron (SE) contrast and a back-scattered electron (BSE)
 9 contrast were used for the morphological and cross-section observations, respectively. Energy
 10 dispersive spectroscopy (EDX) quantifications were carried under a tension of 20 kV (10^6
 11 counts were required to stop the measurements). The electron backscattered diffraction
 12 (EBSD) acquisition was done using a tension of 20 kV (12 bands were required for pattern
 13 indexation) and then post-treated using the ATEX (Analysis Tools for Electron and X-ray
 14 Diffraction) software [29].

15 3. Results

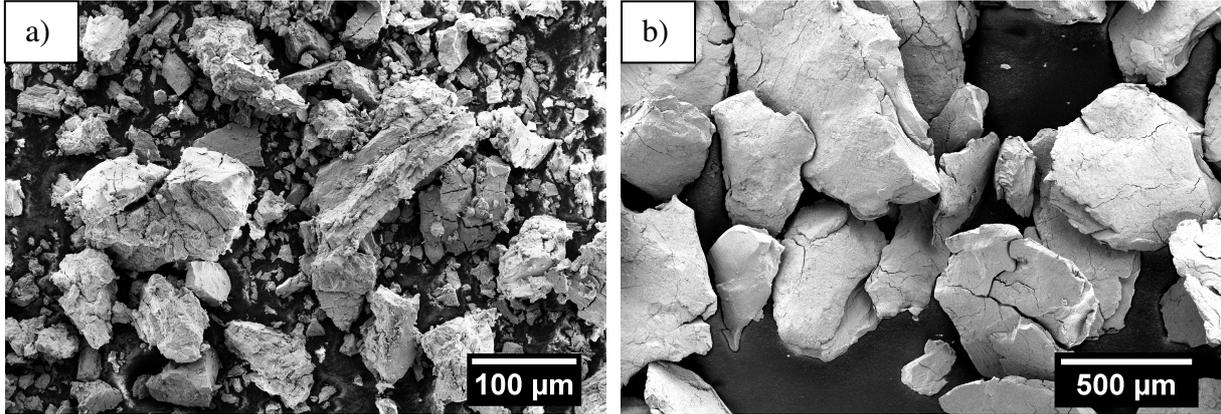

16 3.1 Particle size and morphology

17
 18 Table 1 gives the major features revealed for the two alloys and different processing
 19 techniques (HPT and SMAT) in terms of particle sizes and morphological aspects.

20
 21
 22 **Table 1** Average particles sizes of hydrogenated $Ti_{10}V_{75}Cr_{15}$ and $Ti_{25}V_{50}Cr_{25}$ alloys after
 23 processing by SMAT and HPT.

	SMAT	HPT
$Ti_{10}V_{75}Cr_{15}$	Bimodal 10 μm + 130 μm Sharp edges	900 μm Smooth edges
$Ti_{25}V_{50}Cr_{25}$	Bimodal 10 μm + 325 μm Sharp edges	410 μm Smooth edges

As an example, the particles obtained after hydrogenation of the $Ti_{10}V_{75}Cr_{15}$ alloy are presented in Figures 2a and b for the SMAT and HPT particles, respectively. Two populations of particles are visible for the SMAT particles, one with very small sizes of about $10\ \mu m$ and another one with much larger sizes (Figure 2a). These large SMAT particles have a mean size of $130\ \mu m$ and possess sharp edges. Comparatively, the HPT particles (Figure 2b) are much bigger in size with a mean value of about $900\ \mu m$. Additionally, their shapes are smooth with less fragments than the ones obtained on the SMAT particles (Figure 2a).

Concerning the particles coming from the hydrogenation of the $Ti_{25}V_{50}Cr_{25}$ alloy, the trend is the same as the $Ti_{10}V_{75}Cr_{15}$ alloy: finer particles are generated after hydrogenation of the SMAT-processed sample having also a bimodal distribution. However, the difference in particles size is less pronounced compared with the $Ti_{10}V_{75}Cr_{15}$ alloy: mean sizes of $325\ \mu m$ and $410\ \mu m$ were measured for the SMAT and HPT particles, respectively.

18

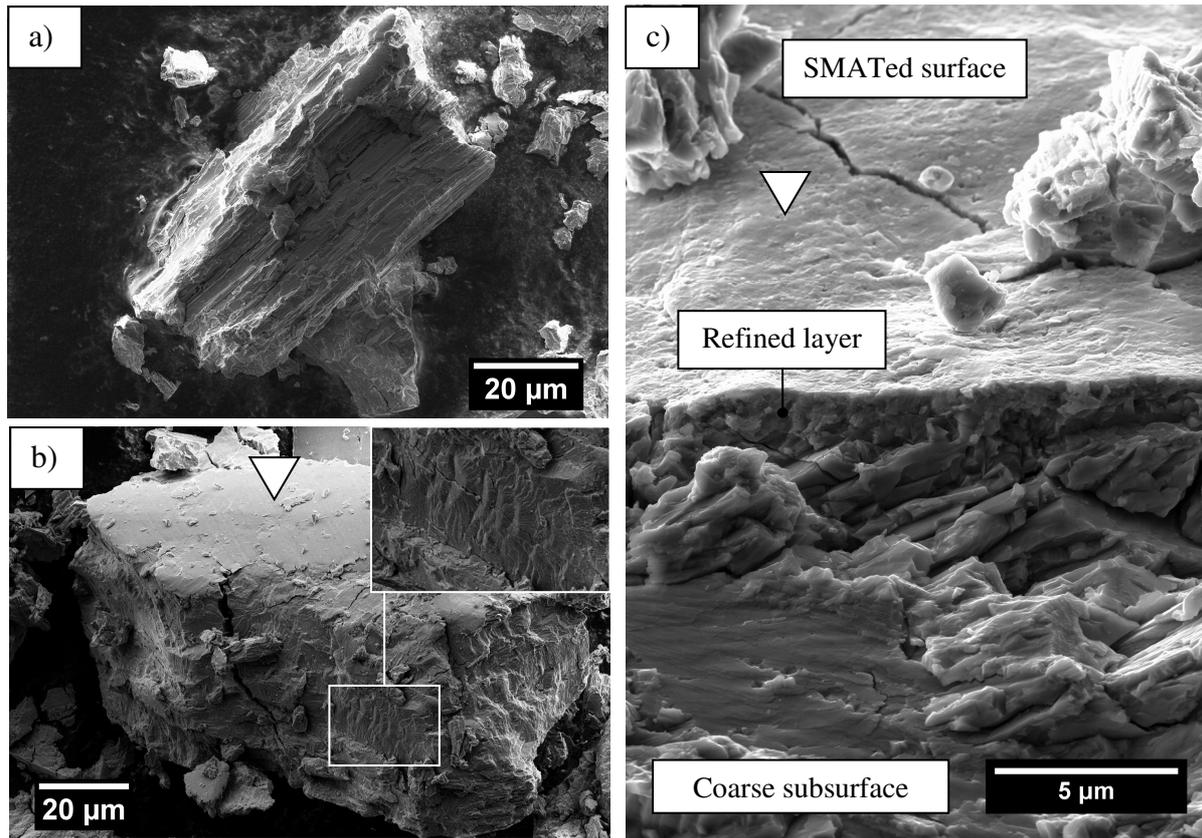

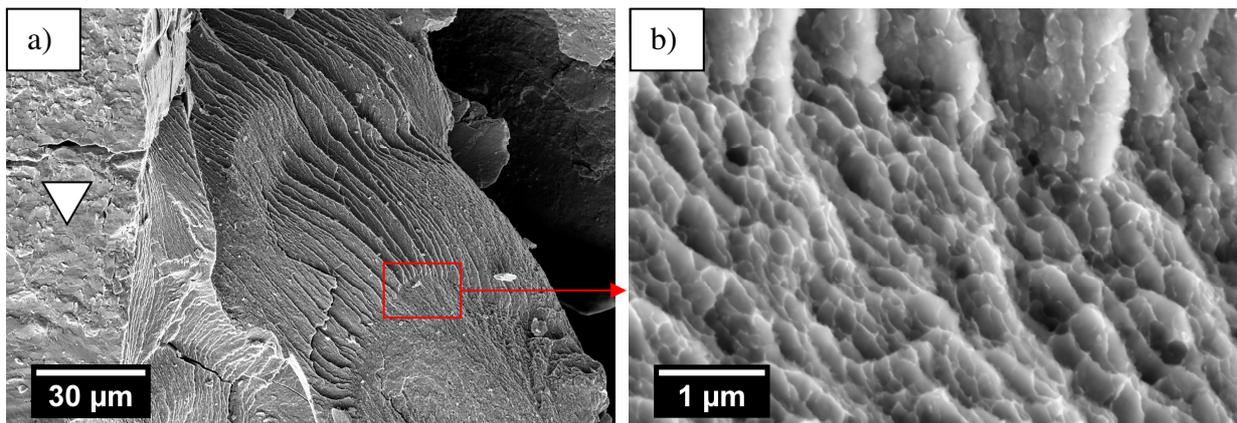

Figure 3 SE contrast SEM observations of the particles obtained on the hydrogenated $\text{Ti}_{10}\text{V}_{75}\text{Cr}_{15}$ after processing by SMAT.

Close-views of the particles coming from hydrogenation of SMAT- and HPT-processed $\text{Ti}_{10}\text{V}_{75}\text{Cr}_{15}$ alloy can be seen in Figures 3 and 4, respectively. Large flat surfaces, that are the external surfaces of the initial disc samples, are marked by white triangles in Figures 3 and 4. The particle in Figure 3a possesses sharp facets which were associated with a brittle fracture. The other particle in Figure 3b also possessed brittle fracture surfaces below the initial surface that is marked with a white triangle in Figure 3b. The close view in the inset of Figure 3b shows a crack path characterized by a crack parallel to the initial surface which has generated several semi-hemispherical stress-concentration sites. This indicates that the crack did not propagate continuously but, instead, was stopped several times during its propagation.

Figure 3c shows a higher magnification SEM image taken directly at the surface that was previously peened by the SMAT process. This surface, on the upper side and marked

1 with a triangle, could be recognized easily by its undulated aspect generated by the shot
2 impacts. The refined layer generated by the SMAT is clearly visible along the first few
3 microns under the treated surface and is followed by a coarser structure. It is interesting to
4 note that this gradient structure is not as pronounced as the gradient structure generally
5 observed after SMAT of ductile materials such as Al [30], Cu [31,32] or austenitic stainless
6 steel [33–36]. This is because of the brittle nature of the Ti-V-Cr alloys.

7
8 **Figure 4** SE contrast SEM observations of the particles obtained on the HPT-processed
9 $\text{Ti}_{10}\text{V}_{75}\text{Cr}_{15}$ sample.

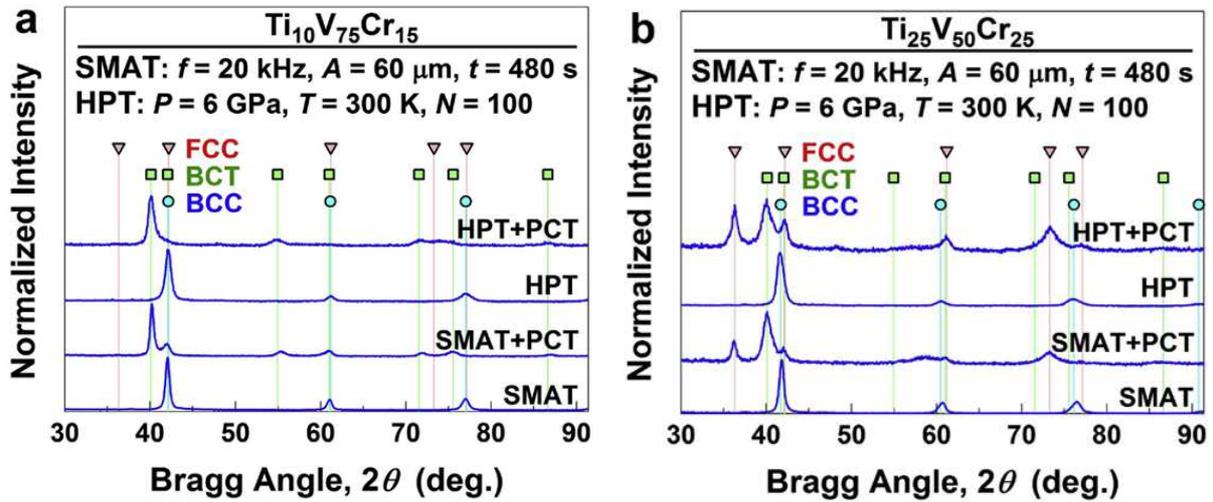

10
11 Detailed views of an HPT particle are presented in Figure 4 for the $\text{Ti}_{10}\text{V}_{75}\text{Cr}_{15}$ alloy.
12 The observed features differ significantly from the ones observed on the SMAT particles. The
13 nanostructure generated by the HPT process before hydrogenation is clearly visible in the
14 close-view in Figure 4b. The ultrafine grains produced under the HPT processing are
15 surrounded by a different type of contrast along the grain boundaries. As grain boundaries are
16 known to be shortcuts for diffusion, it is likely that this contrast witnesses hydrogen diffusion
17 along the grain boundaries where the "brittle" fracture subsequently took place.

18 As seen in the upper part of the image in Figure 4a, a particular structure containing
19 numerous elongated features is visible. It suggests a hydrogen-induced cleavage propagation
20 along the shear direction previously generated during the HPT processing. These structures
21 are indeed thought to be induced by the hydrogen paths created during hydrogen diffusion
22 that are, possibly, driven by some local strain heterogeneities [37].

Figure 5 presents the XRD diffraction patterns obtained before and after hydrogenation/dehydrogenation cycling of the $\text{Ti}_{10}\text{V}_{75}\text{Cr}_{15}$ (Figure 5a) and $\text{Ti}_{25}\text{V}_{50}\text{Cr}_{25}$ (Figure 5b) alloys for both the SMAT- and HPT-processed samples. Initially, both alloys were characterized by a fully body-centred cubic (BCC) structure and no phase transformation was detected by XRD neither for the SMAT- nor the HPT-processed samples despite the severity of the deformation. As a reminder, the hydrogen absorption presents two steps in the V-based alloys: i) the creation of a stable VH monohydride with the body-centred tetragonal (BCT) structure at low-pressure levels (~ 0.1 Pa) followed by the formation of a less-stable VH_2 dihydride with the face-centred cubic (FCC) structure at higher pressures (~ 0.1 MPa).

16

17

18

19

20

21

22

23

24

25

After hydrogenation of the $\text{Ti}_{10}\text{V}_{75}\text{Cr}_{15}$ alloy, only the β -VH (BCT) phase was mainly detected in the SMAT and HPT particles, but small amounts of BCC and FCC phases are also present (Figure 5a). Taking into account the PCT behaviours published previously [21] and keeping in mind that two types of deformation processes were used, this analysis outlines 2 different phenomena. For the SMAT-processed sample, the β -VH (BCT) hydride absorbs the

1 hydrogen to form the γ -VH₂ (FCC) which, thereafter, desorbs the hydrogen. The β -VH (BCT)
2 hydride remains active during further cycling for β -VH (BCT) to γ -VH₂ (FCC) transition.
3 However, for the HPT-processed sample, despite initial activation, the β -VH (BCT) hydride is
4 deactivated in the following cycles and cannot further store the hydrogen. As discussed in this
5 manuscript, the reason for deactivation of β -VH (BCT) phase in HPT-processed sample is due
6 to the presence of large fraction of lattice defects and grain boundaries which hinder the
7 hydrogen reversion.

8 Comparatively, both the BCT and FCC hydrides were indexed for the Ti₂₅V₅₀Cr₂₅
9 samples in Figure 5b. Thus, the γ -VH₂ (FCC) \rightarrow β -VH (BCT) was not completely induced in
10 this alloy to desorb the hydrogen. However, the FCC hydride (111) peak is more intense for
11 the HPT particles than the one measured on the SMAT particles which indicates a higher
12 proportion of remaining γ -VH₂ hydrides in the HPT particles.

13 The presence of three BCC, BCT and FCC phases in Figure 5, especially for the
14 Ti₂₅V₅₀Cr₂₅ alloy, is probably due to the kinetics of hydrogen absorption and desorption.
15 Indeed, since the Ti₂₅V₅₀Cr₂₅ alloy has a lower plateau pressure than the Ti₁₀V₇₅Cr₁₅ alloy, the
16 co-existence of three phases in this alloy is more significant as there is less driving force for
17 dehydrogenation in this alloy.

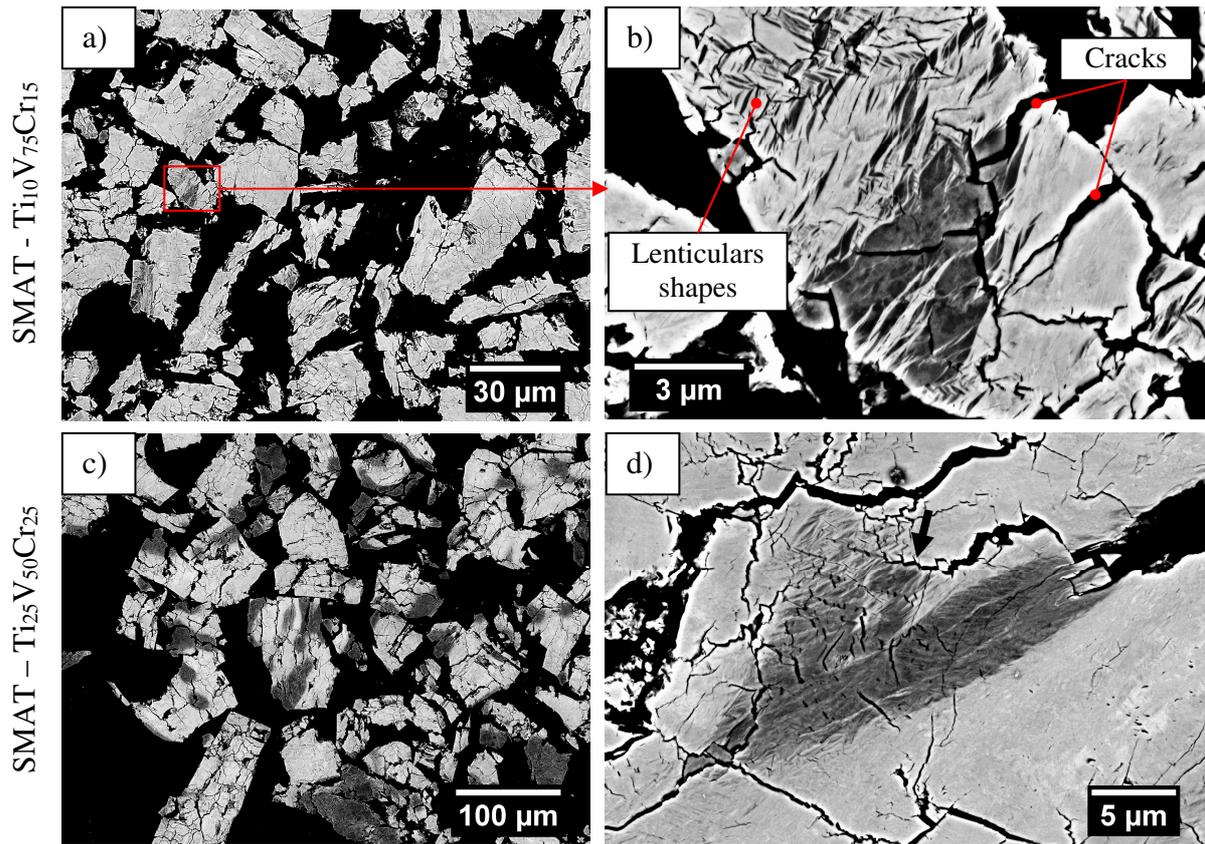

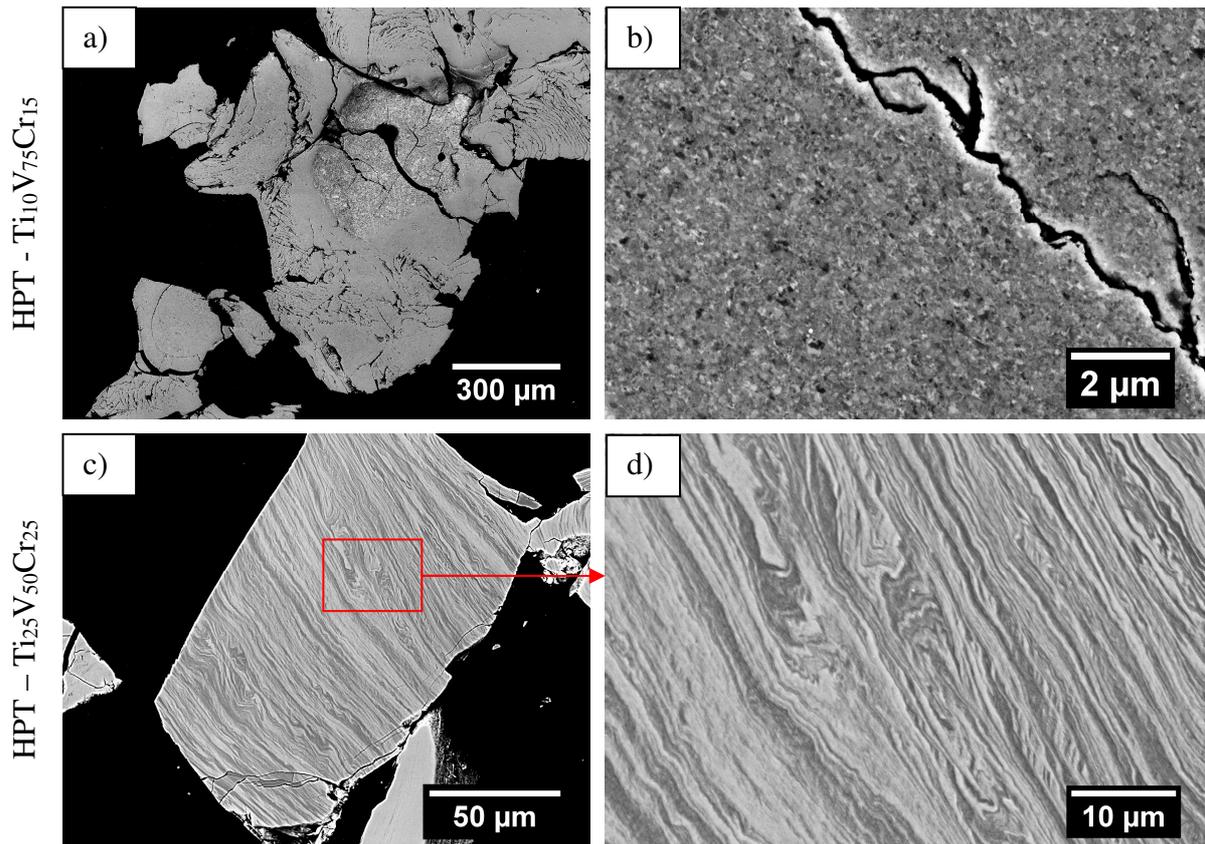

Figure 6 BSE contrast SEM observations of the cross section of SMAT-processed (a-b) $\text{Ti}_{10}\text{V}_{75}\text{Cr}_{15}$ and (c-d) $\text{Ti}_{25}\text{V}_{50}\text{Cr}_{25}$ alloys after hydrogenation.

In order to gain more insights in the inner structures of the cycled particles, SEM observations were carried out on polished cross-sections (Figure 6 and 7). Figure 6a and c shows a general view of the SMAT particles coming from the $\text{Ti}_{10}\text{V}_{75}\text{Cr}_{15}$ and $\text{Ti}_{25}\text{V}_{50}\text{Cr}_{25}$ alloys, respectively. Numerous inner cracks that fragmented the particles can be seen in both alloys. In addition, a very sharp grey contrast can be depicted especially in the $\text{Ti}_{25}\text{V}_{50}\text{Cr}_{25}$ sample (Figure 6c). This contrast consists, for both alloys, in an intricate lenticular aspect, as it can be better seen in the $\text{Ti}_{10}\text{V}_{75}\text{Cr}_{15}$ sample (Figure 6b). Additionally, a particular crack propagation pathway can be seen in Figure 6d, as indicated by a black arrow. This pathway describes a step-by-step crack propagation reflecting that the crack stopped and re-propagated several times during the hydrogenation cycling process.

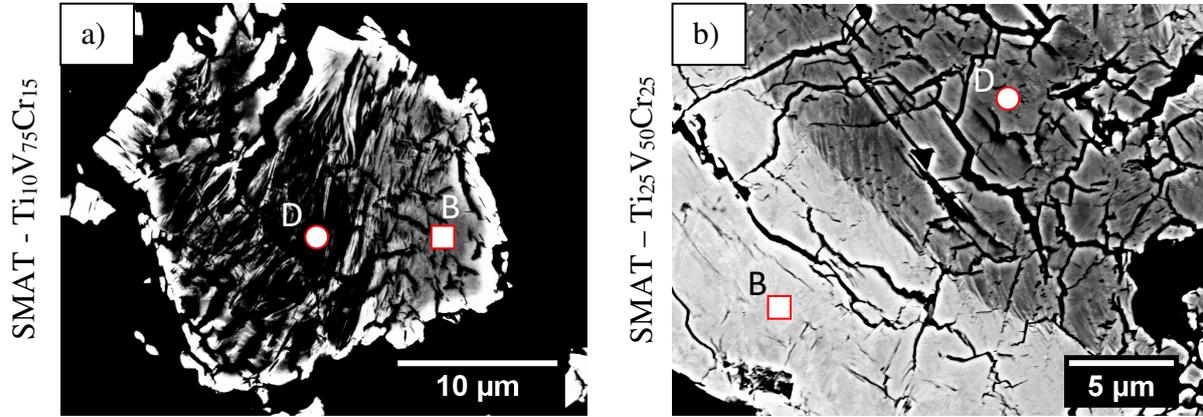

1
2 **Figure 7** BSE contrast SEM observations of the cross section of HPT-processed (a-b)
3 $Ti_{10}V_{75}Cr_{15}$ and (c-d) $Ti_{25}V_{50}Cr_{25}$ alloys after hydrogenation.
4

5 Figure 7 shows the inner structures of HPT particles coming from hydrogenation of
6 $Ti_{10}V_{75}Cr_{15}$ (Figures 7a and b) and $Ti_{25}V_{50}Cr_{25}$ (Figures 7c and d) alloys. The density of inner
7 cracks was much lower than that of the SMAT particles. No sharp contrast was observed on
8 the $Ti_{10}V_{75}Cr_{15}$ sample (Figure 7a) and only the crystallographic orientation coming from the
9 nanostructure generated by the HPT treatment was visible all over the particle cross-sections
10 (Figure 7b). The absence of bright/dark zones is likely due to the fact that this alloy was
11 essentially single phase after the hydrogen storage process (HPT+PCT in Figure 5a).
12 However, the HPT-processed $Ti_{25}V_{50}Cr_{25}$ alloy presented a substantial chemical contrast after
13 hydrogenation (Figure 7c) characterized by elongated domains. Here, the elongated contrast
14 describes a band-like structure, probably an aspect inherited from the shear strain and/or

1 hydrogenation. Contrary to the SMAT particles, no lenticular features were observed on the
 2 HPT particles.

3

4

5 **Figure 8** BSE contrast SEM observations of the a) $Ti_{10}V_{75}Cr_{15}$ and b) $Ti_{25}V_{50}Cr_{25}$ alloys after
 6 processing by SMAT and hydrogenation. EDX quantifications are given in Table 2.

7

8 **Table 2** EDX quantifications carried out on the bright and dark zones of $Ti_{10}V_{75}Cr_{15}$ and
 9 $Ti_{25}V_{50}Cr_{25}$ alloys in Figure 7 after processing by SMAT and hydrogenation.

		Ti [at%]	V [at%]	Cr [at%]
$Ti_{10}V_{75}Cr_{15}$	Bright Zone	10.2	75.7	14.1
	Dark Zone	15.6	69.9	14.5
$Ti_{25}V_{50}Cr_{25}$	Bright Zone	25.4	50.3	24.3
	Dark Zone	35.9	42.0	22.1

10

11 EDX chemical analyses were carried out on two SMAT particles of the $Ti_{10}V_{75}Cr_{15}$
 12 (Figure 8a) and $Ti_{25}V_{50}Cr_{25}$ (Figure 8b) alloys. The rounded and squared shapes in the images
 13 represent the locations of the chemical acquisitions done on the dark and bright contrasted
 14 zones, respectively. The related EDX quantifications are given in Table 2. For both alloys, the
 15 bright zones – which were essentially featureless and did not contain lamellar structures -
 16 correspond fairly well to the initial alloy compositions. Comparatively, the dark zones –
 17 which were more heavily cracked and often presented the lenticular contrast - presented a
 18 higher fraction of titanium associated with a lower fraction of vanadium and a rather stable

1 fraction of chromium. Thus, because of these structural aspects, the Ti-rich and V-lean zones
2 must correspond to the zones that remained hydrided.

3

4

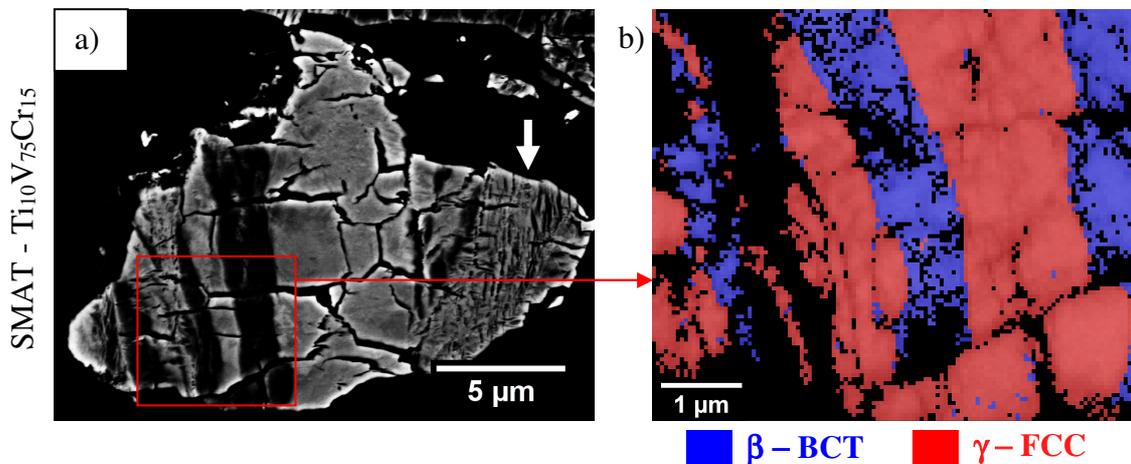

5 **Figure 9** (a) SE contrast SEM observations and associated EDX mapping with b) Ti and c) V
6 carried out on the Ti₂₅V₅₀Cr₂₅ alloy after processing by HPT and hydrogenation.

7

8 Figure 9 shows another EDX acquisition carried out on a Ti₂₅V₅₀Cr₂₅ HPT particle.

9 The successive elongated bright and dark zones which are visible in Figure 9a are also
10 characterized by chemical composition differences, as observed previously on a SMAT
11 particle in Figure 8. Regarding the alloying element maps (Figure 9b and c), the bands
12 alternate successively with elongated Ti-rich (dark zones) and V-rich (bright contrast) zones.

Further details were obtained by EBSD on the sharp contrast seen in the $\text{Ti}_{10}\text{V}_{75}\text{Cr}_{15}$ SMAT particle (Figure 10). Even though these particles gather several features impeding the indexation of EBSP (numerous cracks, high stresses ...), the lattice structures of the different zones were acquired without any problem and were best indexed as the β -BCT and γ -FCC structures. From these results, it is clear that the changes in chemistry in Figure 8 and Table 2 are related to the phase changes. The bright zones correspond to the BCT hydride whereas the dark zones correspond to the FCC hydride. Detailed analysis of the EBSD data has also revealed that the orientation relationship given by Wanagel et al. [38] as $(100)_{\beta} // (110)_{\gamma}$ and $[001]_{\beta} // [001]_{\gamma}$ is followed here with a mean deviation of $\sim 2.5^{\circ}$. This angular deviation is likely due to hydrogen diffusion and metastability of the FCC hydride. An EBSD acquisition was also carried out on the lenticular structures present on the right side of the particle in Figure 10 (white arrow) but no indexation was possible because of their small sizes and highly blurred Kikuchi's patterns that witnessed highly strained areas.

4. Discussion

The purpose of this study was to document the mechanisms taking place during the hydrogenation cycling of initial bulk samples with gradient microstructure and nanostructure processed by a surface (SMAT) or a bulk (HPT) SPD processes. The following discussion will be divided into two sections dealing with (i) the general aspects of the particles formed by the hydrogen-induced pulverization and (ii) the inner structure to get details on the hydrogen diffusion mechanisms.

4.1 Particle sizes and aspects generated after hydrogenation

1 Repeated hydrogenation of metallic samples led to fragmentation of the initially bulk
2 samples toward powder particles. This fragmentation mechanism is known as hydrogen
3 pulverization [39,40] which is governed by the repeated expansion/contraction of the lattice
4 volume induced by the hydrogen diffusion. Such a process is usually considered beneficial in
5 solid-state hydrogen storage studies because the fragmentation process increases the overall
6 interaction surface area and leads to fresh, non-oxidized new surfaces [41].

7 It was shown that the different Ti-V-Cr alloys and processing methods led to different
8 particle sizes (Table 1). Despite an initial coarse microstructure (Figure 1a), the SMAT-
9 processed samples generated a bimodal particle size with fine particles of about 10 μm and
10 larger particles of about 130 μm and 325 μm for the $\text{Ti}_{10}\text{V}_{75}\text{Cr}_{15}$ alloy and the $\text{Ti}_{25}\text{V}_{50}\text{Cr}_{25}$
11 alloys (Figure 2), respectively. Comparatively, the initial nanostructure (Figure 2a) of the
12 HPT-processed samples led to particle sizes of about 900 and 410 μm after exactly the same
13 number of hydrogenation cycles for the $\text{Ti}_{10}\text{V}_{75}\text{Cr}_{15}$ and the $\text{Ti}_{25}\text{V}_{50}\text{Cr}_{25}$ alloys (Figure 2b),
14 respectively. As the HPT-processed samples were able to absorb hydrogen efficiently but
15 unable to desorb it completely, this has led to coarser particles than those for the SMAT-
16 processed samples. Indeed, the SMAT-processed samples absorbed the hydrogen and
17 desorbed it for three cycles, leading to finer particles.

18 The particles coming from the two deformation treatments also showed completely
19 different morphologies. The SMAT particles possessed sharp edges with parallel lines
20 whereas the HPT particles possessed smooth faces with elongated cleavage structures parallel
21 to the shear strain direction taking place during HPT. Along these root-like structures, the
22 HPT particles exhibit smooth faces and a clear nanostructure as seen in Figure 4. This kind of
23 fracture faces was also observed by Hohenwarter et al. [42] on a pure vanadium sample
24 processed by HPT and interpreted as a micro-ductile fracture, leaving each nanograins visible.
25 The question whether the fracture is micro-ductile or has a brittle character is beyond the

1 scope of the present paper. However, it is clear that the hydrogen path was along the grain
2 boundaries in the HPT particles. Since the fracture in the HPT-processed samples occurring at
3 the boundaries of the ultrafine rounded and equiaxed grains, the surface aspects of the HPT
4 particles are overall rather smooth.

5 While it is clear that the pathway for hydrogen diffusion was along the grain
6 boundaries for the HPT-processed samples, it was essentially intragranular within the coarse-
7 grained core of the SMAT-processed samples. Indeed, as a mechanical surface treatment, the
8 SMAT generates a structural refinement at the treated extreme surface with a lot of grain
9 boundaries and plastic defects (Figure 1) promoting the hydrogen diffusion in the early stage
10 of the hydrogenation process. Then, the hydrogen moves towards the coarse grain subsurface
11 where the diffusion becomes essentially intragranular. This leads to the formation of straight
12 brittle fracture surface (Figure 3a). As proposed by Torres et al. [43] who studied the diffusion
13 of hydrogen in vanadium, this involves the formation of barrier which impedes the movement
14 of dislocations, leading to the formation of successive crack fronts, as it can be seen in the
15 close-view of Figure 3b and the particular crack path observed in Figure 6d.

16

17 **4.2 Particles inner structures**

18 Concerning the inner microstructure of the particles, bright and dark zones associated
19 to a two-phase mixture were observed in all powder particles except for the HPT-processed
20 $Ti_{10}V_{75}Cr_{15}$ alloy that was single phased after the PCT experiments (Figure 5a). The EBSD
21 acquisition map in Figure 10 for the $Ti_{10}V_{75}Cr_{15}$ SMAT particle revealed that the dark zones,
22 which were also characterized by different chemistry than the rest of the sample,
23 corresponded to the FCC VH_2 -dihydrides.

1 The FCC dihydride phase was revealed more clearly in the XRD diffractograms of the
2 $Ti_{25}V_{50}Cr_{25}$ alloy in addition to the BCT and small amount of initial BCC phase. The presence
3 of larger amount of FCC phase in this alloy is due to the higher stability of FCC phase in the
4 $Ti_{25}V_{50}Cr_{25}$ alloy compared with the $Ti_{10}V_{75}Cr_{15}$ alloy [21]. Additionally, a chemical
5 composition variation was measured between the two types of zone (Figure 8 and Table 2) in
6 which the dark zones of FCC VH_2 -dihydrides were Ti-rich and V-poor compared with the rest
7 of the material. It could have been considered that these zones were the result of chemical
8 heterogeneities that could build up during the casting of the initial materials. However, these
9 Ti-rich and V-lean alternate areas were also observed after hydrogenation of the $Ti_{25}V_{50}Cr_{25}$
10 HPT-processed alloy (Figure 7 and 9). As the HPT method is known to mix the alloying
11 elements under very high strain (especially by using large number of turns as 100) - as
12 observed for example on the Mg-based systems [44] - the presence of these heterogeneous
13 zones in the $Ti_{25}V_{50}Cr_{25}$ alloy after HPT processing and hydrogenation (Figure 7d) indicates
14 that the differences in chemistry are mainly related to the hydrogenation process. It is possible
15 that they have built up during the hydrogen storage process to facilitate the hydrogen
16 penetration.

17 For the SMAT-processed sample, hydrogen diffused first through the nanostructure
18 and cracks generated on the treated surface. Then, the hydrogen diffused within the coarse-
19 grained matrix to create large domains (Figure 6) of Ti-rich (V-lean) FCC hydrides (Figure 8),
20 as revealed by EBSD analysis in Figure 10. The presence and fraction of bright/dark zones
21 were reasonably consistent with the PCT measurements [21]. Indeed, the $Ti_{10}V_{75}Cr_{15}$ SMAT-
22 processed sample only had few dark zones (Figure 6a) due to the ability of this product to
23 desorb the hydrogen, leaving a small amount of FCC hydrides.

24 In the case of the HPT particles, the diffusion of hydrogen has been promoted along
25 the shear direction imposed during the SPD processing. This is clearly seen in the $Ti_{25}V_{50}Cr_{25}$

1 HPT particles in which the fine contrast of alternate hydrided Ti-rich (V-lean) and non-
2 hydrided domains is visible (Figure 9). When cracks propagate, this creates an elongated
3 structure (Figure 4a) that also stretches along the microscopic shear direction of the HPT
4 particles. This is believed to be related to local strain heterogeneities that can build-up during
5 HPT processing and are known to affect the efficiency of the local hydrogen-activation
6 process [45]. As the grain size in the HPT particles is extremely fine, the quantity of grain
7 boundaries is such that they are the major option for hydrogen diffusion (Figure 4b). The
8 reason why the elongated contrast along the microscopic shear plane is hardly visible for the
9 $Ti_{10}V_{75}Cr_{15}$ HPT particles (Figure 7b) is due to the fact that this sample was essentially single
10 phase after the hydrogenation process (Figure 5a). Thus, in the absence of chemical contrast,
11 only the crystallographic contrast of grain orientations is visible. This is possibly due to the
12 fact that the FCC hydride remained stable in the grain boundaries and its presence hinders the
13 diffusion of hydrogen during cycling.

14

15 **5. Conclusions**

16 The powders generated after hydrogen pulverization of two Ti-V-Cr alloys processed
17 by SMAT or HPT were investigated to gain new insights on the effect of hydrogen storage.
18 Significant differences were observed in the size and aspect of the hydrogen-induced
19 pulverized particles that, also, revealed the different hydrogen diffusion pathways for the
20 materials activated by SMAT or HPT.

21 In both cases (SMAT and HPT particles), the preferential diffusion of the hydrogen
22 atoms was assisted by segregations that led to variations in the chemical and internal hydride
23 phase structure. An orientation relationship $(100)_{\beta} // (110)_{\gamma}$ and $[001]_{\beta} // [001]_{\gamma}$ has been
24 observed between the BCT matrix and FCC hydride with an angular deviation of $\sim 2.5^{\circ}$.

1 For the HPT heavily deformed and ultrafine-grained material, preferential diffusion of
2 hydrogen atoms took place at the grain boundaries. Additionally, diffusion paths were also
3 witnessed by an elongated structure associated with elongated chemical contrasts along the
4 shear axis of the severely deformed products. These are likely due to shear heterogeneities
5 generated during HPT and hydrogenation. In this case, the hydrogen pulverization process has
6 led to the formation of fairly large (despite the nanostructured grains) particles that broke by a
7 step-by-step crack propagation along the fine grain boundaries leading to fairly smooth
8 particles.

9 For the SMAT-processed precursors, the ultrafine-grained structure at the surface of
10 the shot peened samples derived the hydrogen atoms through the oxidized surface (by grain-
11 boundary diffusion) before entering the coarse-grained core structure. Then, the hydrogen
12 diffusion occurred essentially intragranularly in the coarse-grained core, opening and
13 fracturing along transgranular cleavage planes that generate powder particles having sharp
14 edges.

15

16 **6. Acknowledgments**

17

18 This study was supported in part by the MEXT, Japan, through a Grant-in-Aid for
19 Scientific Research (S) (No. 16H04539 and 26220909), and in part by the French State
20 through the program “Investment in the future” operated by the National Research Agency
21 (ANR) and referenced by ANR-11- LABX-0008-01 (Labex DAMAS). The HPT process was
22 carried out in the International Research Center on Giant Straining for Advanced Materials
23 (IRC-GSAM), Kyushu University, Japan, and the ultrasonic SMAT process as well as the
24 SEM microstructural characterizations were carried out within the IMPACT department in
25 LEM3, University of Lorraine, France.
