Abstract. Arctic and boreal peatlands play a major role in the global carbon (C) cycle. They are particularly efficient at sequestering carbon because their high water content limits decomposition rates to levels below their net primary productivity. Their future in a climate-change context is quite uncertain in terms of carbon emissions and carbon sequestration.

Nuuk fen is a well-instrumented Greenlandic fen with monitoring of soil physical variables and greenhouse gas fluxes (CH₄ and CO₂) and is of particular interest for testing and validating land-surface models. But knowledge of soil carbon stocks and profiles is missing. This is a crucial shortcoming for a complete evaluation of models, as soil carbon is one of the primary drivers of CH₄ and CO₂ soil emissions. To address this issue, we measured, for the first time, soil carbon and nitrogen density, profiles and stocks in the Nuuk peatland (64°07′51″ N, 51°23′10″ W), collocated with the greenhouse gas measurements. Measurements were made along two transects, 60 and 90 m long and with a horizontal resolution of 5 m and a vertical resolution of 5 to 10 cm, using a 4 cm diameter gouge auger. A total of 135 soil samples were analyzed. Soil carbon density varied between 6.2 and 160.2 kg C m⁻³ with a mean value of 50.2 kg C m⁻³. Mean soil nitrogen density was 2.37 kg N m⁻³. Mean soil carbon and nitrogen stocks are 36.3 kg C m⁻² and 1.7 kg N m⁻². These new data are in the range of those encountered in other arctic peatlands. This new dataset, one of very few in Greenland, can contribute to further development of joint modeling of greenhouse gas emissions and soil carbon and nitrogen in land-surface models. The dataset is open-access and available at <https://doi.org/10.1594/PANGAEA.909899> (Morel et al., 2019b).

1 Introduction

The terrestrial biosphere plays an important role in regulating atmospheric greenhouse gas composition and climate through gas exchanges and its capacity to act as a carbon (C) sink (Friedlingstein et al., 2019). For instance, northern latitude wetlands account for one-third to one-half of the methane emissions from natural wetlands (Schlesinger and Bernhardt, 2013). Among all terrestrial ecosystems, peat-

lands are arguably the most efficient at sequestering C over long time scales (Loisel et al., 2014; Leifeld and Menichetti, 2018). Peatlands are permanently saturated wetlands and cover 3 % of the global land surface (Xu et al., 2018). In these ecosystems, the anaerobic conditions created by high water content lead to slow carbon decomposition. Because the accumulation rate of organic matter is greater than its decomposition rate, peatlands are an important long-term soil carbon reservoir (Gorham, 1991). When undisturbed, these

ecosystems are a net sink for atmospheric CO₂ (Jungkunst et al., 2012). Peatlands have consistently sequestered C although at variable rates throughout the entire Holocene period (Yu et al., 2011). Globally they are estimated to store between 550 and 694 Gt C, about a third of global soil organic carbon stocks (Yu et al., 2010; Yu, 2012). Peatlands play a major role in the global carbon cycle (Harenda et al., 2018; Limpens et al., 2008).

Their future in a changing climate is quite uncertain, in terms of the magnitude of carbon emissions and sequestration (Yu et al., 2011). Recent projections suggest that peatlands may remain a carbon sink in the future, although a weaker one (Gallego-Sala et al., 2018). Primary productivity and soil carbon decomposition depend on multiple factors such as solar irradiance, air temperature, vegetation type, soil moisture, soil temperature, soil carbon and soil nutrient content, all of which depend on climate. To be able to estimate how much litter and soil carbon might be decomposed, it is necessary to know the carbon stock at present time. It is also important to know its vertical profile in the soil because the decomposition rate and ratio of CH₄ to CO₂ production depend on depth through soil temperature and soil moisture vertical profiles.

Nitrogen (N) is a limiting factor for plant growth and microbial activity in northern soils (Vitousek and Howarth, 1991) and could play an important role in future northern land carbon storage (Kicklighter et al., 2019) and greenhouse gas emissions (Luan et al., 2019). Increased nitrous oxide release from northern soils with permafrost thaw has been reported (Elberling et al., 2010; Voigt et al., 2017). However, very little is known on nitrogen stocks in these soils.

Knowledge of carbon and nitrogen stocks and profiles is hence particularly important. In the last decades, a growing number of sites in the arctic and boreal regions were instrumented in order to measure the greenhouse gas emissions of these ecosystems, such as Abisko in Sweden (Jammet et al., 2017), Samoylov in Russia (Siewert et al., 2015, 2016) or Zackenberg in Greenland (Pirk et al., 2016, 2017) (see Table 1). Similarly, more and more measurements of soil carbon stocks and profiles are conducted every year. Unfortunately, although large-scale soil carbon databases already exist (e.g. the Harmonized World Soil Database, FAO et al., 2012, or the Northern Circumpolar Soil Carbon Database (Hugelius et al., 2013), very few sites have both greenhouse gas flux and soil carbon content measurements (see Table 1). This is a substantial shortcoming that needs to be addressed, as carbon profiles are one of the primary drivers of CO₂ and CH₄ production and emission (Raich and Schlesinger, 1992). Moreover, for the few sites for which soil carbon stocks and greenhouse gas fluxes are available, both are quite often not measured at the same location (sometimes more than a few kilometers apart). Due to fine-scale heterogeneity (vegetation, microtopography, etc.), they may reflect completely different conditions (e.g. first datasets from the Zackenberg site; Sigsgaard et al., 2007; Palmtag et al., 2015). From a site-

scale modeling point of view, it is therefore important to have greenhouse gas flux data (e.g. CH₄ and CO₂) and state variable data (C stocks and profiles) available at the same locations.

There are many challenges to simultaneously modeling greenhouse gas emissions and soil carbon in land-surface models. For instance, Chadburn et al. (2017) noted that models that simulate realistic soil temperature and soil carbon currently produce unrealistically low methane fluxes. It appears therefore necessary to improve the coupling of biogeochemical and physical processes of land-surface models. An example of recent attempts at this is the biogeochemical carbon and greenhouse gas emissions model presented in Morel et al. (2019a) and embedded in the land surface model Interactions between Soil, Biosphere, and Atmosphere (ISBA; Noilhan and Planton, 1989). Although the biogeochemical and physical parts of this model have been validated on three distinct boreal and arctic sites, the lack of soil carbon data did not allow a complete evaluation of this model. Hence, we conducted a field experiment in a well-instrumented Greenlandic peatland, Nuuk fen, to collect soil carbon stocks and profile data at the location of the automatic chambers measuring CH₄ and CO₂ fluxes and along two transects.

There are very few data available on wetlands in Greenland in general and fens in particular due to logistical difficulties to reach them. Fen extent in Greenland was recently estimated using a combination of remote sensing data and ground measurements (Karami et al., 2018). Karami et al. (2018) find the extent of fen to be 4461 km², about 1.4 % of the ice-free area and 5 % of the vegetated area of Greenland. In terms of in situ data Palmtag et al. (2015, 2018) sampled a few fens for soil carbon and nitrogen in the Zackenberg valley. Barthelmes et al. (2015) in their review only list a dozen published in-situ measurements of peat deposits (both active and inactive), fairly shallow (less than 1 m) for the active ones. Among those, only two deal with carbon fluxes or stocks (MacDonald et al., 2006; Horwath Burnham and Sletten, 2010), the others being mostly paleoecological and archeological studies. Except for Palmtag et al. (2018), none include nitrogen data. Hence, a new dataset on carbon and nitrogen content of a Greenland fen is important.

The aim of this paper is to present and validate this new dataset of soil carbon and nitrogen stocks and profiles from Nuuk fen. In Sect. 2 we present the Kobbefjord site, in particular the fen's physical characteristics and specificities. We present in Sect 3 the experimental protocol and the methods of the field and laboratory studies. Section 4 presents collected data of soil bulk density, water content, soil carbon content, profiles and stocks, as well as nitrogen and carbon / nitrogen (C / N) weight ratios. Finally, we discuss the dataset robustness and possible uses. These soil carbon and nitrogen data will complement the existing dataset of greenhouse gas fluxes from the fen. The combined dataset will allow the evaluation of the fluxes and stocks simulated by land-surface models in a completely

2 Study area

The studied fen (Nuuk fen) is located within the Nuuk Ecological Research Station and is part of the Greenland Ecosystem Monitoring program, which provides detailed reports on an annual basis, dating back to 2007 (Nuuk Ecological Research Operations – NERO – Annual reports; Tamstorf et al., 2008). The Research Station is well-instrumented and participates in several research programs, studying the dynamics of organisms and biological processes, the physical characteristics of marine, coastal and terrestrial environments and performing climate and hydrology monitoring as well. Related data are public and open-access on the Greenland Ecosystem Monitoring database repository, to be found at <http://data.g-e-m.dk/> (last access: 29 September 2020).

Nuuk Research Station is located in the southwest of Greenland, in Kobbefjord (64°07' N, 51°21' W), approximately 20 km from Nuuk. It is not in the permafrost region (Geng et al., 2019). According to the classification of Glooschenko et al. (1993) of Arctic and subarctic wetlands, Nuuk fen is in the low subarctic wetland region. The research station consists of a drainage basin of 32 km² situated at the head of a fjord. The local climate is subarctic with a mean annual temperature of −1.4 °C and mean annual precipitation of 752 mm (1961–1990). Despite cold winter temperatures, the fen never freezes at depths below 10–15 cm. NERO annual reports (Tamstorf et al., 2008; Raundrup et al., 2010) show a significant variability in soil texture, soil moisture, vegetation and microtopography. The studied zone, the only fen of the fjord, is surrounded by high rocks (left top panel of

Fig. 1). The fen is located between the fjord and the Bade So lake. Datings of the sedimentary layer of Bade So (Larsen et al., 2017) showed that the lake was under sea level until 8500 BP. Hence, the fen cannot be older. The underlying geology of the parent material is bedrock composed of Archaean tonalitic to granodioritic gneiss and Qorqût granite (Larsen et al., 2017).

The fen is instrumented with automatic chambers, an eddy flux tower and a regular automated weather station, particularly useful for land-surface models. Nuuk CO₂ and CH₄ automatic chamber flux measurements started in 2007 and are still ongoing. The chambers usually operate from mid-May to mid-October. Each year, the CH₄ flux peaks in July–August with values around 6 mg CH₄ m^{−2} h^{−1} and declines to about half of the maximum in early September. Peak CO₂ fluxes happen at the end of July–early August, reach about −300 mg CO₂ m^{−2} h^{−1}, and occur at the peak of the growing season when photosynthesis is a much larger flux than soil respiration. These fluxes are described in Pirk et al. (2017) and Morel et al. (2019a).

The main water inputs to the fen are from snowmelt and runoff from adjacent hills and inflow from a nearby stream located at the southern border of the fen (bottom panel of Fig. 1). One key factor of this site appears to be the snowmelt date, as snowmelt water runs through the fen, leading to saturated moisture conditions during the growing season. We show that the darker areas in the center roughly correspond to the wetter areas. In these zones, the vegetation is adapted to saturated conditions. This vegetation for instance, has a lower albedo than in the fen's outer area, thereby absorbing more solar radiation and compensating for the colder conditions. Figure 2 shows the different vegetation types encountered throughout the fen: green herbaceous species and mosses in the outer part and aquatic plants with aerenchymas

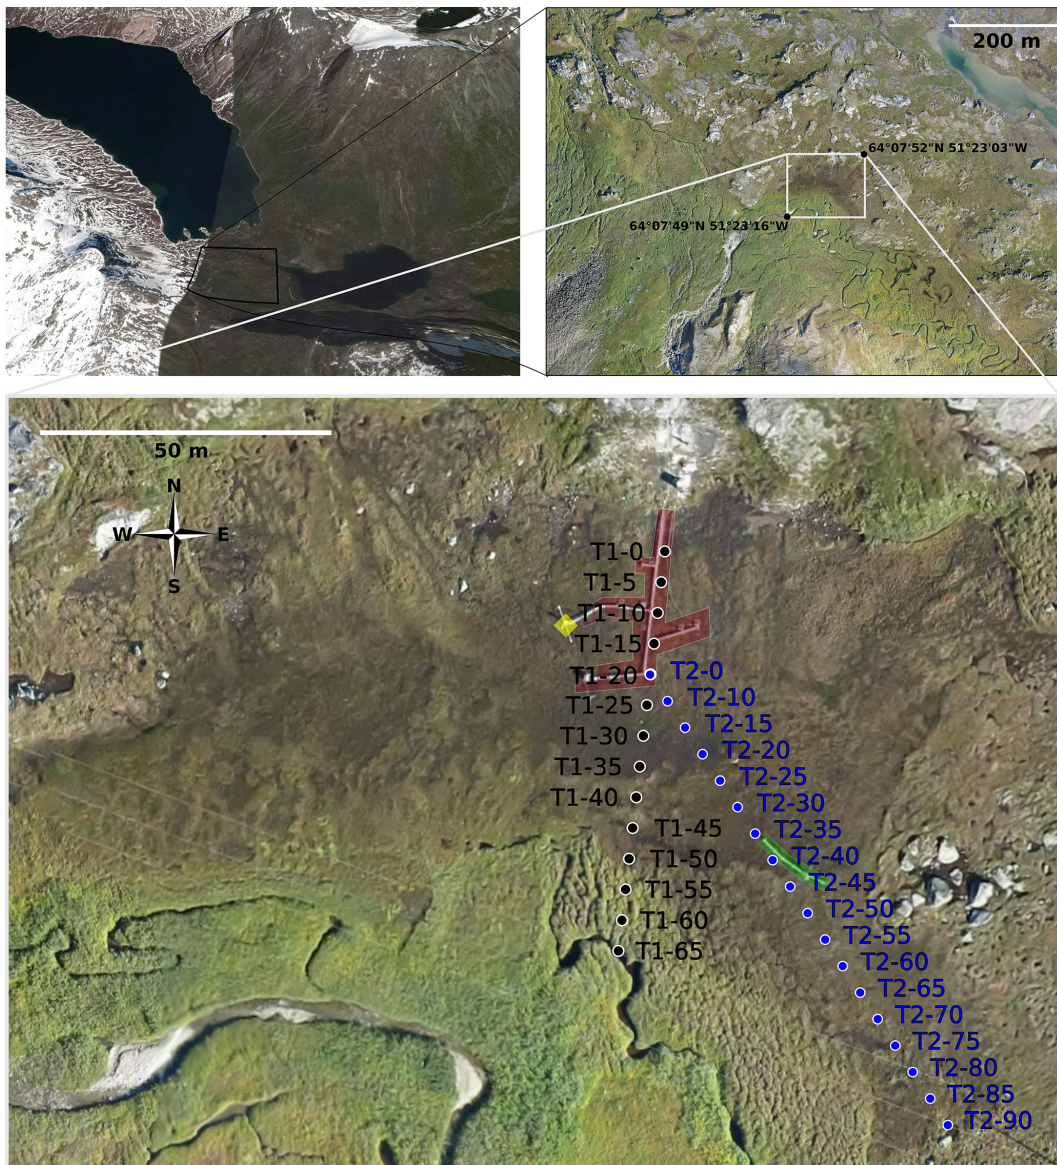

Figure 1. Left top panel: satellite image (© Google Earth – 2009) of Kobbefjord, centered on $64^{\circ}7'51.5''$ N, $51^{\circ}23'10.5''$ W. Right top panel: high-resolution photography (taken by a drone in 2015) of the valley floor. The white rectangle surrounds the fen. Zones highlighted in red represent the location of the automatic chambers, in green the soil temperature probes, and in yellow the eddy flux tower.

and *Sphagnum* in the center of the fen. Section 3.1 explains more precisely the differences in vegetation.

3 Material and methods

All the measurements were made in July 2017 along two transects, shown in the bottom panel of Fig. 1. Each transect was sampled every 5 m, thus defining the plots T1–0, T1–5, T1–10 and so on.

The first transect (T1) roughly follows a N–S axis. The automatic chambers are situated on either side of the transect

between plots T1–0 and T1–20. The second transect (T2) starts at the last automatic chamber, at the 20 m plot of the first transect, in the middle of the fen and goes through the fen in its larger axis. The soil temperature probes can be seen between plots T2–30 and T2–45.

3.1 Fen physical characteristics

First, we measured the topography of the fen and the depth of the sediment layer that delimits organic and mineral soil horizons at every plot for both transects. The elevation was measured with a topographer rod. The depth of the organic–

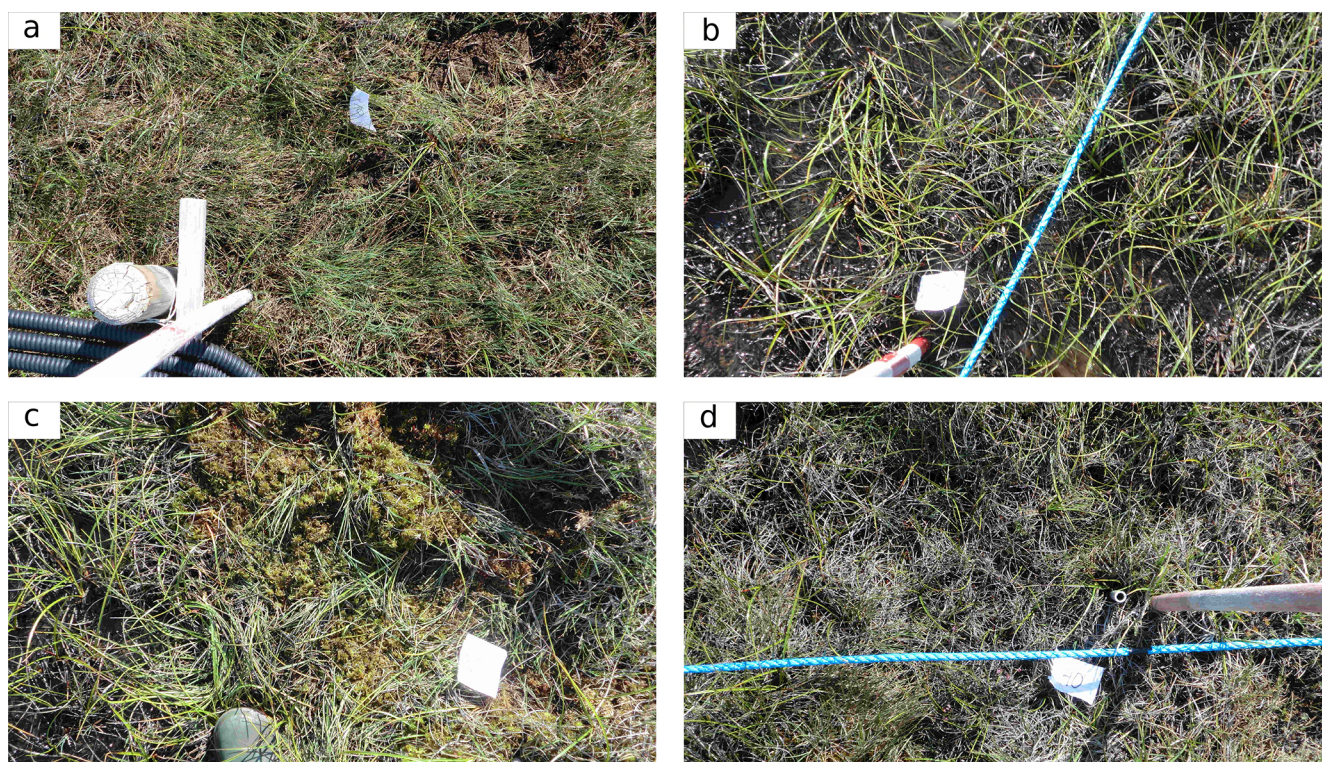

Figure 2. Soil surface photographs along the first transect at several plots. (a) T1–10; (b) T1–30; (c) T1–35; (d) T1–40.

mineral interface (OMI) was measured with a rigid metallic probe. The probe was lowered into the ground until a strong resistance, characteristic of mineral soils, was encountered.

The first transect clearly revealed an accumulation basin at the center of the fen: while the ground elevation remained approximately constant, the OMI depth strongly increased between plots T1–0 and T1–25 (Fig. 3). This depression is characteristic for peatland formation and contributes to organic material accumulation and burial in these ecosystems. Its maximal depth, of approximately 1 m, was situated at T1–25 and roughly corresponds to the darker part of the fen surface (Fig. 1) and standing water (Figs. 3a and 2b). The OMI depth sharply increased in 15 m, then stayed relatively stable. The plot T1–40 seemed to mark the end of the fen. In this intermediate area from T1–40 to T1–60, surface moisture conditions were much drier (Fig. 2d) and the vegetation did not consist of aquatic plants such as *Sphagnum* anymore. Green herbaceous vegetation and mosses then became predominant. T1–40 to T1–60 are characterized by a hummocky topography (little mounds and depressions) that cannot be picked up by 5 m resolution measurements. The plot T1–65 was located at the shore of the nearby water stream.

The second transect started at the 20 m plot of the first transect (T2–0 = T1–20), in the middle of the fen. Until plot T2–30, the soil elevation and the OMI depth did not vary much. There was a peak in the OMI depth at T2–45, surrounded by two small depressions, while the soil elevation decreased.

The end of the transect matched with the boundary of the fen. Approaching this boundary, the soil elevation and the mineral layer both rose.

3.2 Soil sampling along the transects

Soil samples were taken every 5 m along the first transect from the plots T1–0 to T1–35, as we focused solely on the peat deposit. As the second transect fully lay in the peat deposit, soil samples were taken every 10 m for the whole transect, i.e. between the plots T2–0 and T2–80. Samplings were made using a manual gouge auger, with double spade grip and a cylindrical semi-open lower part of 1 m depth and 4 cm in diameter. The general target depth of sampling was to reach below the peat–mineral transition. Samples were then extracted along the full soil core at regular intervals: every 5 cm in the top 15 cm, every 10 cm below. Soil samples were individually stored in small sealed plastic bags just after extraction in order to limit oxygen exchanges and halt decomposition.

Ideally, soil samples should be stored at a 4 °C temperature before being transferred to the lab. With no fridge on the site, we used an insulated cooler in order to best control the samples' temperature. The maximum elapsed time between sample collection and their deposit at the laboratory was 3 d. Although the temperature control of the samples may not have

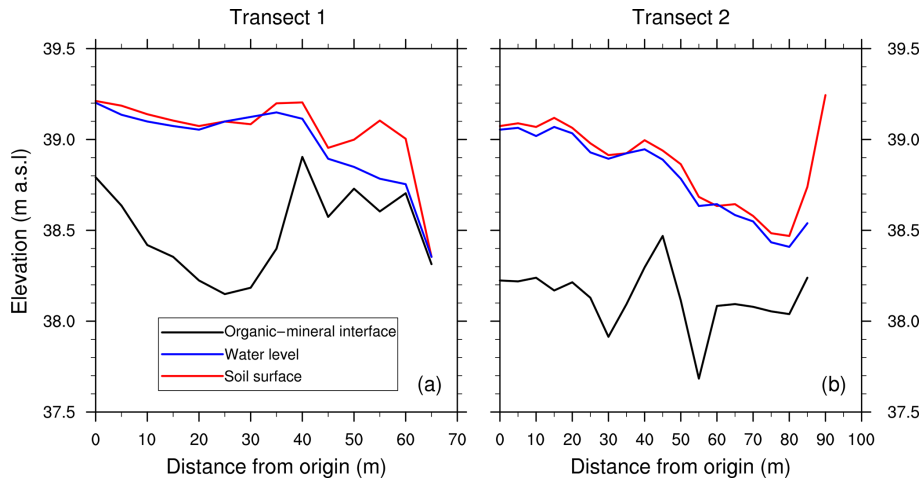

Figure 3. Topographical measurements of soil surface (red) and manual measurements of water level (blue) and organic–mineral interface (black) along both transects. Manual measurements of water level were made on 27 July 2017.

been optimal, this short delay between sample collection and handling prevented any significant decomposition.

3.3 Soil sample handling and analysis

Soil samples ($n = 135$) were first analyzed at the Greenland Institute of Natural Resources, located in Nuuk. For each sample, volume and mass were carefully measured following the method of Chambers et al. (2010) by removing a known-volume sample of peat using a volumetric sampler, measuring it again with a 0.1 mm precision vernier, and weighing it in a crucible in order to determine the sample's density ρ_{sample} (g m^{-3}).

Despite careful measurement and a method designed to limit sample compaction, we recognize that some uncertainties on the samples' densities difficult to quantify are the following.

1. The act of measurement and the soil core extraction can compress the samples within the manual gouge auger, hence modifying their structure.
2. Extracting the samples from the water-saturated soil layers without loss of water is obviously challenging, hence modifying the sample total mass. This potential loss of water can also change the available space within the soil pores, making the sample potentially more sensitive to any compaction.
3. The almost liquid texture of the water-saturated samples made it difficult to measure the sample volume. For these water-saturated samples, we used known-volume vials for volume measurements instead of the 0.1 mm precision vernier.

Peat samples were then oven-dried at 80 °C for 48 h until a constant weight was reached (Djukic et al., 2018). Figure 4

shows samples at different depths for the soil cores T1–10 and T1–25 after drying. The samples of the T1–10 soil core present a well-marked color gradient indicating the different soil horizons. For example, the color and texture of sample 10–60/65 (taken at 60–65 cm depth) of plot T1–10 is characteristic of a mineral soil and indeed corresponds to the OMI (Fig. 3). Conversely, the T1–25 soil core (in the center of the fen) did not have any significant gradient of color and texture, except for a mixed-appearance zone at 60–65 cm depth. We show later that these differences in color could be mainly explained by soil carbon content.

After drying, we determined the mass fraction of water of each sample, f_{wet} . In order to estimate the carbon density within the soil, we need the soil bulk density, ρ_{bulk} , defined as the dry mass per unit of total volume (Boelter, 1969; Hossain et al., 2015). The observed bulk density $\rho_{\text{bulk}}^{\text{obs}}$ was computed as

$$\rho_{\text{bulk}}^{\text{obs}} = \rho_{\text{sample}}(1 - f_{\text{wet}}). \quad (1)$$

Dried peat samples were then sent to the Center for Permafrost (CENPERM – University of Copenhagen – Denmark) for further C and N analysis. Briefly, 10 mg portions of thoroughly mixed and finely ground sample material were weighed into tin combustion cups for Dumas combustion (1700 °C) on an elemental analyzer (CE 1110, Thermo Electron, Milan). Peat standards (Elemental Microanalysis, Okehampton, UK) were included for elemental analyzer mass calibration in order to obtain percentage of C and N content, f_{C} and f_{N} , respectively.

Soil carbon density ρ_{C} ($\text{g C m}_{\text{soil}}^{-3}$) was then computed as

$$\rho_{\text{C}} = \rho_{\text{sample}}f_{\text{C}}(1 - f_{\text{wet}}) = \rho_{\text{bulk}}f_{\text{C}}. \quad (2)$$

Similarly, soil nitrogen density ρ_{N} ($\text{g N m}_{\text{soil}}^{-3}$) was computed as

$$\rho_{\text{N}} = \rho_{\text{sample}}f_{\text{N}}(1 - f_{\text{wet}}) = \rho_{\text{bulk}}f_{\text{N}}. \quad (3)$$

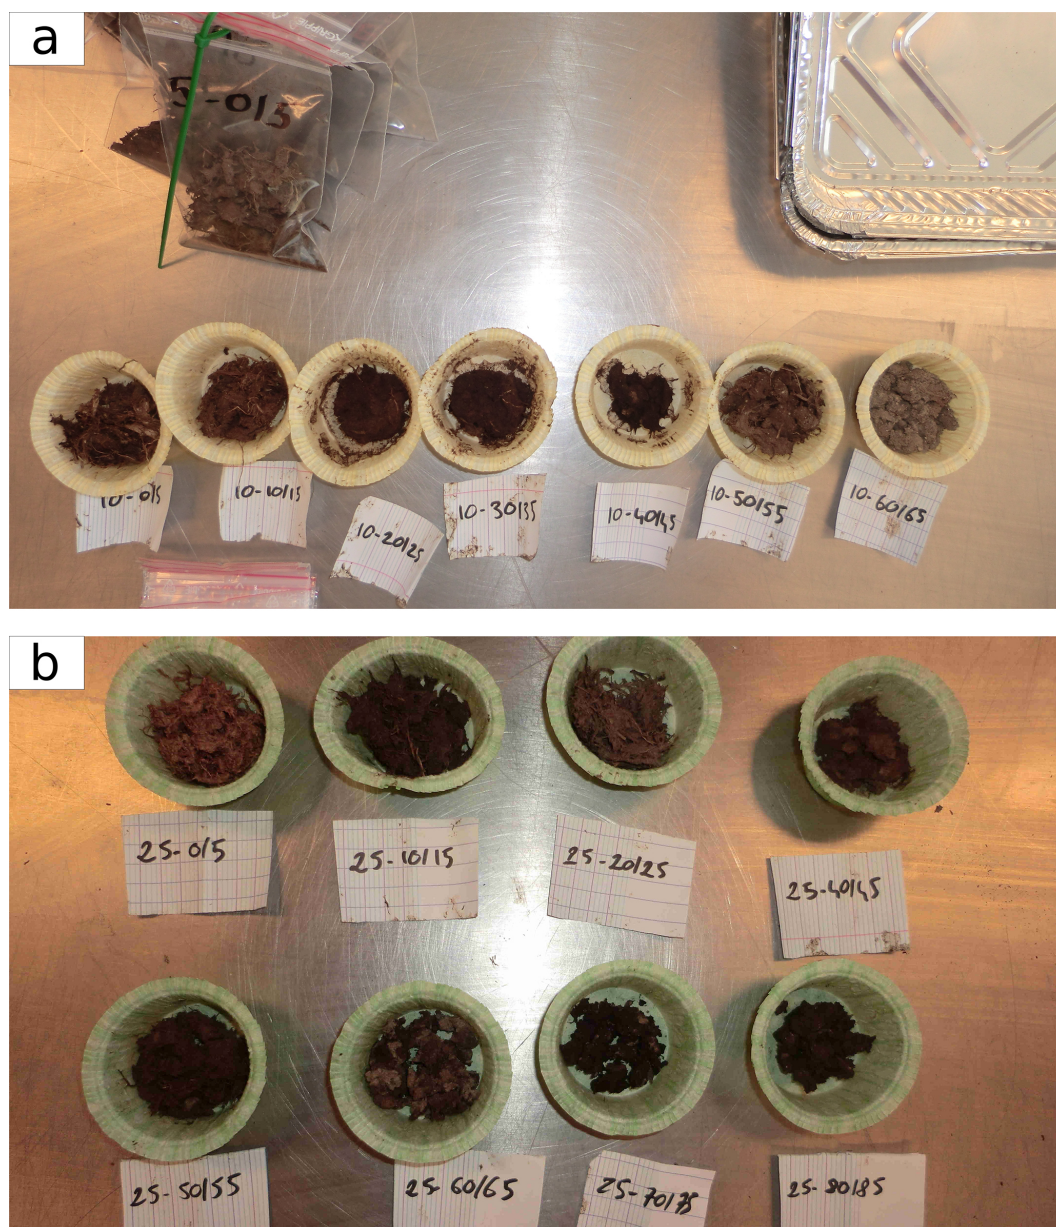

Figure 4. First transect soil samples after 48 h of oven drying at 80 °C. Different samples depths are shown for plots (a) T1–10 and (b) T1–25.

A total of $n = 135$ samples were collected along both transects ($n_1 = 65$ and $n_2 = 70$). For each of these samples, values of mass, volume, density, dry mass, bulk density, carbon and nitrogen content (%), and density (kg m^{-3}) and carbon/nitrogen (C/N) weight ratios were measured and/or calculated. Figure 5 shows distribution histograms for all data, and descriptive statistics (mean, median, upper and lower deciles) are presented in Table 2.

Figure 6 presents soil profiles of bulk density, water mass fraction, carbon and nitrogen content, and density along both transects. These soil profiles ($n = 17$) were averaged over

depth for both transects (Fig. 7). As the fen depth showed a substantial variability along the transects, resulting averaged profiles are noisy. For instance, samples extracted at 50 cm depth may be in a purely organic soil horizon or a quasi-mineral one depending on the fen area it was extracted from. Hence, mean soil profiles do not necessarily reflect the vertical distribution of data with respect to the OMI.

To reduce the noise due to the OMI heterogeneity, we renormalized all the data with respect to the OMI. For a sample extracted at a depth z from a peat core with an OMI depth z_{OMI} , we define its normalized distance from OMI d_{OMI} (%)

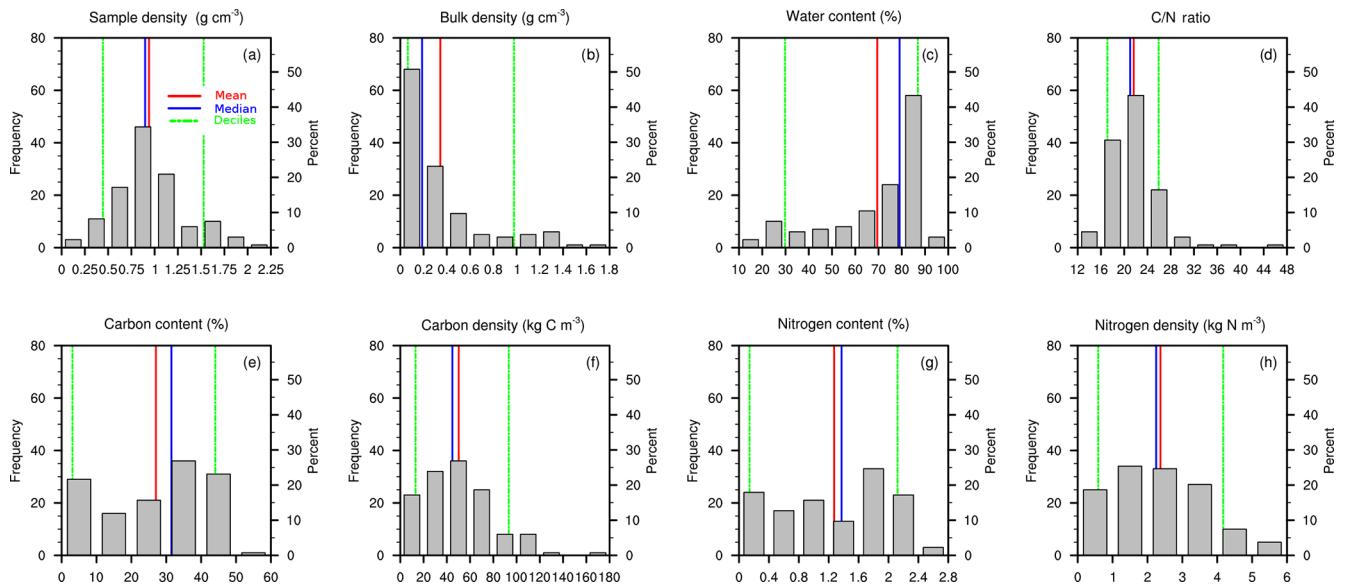

Figure 5. Distribution histograms ($n_{\text{samples}} = 135$) of (a) soil sample density ρ_{sample} (g cm^{-3}), (b) soil bulk density $\rho_{\text{bulk}}^{\text{obs}}$ (g cm^{-3}), (c) soil water content (%), (d) C/N ratio (–), (e) soil carbon content f_{C} (%), (f) soil carbon density ρ_{C} (kg C m^{-3}), (g) soil nitrogen content f_{N} (%), and (h) soil nitrogen density ρ_{N} (kg N m^{-3}). Red lines represent mean values, blue lines median values, dashed green lines upper and lower deciles.

Table 2. Data statistics and dispersion (mean, median, lower and upper decile).

	Mean	Median	Lower decile	Upper decile
Soil sample density ρ_{sample} (g cm^{-3})	0.940	0.898	0.445	1.528
Soil bulk density $\rho_{\text{bulk}}^{\text{obs}}$ (g cm^{-3})	0.345	0.187	0.065	0.978
Soil water content f_{wet} (%)	69.5	79.0	29.8	86.9
C/N ratio (–)	21.6	21.0	17.1	25.9
Soil carbon content f_{C} (%)	27.0	31.5	3.1	44.1
Soil carbon density ρ_{C} (kg C m^{-3})	50.2	44.8	13.1	93.3
Soil nitrogen content f_{N} (%)	1.27	1.37	0.44	2.12
Soil nitrogen density ρ_{N} (kg N m^{-3})	2.37	2.25	0.59	4.17

as

$$d_{\text{OMI}} = \frac{z}{z_{\text{OMI}}} \times 100. \quad (4)$$

These normalized profiles are shown in Fig. 8.

For each peat core, total carbon stocks C_{T} (kg C m^{-2}) were calculated by vertically integrating carbon density profiles using the trapezoidal rule:

$$C_{\text{T}} = \sum_j (z_{j+1} - z_j) \frac{\rho_{\text{C},j+1} + \rho_{\text{C},j}}{2}, \quad (5)$$

with z_j the sample depth and $\rho_{\text{C},j}$ the soil carbon density, computed using Eq. (2).

Similarly, total nitrogen stocks N_{T} (kg N m^{-2}) were computed as

$$N_{\text{T}} = \sum_j (z_{j+1} - z_j) \frac{\rho_{\text{N},j+1} + \rho_{\text{N},j}}{2}, \quad (6)$$

with $\rho_{\text{N},j}$ the soil nitrogen density, computed using Eq. (3).

Note that because of the difficulties setting the manual gauge auger substantially below the OMI, the maximum sampling depth varied between the different peat cores. Hence, the integration depth also varied between peat cores. However, the carbon content below this interface did not exceed 7% except for two unusual samples (Fig. 9), and we can consider that not taking into account the soil horizons below the OMI did not underestimate the computed total C stocks much. Similarly, nitrogen content below the OMI is much lower than in the organic horizons (Fig. 8), and not taking them into account did not underestimate the computed total N stocks much.

3.4 Calculation of 95% confidence interval soil profile

The sampling mean most likely follows a normal distribution. Under this hypothesis, for a variable X , the standard

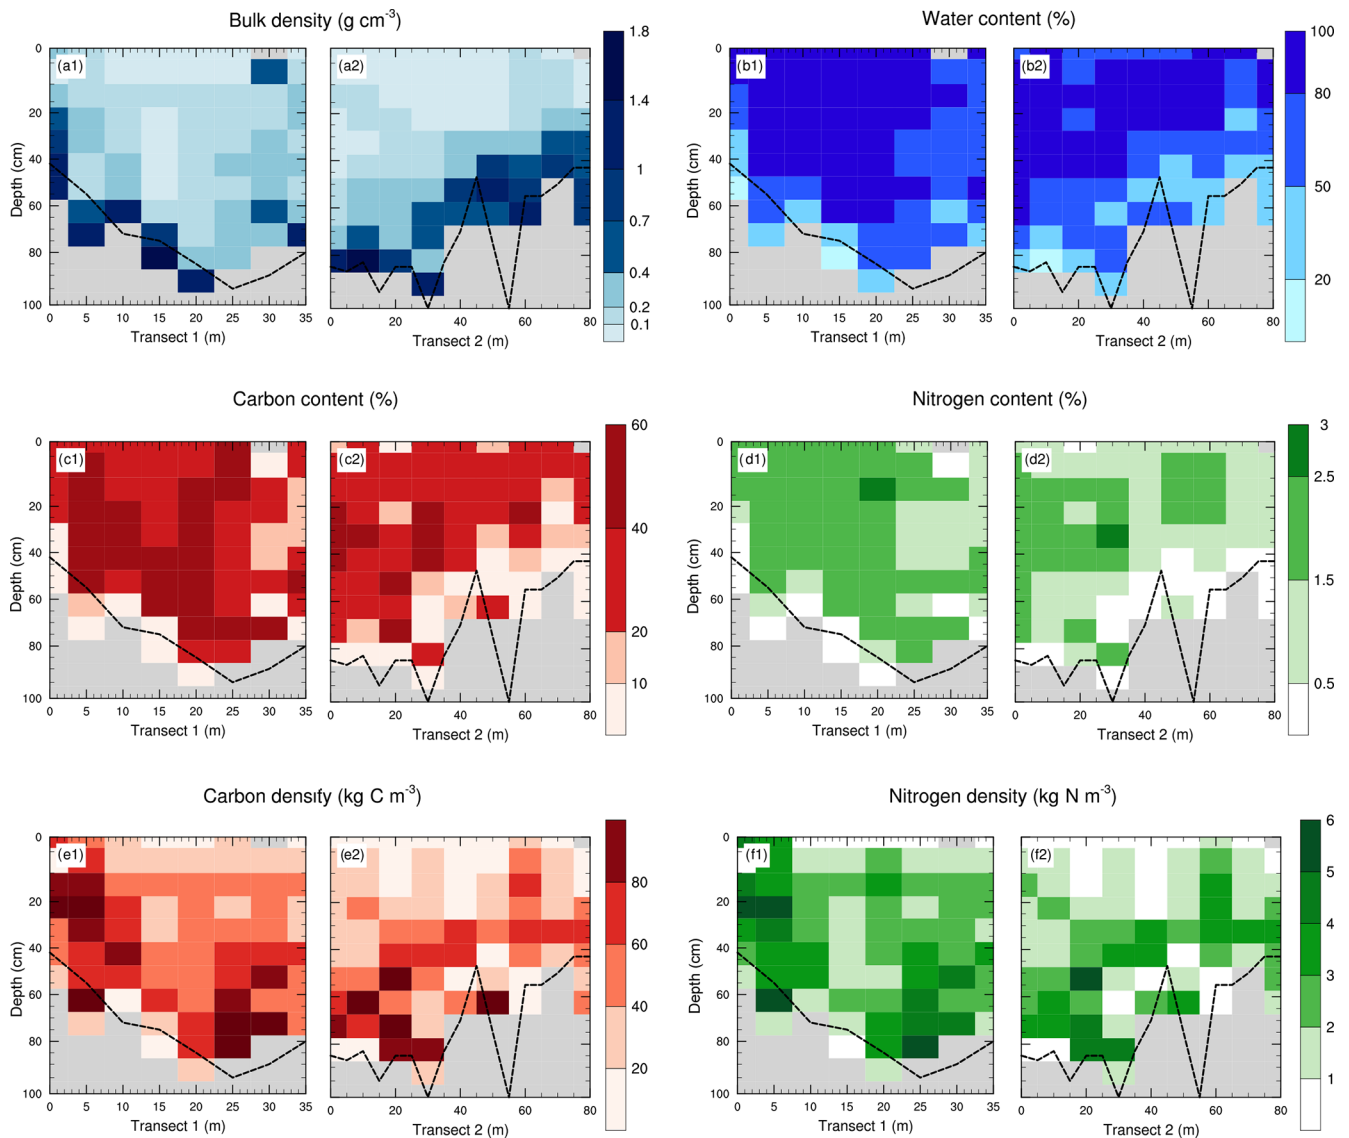

Figure 6. Soil profiles of (a) soil bulk density $\rho_{\text{bulk}}^{\text{obs}}$ (g cm^{-3}), (b) soil water content (%), (c) soil carbon content f_C (%), (d) soil nitrogen content f_N (%), (e) soil carbon density ρ_C (kg C m^{-3}), and (f) soil nitrogen density ρ_N (kg N m^{-3}) along both transects. The dashed black line represents the measured organic–mineral interface. Grey zones indicate the absence of data (mineral soil).

error of the mean can be calculated as $\sigma_{\bar{X}}(z) = \frac{\sigma(z)}{\sqrt{N(z)}}$ with $N(z)$ the number of samples collected at a depth (z) and $\sigma(z)$ the standard deviation over those samples. The confidence interval at 95 % is defined as $I(z) = \bar{X}(z) \pm 1.96 \times \sigma_{\bar{X}}(z)$.

4 Results and discussion

4.1 Bulk density

Variation in bulk density is attributable to the relative proportion of organic and inorganic soil particles and is a reliable indicator of the mineral or organic nature of a soil. More than 50 % of the samples have a bulk density below 0.187 g m^{-3} (Fig. 5), characteristic of organic-rich material.

Samples with bulk density between 0.5 and 1 g cm^{-3} correspond to mixed organic–mineral material (Loisel et al., 2014). The higher the bulk density, the higher the mineral content. Finally, the 10 % remaining samples with bulk densities higher than 0.978 g cm^{-3} (Table 2) correspond to the part of the soil with the highest mineral fraction, near or below the OMI, as most mineral soils have bulk densities between 1.0 and 2.0 g cm^{-3} (Rezanezhad et al., 2016).

Strong vertical gradients in bulk density could be seen throughout both transects (Fig. 6a). The measured OMI depth delimited the transition between organic and mineral material well, as expected.

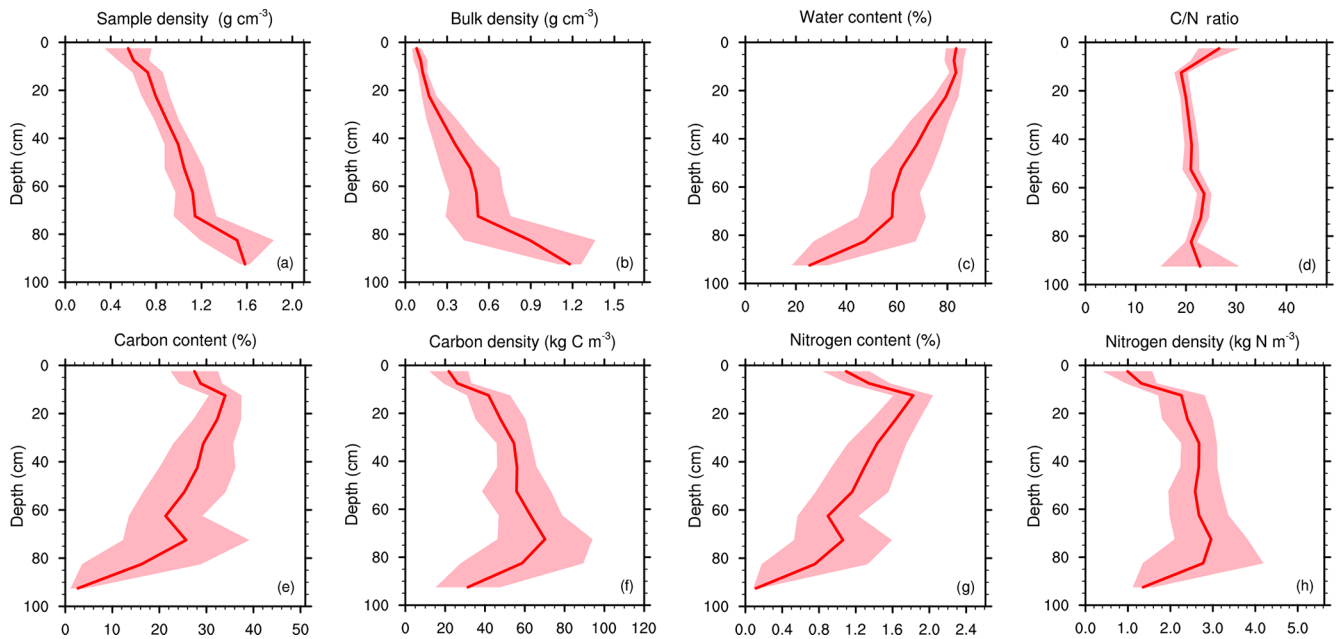

Figure 7. Mean soil profiles over both transects ($n_{\text{samples}} = 135$; $n_{\text{profiles}} = 17$) of (a) soil sample density ρ_{sample} (g cm^{-3}), (b) soil bulk density $\rho_{\text{bulk}}^{\text{obs}}$ (g cm^{-3}), (c) soil water content (%), (d) C / N ratio (–), (e) soil carbon content f_{C} (%), (f) soil carbon density ρ_{C} (kg C m^{-3}), (g) soil nitrogen content f_{N} (%), and (h) soil nitrogen density ρ_{N} (kg N m^{-3}). The shaded area represents the 95 % confidence interval.

Typical bulk density profiles in peatlands tend to show a gradual increase with depth (Quinton et al., 2000): as peat decomposition reduces the proportion of large pores by breaking down plant debris into smaller fragments (Rezanezhad et al., 2016), it increases the mass of dry material per volume of peat. Normalized mean profiles of bulk density (Fig. 8b) clearly show this abrupt transition from mixed organic–mineral material to pure mineral soil below the OMI.

4.2 Carbon mass percentage

Mass percentage of carbon reached 50 % (Fig. 6c), which is coherent with the data given in the review of Yu (2012) on northern peatland carbon stocks.

As expected, concentration of soil organic carbon in the organic layer was much higher than in the mineral horizons. High carbon content in the depth of the first transect seemed to indicate a carbon burial in the natural accumulation basin. We also note that the limit between the soil horizons with high and low carbon content also follows the OMI. In particular, the drop of the sedimentary layer in the first transect is clearly visible and the variations in the mineral layer of the second transect between T2–30 and T2–60 as well. Normalized mean carbon content profiles (Fig. 8e) clearly showed the abrupt decrease in carbon content near the OMI. Below the OMI, carbon content values were below 10 %, which is coherent with the mineral characteristics of the soil horizons below.

4.3 Soil carbon density and soil carbon profiles

More than 70 % of the soil samples had soil carbon densities comprised between 20 and 80 kg C m^{-3} (Fig. 5f). Those values are coherent with those encountered in other arctic and boreal fen and peatlands (see Chadburn et al., 2017, Fig. 5). Mean local maximum of soil carbon density reached values up to 80 kg m^{-3} at 80 cm depth (Fig. 7f).

As expected, soil carbon density matched the measured organic–mineral interface well (Fig. 6.e1). The assumed carbon accumulation in the accumulation basin of the fen discussed in the previous section is confirmed, as a local maximum of soil carbon density was clearly visible at the bottom of the soil plots T1–25 and T2–30 (Fig. 6a1).

Mean soil carbon density profiles were non-monotonous. In the organic horizons, soil organic content (SOC) density increased with depth and reached its local maximum between 60 and 80 % of the organic–mineral interface depth (Fig. 8f). Near the OMI, coherent with the abrupt decrease in carbon content and increase in bulk density discussed in the previous sections, the soil carbon density decreased. Soil carbon density profiles that first increased and then decreased with depth are characteristic of arctic and boreal fens (see Chadburn et al., 2017, Fig. 5).

4.4 Integrated soil carbon stocks

Tables 3 and 4 present the carbon stocks and the maximum sampling depth for each peat core along both transects. Mean carbon stocks over both transects were 36.3 kg C m^{-2} .

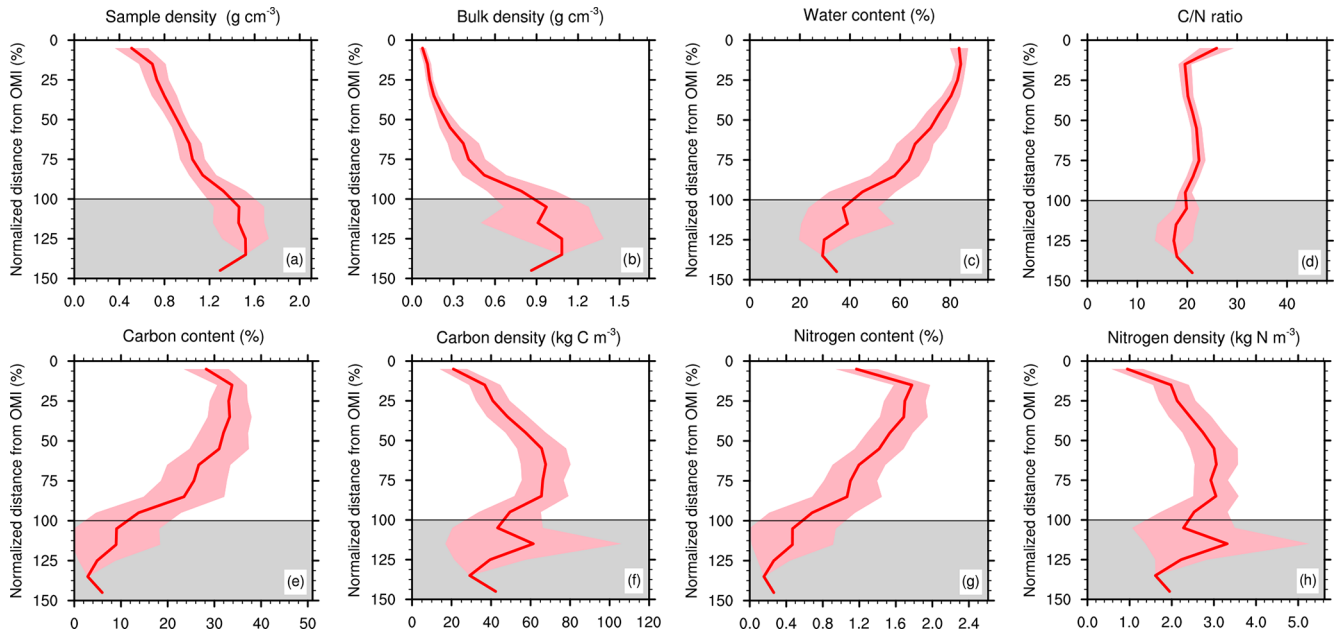

Figure 8. Same as Fig. 7, except profile depths are re-normalized from the organic–mineral interface. The grey area represents the zone below the OMI.

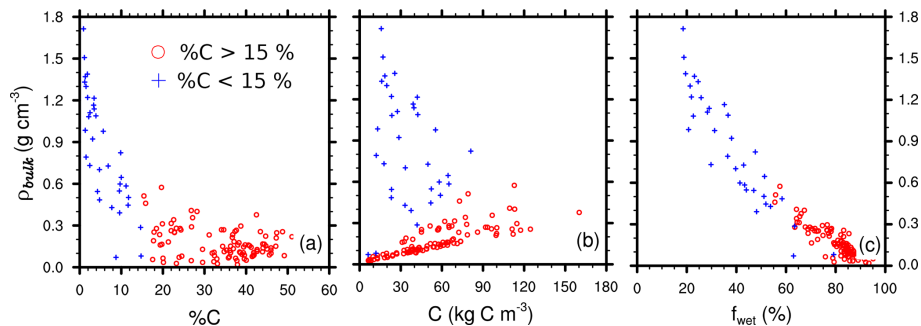

Figure 9. Scatter plots of soil bulk density $\rho_{\text{bulk}}^{\text{obs}}$ versus (a) soil carbon content f_C (%), (b) soil carbon density ρ_C (kg C m^{-3}), and (c) soil water content (%) for the 135 samples. Red circles represent samples with carbon content exceeding 15 % and blue crosses less than 15 %.

The review of Yu (2012) on high-latitude fens and peatlands reports integrated soil carbon stock values between 58.7 and 73.4 kg C m^{-2} , except one extraordinary value of 113.6 kg C m^{-2} . Those values are higher than those found in Nuuk. But they were computed by considering a fen depth of 1 m, which was not the case here, as the Nuuk fen is quite shallow: the mean sampling depth – which was often deeper than the OMI – did not exceed 76.3 cm in both transects (Tables 3 and 4). Hence, the results of our soil carbon stock measurements were then coherent and consistent with current estimates from similar ecosystems.

Finally, a basic estimate of total soil carbon content over the whole fen area is given by multiplying the mean soil carbon mass per unit surface (36.3 kg C m^{-2}) by a rough estimate of the fen area (approx. 7500 m^2 ; see Fig. S2). This gives a total carbon storage in the fen of 272 250 kg C.

4.5 Soil nitrogen density and soil nitrogen profiles

More than 70 % of the soil samples had soil nitrogen densities between 1 and 4 kg N m^{-3} (Fig. 5h), with a mean value of 2.37 kg N m^{-3} . The lowest values of N mass indicated the OMI (Fig. 6d). A local maximum of soil N density was clearly visible at the bottom of the soil plots T1–25 and T2–20 (Fig. 6a1), indicating that nutrients tend to accumulate in the fen basin.

Soil N profiles closely follow the soil C profiles (Fig. 7f, h), indicating a quite uniform C/N ratio through the soil profile (see Sect. 4.7).

4.6 Integrated soil nitrogen stocks

Nitrogen stocks range from 0.8 to 2.9 kg N m^{-2} , with a mean value of 1.7 kg N m^{-2} (Tables 3 and 4). This is very similar

Table 3. Carbon and nitrogen stocks from peat cores along the first transect.

Peat core of transect 1 (m)	0	5	10	15	20	25	30	35	Mean	SD
Maximum sampling depth (cm)	55	75	65	85	95	85	75	75	76.3	12.5
Number of samples (–)	7	8	7	9	10	8	8	7	8	–
C _T (kg C m ^{–2})	31.8	58.9	37.2	29.2	46.7	55.4	40.5	34.5	41.8	10.9
N _T (kg N m ^{–2})	1.7	2.9	1.6	1.4	2.2	2.4	1.9	1.7	2.0	0.5

Table 4. Carbon and nitrogen stocks from peat cores along the second transect.

Peat core of transect 2 (m)	0	10	20	30	40	50	60	70	80	Mean	SD
Maximum sampling depth (cm)	85	85	85	95	65	65	65	45	70	73.3	15.4
Number of samples (–)	8	9	10	11	7	7	7	5	7	7.8	–
C _T (kg C m ^{–2})	35.4	38.4	53.4	39.1	22.2	21.6	27.3	16.6	28.6	31.4	11.3
N _T (kg N m ^{–2})	1.6	1.8	2.3	2.0	1.0	1.0	1.5	0.8	1.4	1.5	0.5

to the $1.9 \pm 0.7 \text{ kg N m}^{-2}$ value obtained by Palmtag et al. (2018) (Table 2) for the fens on alluvial fans in the Zackenberg valley, to our knowledge the only available in situ N data for Greenland peatlands. In a broader Arctic context, these values are in the same range of terrestrial deposits on the Alaskan Beaufort Sea coast with 1.9 kg N m^{-2} (0–100 cm; Ping et al., 2011) and slightly higher than an estimation for Arctic Alaska soils with 2.7 kg N m^{-2} (0–100 cm; Michaelson et al., 2013).

A basic estimate of total soil nitrogen storage for the whole fen area is given by multiplying the mean soil nitrogen mass per unit surface (1.7 kg N m^{-2}) by a rough estimate of the fen area (approx. 7500 m^2 ; see Fig. S2). This gives a total nitrogen storage in the fen of $12\,882 \text{ kg N}$.

4.7 C/N ratios

Carbon/nitrogen (C/N) weight ratios can give useful information about the nutrient content and the quality and humification degree of organic matter: a low C/N ratio is usually equivalent to a high humification level. With a mean value of 21.6, observed C/N ratios were in the range of those observed from a variety of field and laboratory studies (Bridgman et al., 1998; Rezanezhad et al., 2016; Wang et al., 2015).

C/N ratios were higher in the first few centimeters of depth (approx. 25%), potentially indicating less microbial transformation of the peat in the upper layers (Kuhry and Vitt, 1996). At greater depth of the fen, C/N ratios were lower because microorganisms slowly consume the carbon and recirculate the nitrogen, resulting in a gradual reduction of C/N values (Rydin and Jeglum, 2013). In northern regions, due to colder temperatures, the decomposition activity is slow, explaining the small difference between maximal and minimal C/N values. The C/N profiles remained relatively stable throughout the depth (21.6%), and the OMI did not seem to distinguish separate zones.

Although bulk density and C/N ratios are reliable indicators for peat degradation, the lack of ash content data and isotopic measurements did not allow a quantification of carbon accumulation rate or carbon loss in the peatland (Krüger et al., 2015).

4.8 Discussion

Overall, this new dataset of soil bulk density, carbon and nitrogen content, profiles, and stocks from Nuuk fen was in the range of previous estimates of northern and Arctic wetlands (Yu, 2012; Loisel et al., 2014; Chimner et al., 2014).

As noted by Loisel et al. (2014), the accuracy of this type of measurement mostly depends on sample handling, in particular the care taken to avoid any peat compaction. Our sample density measurements may have been uncertain. On the other hand, mass carbon percentages are independent of any uncertainties or hazards in sample handling. It is known that soil carbon content and bulk density are strongly correlated. For instance, Hossain et al. (2015) noted that bulk density ρ_{bulk}^H and carbon content f_C follow an exponential relationship:

$$\rho_{\text{bulk}}^H = ae^{-bf_C}, \quad (7)$$

with $a = 1.5641$ and $b = 0.0631$.

We find a similar exponential behavior (Fig. 9a) between bulk density and carbon content with a strong correlation between our measured bulk density and Hossein's exponential ($r^2 = 0.801$, Table 5). Different types of two-parameter regressions could also be used to infer bulk densities from carbon content, as shown in Table 5. Soil carbon density profiles can hence be computed with two different methods: a “direct” method, using bulk density data (see Eq. 2), and an “indirect” method by computing bulk density using carbon content via one of these functional fits. This comparison shows that our measurements of bulk densities were at the

Table 5. Statistical scores for different regressions between bulk density ρ_{bulk} and carbon content f_{C} .

Regression type		r^2 ¹	c-RMSE ²	MAE ³	Bias ⁴
Hossain et al. (2015)	$\rho_{\text{bulk}}^H = 1.5641 \times e^{-0.0631 f_{\text{C}}}$	0.801	0.196	0.154	-0.10
Exponential	$\rho_{\text{bulk}}^{\text{exp}} = 0.7276 \times e^{-0.04583 f_{\text{C}}}$	0.760	0.222	0.147	0.07
Power	$\rho_{\text{bulk}}^{\text{pow}} = 1.8975 \times f_{\text{C}}^{-0.73794}$	0.817	0.164	0.117	0.032
Logarithmic	$\rho_{\text{bulk}}^{\text{log}} = -0.3281 \times \ln(f_{\text{C}}) + 1.31736$	0.832	0.152	0.114	-10^{-4}

$$^1 r^2 = \left(\frac{\sum_{i=1}^n (x_i - \bar{x})(f(x_i) - \bar{f})}{\sqrt{\sum_{i=1}^n (x_i - \bar{x})^2} \sqrt{\sum_{i=1}^n (f(x_i) - \bar{f})^2}} \right)^2$$

$$^2 \text{c-RMSE} = \frac{1}{n} \sqrt{\sum_{i=1}^n (x_i - \bar{x} - (f(x_i) - \bar{f}))^2}$$

$$^3 \text{mae} = \frac{1}{n} \sum_{i=1}^n |x_i - f(x_i)|$$

$$^4 \text{bias} = \frac{1}{n} \sum_{i=1}^n (x_i - f(x_i))$$

right order of magnitude. But these relationships cannot capture the vertical variability of the observed soil carbon profiles. Mass percentage of carbon f_{C} (% C) does not encapsulate all the causes of the variability of ρ_{bulk} . Consequently, inferred carbon profiles from indirect methods were deceptively flat and smooth (see Fig. S1). Hence, although testing whether bulk density and soil carbon content measurements follow this type of relationship provides a good indicator of the dataset quality, it is not recommended to infer soil carbon profiles from these empirical relationships.

Loisel et al. (2014) choose an arbitrary cutoff value of 0.5 g cm^{-3} to distinguish peat and non-peat material. It also roughly corresponds to the separation between samples with carbon content exceeding 15 % and the others (Fig. 9a–c). Below this threshold (i.e. for fully organic samples), there was a linear relationship between bulk density ρ_{bulk} and soil carbon density ρ_{C} (Fig. 9b), indicating a rather homogeneous soil carbon content f_{C} for organic samples. For mixed-material and mineral samples, such a relationship is not true.

The well-known high water retention capacity of peat soils (e.g. Boelter, 1969) was also observed here (Fig. 9c) as the higher values of soil water content were found in the samples with the highest carbon content and lowest bulk density.

Finally, when using these data for performing a detailed one-dimensional evaluation of the litter and soil carbon together with the CO_2 and CH_4 emissions simulated by a land-surface model, it is best to use the soil carbon data corresponding to the automatic chambers area, that is the profiles from plots T1–0 to T1–20.

5 Code and data availability

All the data used to produce the tables and figures of the paper are freely available in the repository: <https://doi.org/10.1594/PANGAEA.909899> (Morel et al., 2019b).

6 Conclusions and perspectives

In this paper, we have provided a complete description of a new dataset of the current distribution of soil organic carbon and nitrogen storage at the Nuuk peatland. This dataset is one of the very few on Greenland fens and will help in better understanding these poorly documented ecosystems. All data are in the range of the existing Arctic and low-Arctic fen studies. All data are in the range of previous studies. Automatic chamber flux measurements and carbon sampling are being recorded at the same location, making the Nuuk fen dataset an ideal candidate for evaluating the accuracy of land-surface model simulations of both soil carbon profiles and greenhouse gas emissions.

In the near future it will allow a complete evaluation of the biogeochemical model presented in Morel et al. (2019a). Completing this evaluation could help eventually resolve issues concerning biogeochemical models that model both soil carbon stocks/profiles and soil greenhouse gas fluxes raised by Chadburn et al. (2017). It could also be used to further validate recent developments in carbon and/or peatland modules for larger-scale studies, such as the specific peatland module developed by Langeron et al. (2018) or the soil carbon representation specific to fen and peatlands of Qiu et al. (2018).

Supplement. The supplement related to this article is available online at: <https://doi.org/10.5194/essd-12-2365-2020-supplement>.

Author contributions. XM, BUH, MM, CD and BD designed the field campaign. XM and BUH conducted the fieldwork and collected and prepared the samples for analysis. PA conducted the laboratory analysis. XM, CD and BD designed the manuscript. All authors contributed to the writing.

Competing interests. The authors declare that they have no conflict of interest.
