## RESEARCH ARTICLE

10.1029/2020JD032565

### Key Points:

- Tree rings from the Andean headwaters of the Peruvian Amazon Basin allow the reconstruction of regional rainfall variability since 1817
- Reconstructed rainfall reveals imprints of El Niño and the Atlantic Multidecadal Oscillation
- There is a recurrent alternation between wet and dry periods in the past two centuries, but an increase in droughts is evident from 1980 to present

**Abstract** Almost half of the tributaries of the Amazon River originate in the tropical Andes and support large populations in mountain regions and downstream areas. However, it is difficult to assess hydroclimatic conditions or to evaluate future scenarios due to the scarcity of long, high-quality instrumental records. Data from the Global Precipitation Climatology Project (GPCP) provide a complete record since 1979 and offer a good representation of rainfall over the tropical Andes. Longer records are needed to improve our understanding of rainfall variability and summer monsoon behavior at various scales. We developed the first annually resolved precipitation reconstruction for the tropical Andes in Peru, based on tree-ring chronologies of *Cedrela* and *Juglans* species. The annual (November–October) reconstruction extends the short instrumental records back to 1817, explaining 68% of the total variance of precipitation over the 1979–2007 calibration period. The reconstruction reveals the well-documented influence of El Niño–Southern Oscillation (ENSO) on Amazon Rainfall at interannual scales (~19% of total variance) and significant multidecadal variability with alternating periods of about 40 years (~13% of rainfall variability) related to the Atlantic Multidecadal Oscillation (AMO). Both oscillatory modes can explain dry and humid periods observed within the reconstruction and are likely associated with the negative trends of rainfall in the short instrumental records and the increased drought recurrence in recent decades. Our results show that montane tropical tree rings can be used to reconstruct precipitation with exceptionally high fidelity, characterize the interannual to multidecadal variability, and identify remote forcings in the hydroclimate over the Andean Amazon Basin of Peru.

## 1. Introduction

The Amazon Basin plays an important role in the South American summer monsoon (SAMS) dynamics. The large area of tropical forests modulates its own hydrological regime through the maintenance of deep atmospheric convection and recirculation of precipitation (Gloor et al., 2013; Vera et al., 2006). Over the western area of the basin, the Andes Mountains form a topographic barrier that produces a strong gradient in precipitation (Garreaud et al., 2009). The rainiest areas or “rainfall hotspots” in the Amazon Basin are found in the eastern flank of the tropical Andes (Espinoza et al., 2015). Seven of the 15 tributary rivers of the Amazon (the so called “white-water rivers”) emerge from these mountain regions (Barthem et al., 2005). However, the complex topography and low density of instrumental data hinder the proper characterization of the hydroclimate variability across the region.

Analyses of the Amazon River discharge at Óbidos (77% of total drainage) indicate that the hydrological cycle of the Amazon has been intensifying during the 1990–2010 period, with an increase in the annual amplitude and severity of extreme events in the river discharge compared to previous decades (Barichivich et al., 2018; Gloor et al., 2013). Precipitation data over the Amazon Basin show an upward trend in the last decades (Gloor et al., 2015), but at the same time, some extreme droughts have occurred during the years 1998 (Marengo, 2004), 2005, and 2010 (Malhi et al., 2008; Marengo et al., 2008, 2011). These results

suggest an increase in climate variability, with increased moisture as a response to global climate change (e.g., Gloor et al., 2013) but with opposite drying trends affecting different sectors of the Amazon Basin during the 21st century (Fu et al., 2013; Marengo et al., 2011). At regional scales, climate data from instrumental stations display complex spatiotemporal precipitation patterns. For example, rain-gauge stations over the equatorial Andes display different rainfall patterns than those in the southern tropical Andes (Segura et al., 2019). These discrepancies are in part attributed to the local variability due to the complex topography and steep climatic gradients, but also result from a scarce instrumental network and a short temporal span of satellite-based climate records. These limitations have resulted in different predictions and evaluations of precipitation trends and a major challenge for climate modeling (particularly of precipitation) over the tropical Andes (Urrutia & Vuille, 2009).

During the monsoon season, two precipitation bands are prominent over South America: one extends from the equatorial oceans (Zhou & Lau, 1998), while the second belt of moisture flux convergence and convection extends from the Amazon Basin toward southeastern Brazil and the adjacent ocean (the South American Convergence Zone, SACZ; Carvalho et al., 2004). Easterly winds from the tropical Atlantic Ocean and the central Amazon Basin are mechanically forced by the Andes in a low-level jet structure (the South American Low Level Jet, SALLJ; Campetella & Vera, 2002; Marengo et al., 2002) and reinforce the moisture transport from the monsoon core region to tropical and subtropical latitudes (Garreaud et al., 2009; Vera et al., 2006). Precipitation variability at the monsoon region fluctuates on interannual to multidecadal scales, largely modulated by sea surface temperatures (SSTs) (Vera et al., 2006). El Niño-Southern Oscillation (ENSO) event is the major source of interannual climatic variability (Vuille & Keimig, 2004), and decadal variability has been associated, for example, with the Pacific Decadal Oscillation (PDO; Garreaud et al., 2009). However, important linkages have been found between low-frequency tropical rainfall variations and SST fluctuations over the tropical/equatorial Atlantic Ocean through the Atlantic Multidecadal Oscillation (AMO; e.g., Jones & Carvalho, 2018).

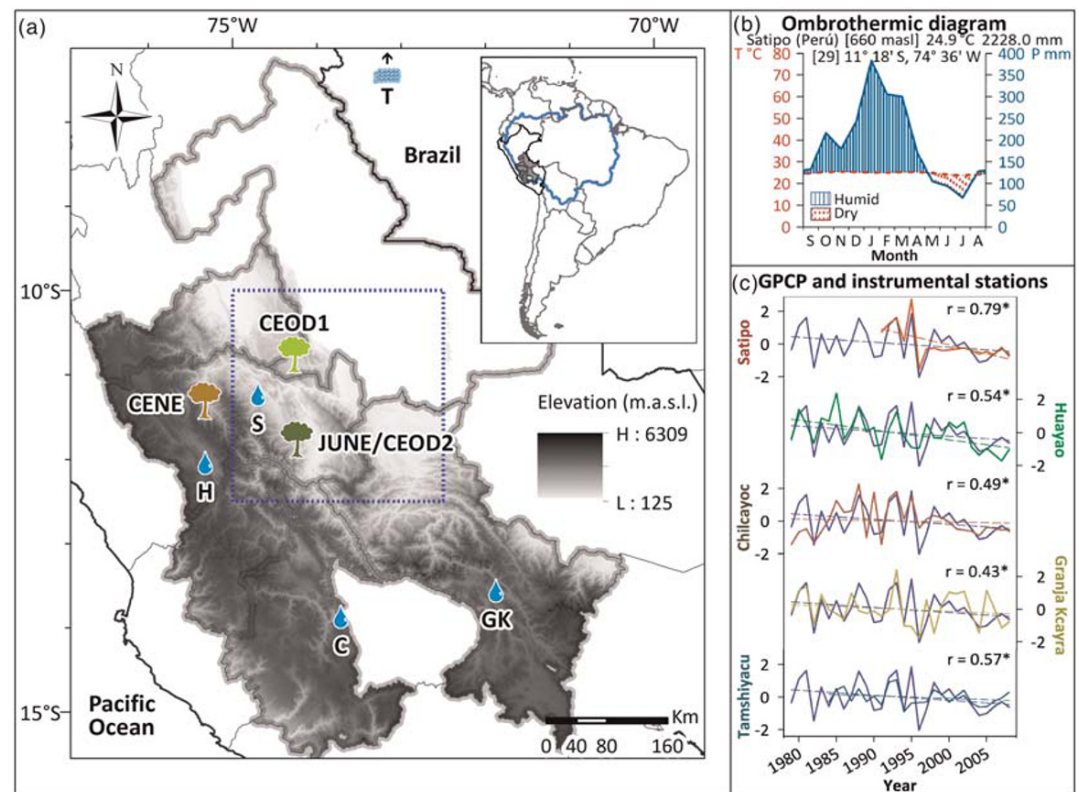

To characterize the monsoon variability at long-term scales, several paleohydrological reconstructions based on speleothem and lake sediment records were generated along Brazil (Novello et al., 2012, 2016, 2018; Vuille et al., 2012; Wang et al., 2017; Wortham et al., 2017), Peruvian Andes (Apaéstegui et al., 2014; Bird et al., 2011; Bustamante et al., 2016; Parsons et al., 2018; Reuter et al., 2009), and Bolivian Andes (Apaéstegui et al., 2018). Yet knowledge on the changes in the tropical hydrological cycle between the Andes and Amazon lowlands, at high temporal resolution, is still rudimentary. To improve our understanding on the tropical Andes' hydroclimate and the interactions with the Amazon, high-resolution palaeoclimatic records are needed to bridge the gap between the (monthly seasonal) instrumental records and long-term (often millennial) climatic proxies. Recent studies (e.g., Ferrero et al., 2015; Granato-Souza et al., 2018; Layme-Huaman et al., 2018; López et al., 2017; Pereyra-Espinoza et al., 2014; Pucha-Cofrep et al., 2015; Schöngart et al., 2002) demonstrate the feasibility of using tree-ring records to reconstruct and characterize interannual variability and trends in local and regional climate of the tropics in South America. Here, we present the first annually resolved tree-ring rainfall reconstruction over the last two centuries from tropical Peruvian montane forests to (1) document present and past changes in precipitation variability over the Andean headwaters of the Amazon Basin and (2) assess its relationship with large-scale spatial and temporal climate forcings.

## 2. Materials and Methods

### 2.1. Study Area and Climatic Data

The study area is located in the humid eastern slopes of the Peruvian Andes, between 1,250- and 2,150-m in altitude (Figure 1a), and corresponds to *Yungas* montane forests. This region includes the upper watersheds of the Peruvian Amazon River and encompasses areas of little disturbed montane forests.

Low-elevation (<500 m) Amazonian forests lack climate seasonality (Britto, 2017), while tropical inter-Andean valleys and western slopes are typically drier. Rainfall increases with elevation up to the tree-line at approximately 3,500 m, and relative humidity increases at these altitudes due to cooler temperatures (Catchpole, 2012). The eastern Andes/western Amazon Region is the rainiest in the Amazon Basin, but a complex distribution of rainfall in the eastern part of the Andes results from the steep topography and large-scale humidity transport (Espinoza et al., 2015; Killeen et al., 2007). Instrumental records are very

**Figure 1.** Map of the study sites and meteorological/hydrometric stations in the tropical Andes of Peru. (a) Location of the tree-ring chronologies (tree icons), weather stations (water drops), hydrometric station (wavy lines), and GPCP precipitation grid (blue dashed square) used for analyses. CEOD1, CEOD2, CENE, and JUNE correspond to the tree-ring chronologies (Table S1). Precipitation stations are Satipo (S), Huayao (H), Chilcayoc (C), and Granja Kcayra (GK); hydrometric station is Tamshiyacu (T). The gray shaded areas are the different provinces in which tree-ring chronologies and stations are located: Ucayali (CEOD1), Junín (CEOD2, CENE, and JUNE; S, and H), Ayacucho (C), and Cusco (GK). The blue polygon in the South American map marks the Amazon Basin. (b) Ombrothermic diagram of Satipo weather station for the periods 1990–2009. The hydrological year in Peru is from September (year  $t$ ) to August (year  $t + 1$ ). (c) Validation of GPCP precipitation product (blue line) with instrumental data from the five stations shown in (a). Values have been normalized to analyze the variation of GPCP rainfall against different magnitude data. Pearson's correlation values between November–October annual precipitation from instrumental stations and GPCP data are significant (\*) at  $p < 0.05$ .

scarce in the Amazon Basin, both in distribution and in length (Espinoza-Villar et al., 2009; Marengo, 2006). The closest weather station to our study area is in the city of Satipo (located 80 km away from the Andes Range) with rainfall records from 1990 to 2009.

An extensive search through the National Service of Climatology and Hydrology of Peru (SENAMHI) confirms the lack of climatic stations near the study site. We, therefore, used a gridded product as an alternative: the Global Precipitation Climatology Project (GPCP v2.3) rain gauge and satellite-merged data, which provides continuous monthly precipitation records on a global  $2.5^\circ \times 2.5^\circ$  grid for the period 1979 to the present (Adler et al., 2018), with proven reliability over the study region (Hurley et al., 2015). We selected the grid encompassing the  $10\text{--}12.5^\circ\text{S}$  and  $72.5\text{--}75^\circ\text{W}$  region (extracted from the KNMI Climate Explorer; <https://climexp.knmi.nl/>). This area contains three of the four sampling sites, and the remaining one, CENE, is located  $<20$  km away from the boundary of the GPCP grid. The selected GPCP grid was compared to Satipo weather station (656 m, 1990–2009 common period) and with other available weather and hydroclimatic stations as Huayao (3,350 m), Chilcayoc (3,412 m), Granja Kcayra (3,219 m), and Tamshiyacu (95 m) (Table S2), located farther away from the study region (Figure 1c). These stations are not as close as Satipo (the only station used as input for GPCP grid) but were used to validate the regional variability of the GPCP product.

## 2.2. Tree-Ring Analyses and Precipitation Reconstruction

The species sampled in this study were *Cedrela odorata*, *Cedrela nebulosa*, and *Juglans neotropica*, collected in primary forests of the Central Andes of Peru (Table S1). *C. odorata* (CEOD1, CEOD2) and *J. neotropica* (JUNE) samples were collected in 2010, while *C. nebulosa* (CENE) collection was made during 2016. Samples were processed following standard dendrochronological methods (Stokes & Smiley, 1968), dated following the Schulman (1956) convention and measured with a precision of 0.001 mm. The visual dating was statistically checked with the program COFECHA (Holmes, 1983), and tree-ring width series were standardized with the program ARSTAN 41 (Cook & Krusic, 2005) by applying negative exponential curves or linear regression with negative or zero slopes to remove nonclimatic effects (Fritts, 1976). The Expressed Population Signal (EPS) and Rbar statistics are reported to evaluate the quality of the chronologies (Briffa, 1995) (Table S1).

Simple correlation analyses were computed between the four independent tree-ring chronologies (at years  $t$ ,  $t + 1$ , and  $t + 2$ , to account for possible tree-growth delayed responses to climate) and monthly precipitation from the GPCP data set following the methods described by Fritts (1976). The period from November (year  $t$ ) to October (year  $t + 1$ ) showed the highest correlations with tree-ring chronologies and was subsequently selected as a reconstruction target. Following the Schulman (1956) dating convention for the Southern Hemisphere (where the year ( $t$ ) in which the ring formation begins is assigned as that ring's calendar year), each year ( $t$ ) for the instrumental November–October precipitation series is composed by parts of two consecutive calendar years: year ( $t$ ) = [(Nov–Dec) $_t$ ] + [(Jan–Oct) $_{t+1}$ ].

A stepwise multiple regression model was applied to develop the precipitation reconstruction by regressing the November–October precipitation with tree-ring chronologies. To maximize the final length of our reconstruction, we used a nested approach by which the shorter chronologies already used for reconstruction were excluded from the regression analyses to produce a longer reconstruction with the remaining series (Cook et al., 2004; Meko, 1997). A period of either 29 (1979–2007) or 32 years (1979–2010) was used to calibrate each reconstruction model using the “leave-one-out” cross-validation procedure (Meko, 1997; Michaelsen, 1987). Each model had its own calibration period. The lengths of the four independent chronologies are different, thus the resulting precipitation reconstruction (Model 1, Table 1) developed with all the chronologies was limited by the initial year of the shorter one (CENE, 1883) and the final year of CEOD2 and JUNE (in 2009). As we allowed the use of these predictors lagged at  $t + 1$  and  $t + 2$ , the selection of JUNE at  $t + 1$  as a predictor limits the final year of Model 1 to 2008. We developed a second model which allowed extending the reconstruction back to 1794 using the chronology CEOD2 (Model 2, Table 1). However, we discarded the first 23 years from this second reconstruction because of the large changes in variance related to the poor sample depth in those early years. Finally, we added two more years to the reconstruction (Model 3, Table 1) in order to extend it to recent years, without losing predictive ability with the model. To generate the final nested reconstruction, we spliced together the segments from each model, adjusting their variance to that of the best replicated model (Model 1). The explained variance between observed and predicted values for each model was assessed by the coefficient of determination adjusted for loss of degrees of freedom  $R^2$  ( $R^2_{\text{adj}}$ ). We computed the reduction of error (RE) statistics (Cook et al., 1994; Fritts, 1976) to account for the relationship between the actual value and its estimate. The root mean square error of validation (RMSEv; Weisberg, 1985) and the standard error of estimate (Se) were calculated as an estimate of the uncertainties of the reconstructions; Durbin-Watson test (Ostrom, 1990) determines the degree of autocorrelation of the residuals. The variance inflation factor (VIF) was used to evaluate the possibility of multicollinearity in the predictors (Ostrom, 1990): a VIF close to 1 means low or no multicollinearity (Haan, 2002).

## 2.3. Identification of Hydroclimatic Variability, Cycles, and Large-Scale Climate Forcings

To detect precipitation trends within the tree-ring based reconstruction, we estimated the recurrence rate of drought ( $\leq 10$ th percentile) and pluvial ( $\geq 90$ th percentile) events utilizing a kernel estimation technique with a Gaussian function and 50-year bandwidth. This procedure allows the detection of nonlinear and non-monotonic trends without imposing parametric restrictions, and a smooth kernel function produces a more realistic estimation of drought and pluvial recurrences. We calculated a confidence interval at the 95% level based on 2,000 bootstrap resampling steps (Cowling et al., 1996) to estimate the bias and variance properties of drought recurrence in the reconstruction. The kernel estimation, bandwidth selection, and bootstrap algorithm were computed in the free R Project platform software (R Core Team, 2016). To assess the intervals of

**Table 1**

Calibration and Verification Statistics for the Three Independent Models That Constitute the Final Nested Reconstruction, Where  $R^2$  Stands for the Square of the Multiple Correlation Coefficients and  $R^2_{adj}$  is Adjusted to the Loss of Degrees of Freedom

Model	Predictors (chronologies)	Calibration period	$R^2/R^2_{adj}$	Se	DW	RE	RMSEv	Reconstructed period
1)	CEOD1, CEOD2, CENE, JUNE	1979–2007	0.73/0.68	93.15	1.92	0.60	100.51	1883–2008
2)	CEOD2	1979–2007	0.38/0.30	134.79	2.28	0.26	136.64	1817–2007
3)	CEOD1, CENE	1979–2010	0.53/0.44	124.14	2.20	0.22	144.67	1883–2010

Note: Se for standard error of estimate; DW for the Durbin-Watson statistics; RE for the reduction of error; and RMSEv for the root mean squared error of validation.

low and high precipitation, we ranked periods of 1, 5, and 10 years according to their departure from the mean. The lengths of the windows were defined to provide a wider context for the occurrence of droughts and pluvials.

Spectral analyses were applied to identify the main oscillatory variability in the reconstruction. The multi-taper method (MTM; Mann & Lees, 1996) was used to extract the cycles that explained the significant percentage of variance using continuous wavelet transform (WT) analysis (Grinsted et al., 2004). The WT localizes changes in the periodicities across the reconstruction. The decomposition of the reconstruction's main oscillatory modes was developed using Singular Spectral Analysis (SSA; Vautard & Ghil, 1989). To measure the common variance as a function of frequency, we conducted coherence spectral analyses (Jenkins & Watts, 1968) between the reconstructed precipitation, the mean November–October Niño 3.4 SST (1950–2010 period) and the mean November–October AMO index (1854–2010 period). The AMO index (Huang et al., 2017) was extracted from <https://climexp.knmi.nl/>. Additionally, we correlated our reconstruction with several ENSO indexes from different Pacific regions (see Table S3). Niño indexes were extracted from <https://www.psl.noaa.gov/data/climateindices/list/>.

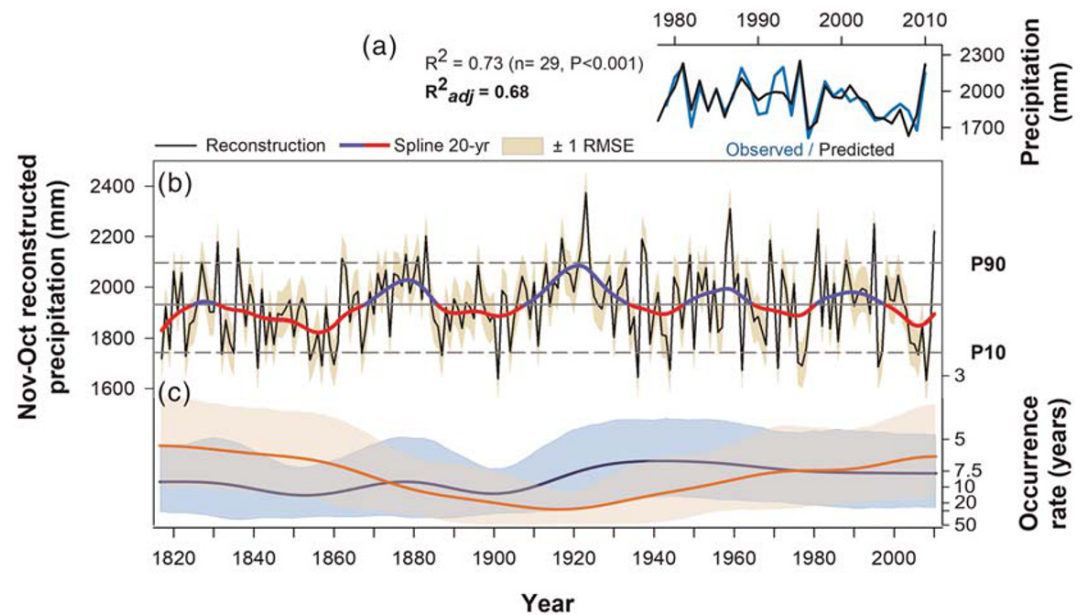

Spatial correlation patterns between SST (GISSTv2.2 data set; Kalnay et al., 1996) and the reconstructed precipitation were conducted to identify the large-scale modes of climate forcings over our study area. The spatial correlation between the reconstructed precipitation and the outgoing longwave radiation (OLR) was also calculated to identify the areas of deep convection over South America that influence on tropical montane Andes precipitation. Additionally, the reconstructed precipitation data were compared with the continental precipitation gridded data set from the Climatic Research Unit (CRU TS v4.01) to assess spatial representativeness of the signal captured by the reconstruction. The NCEP-NOAA data available at the Physical Sciences Laboratory webpage were used to conduct the spatial correlation analyses (<https://www.esrl.noaa.gov/psd/data/correlation/>).

### 3. Results

#### 3.1. Precipitation Reconstruction and Recurrence of Dry and Wet Events

The GPCP-gridded product presents significant correlations with stations located in or near the grid (Satipo:  $r = 0.79$ ,  $p < 0.05$ , Huayao:  $r = 0.54$ ,  $p < 0.05$ ) (Figure 1c). The stations located above 3,400 m (Chilcayoc:  $r = 0.49$ ,  $p < 0.05$ ) or farther away from the study area (Granja Kcayra:  $r = 0.43$ ,  $p < 0.05$ ) show lower (but still significant) correlations with precipitation from this GPCP grid. Interestingly, the correlation between GPCP and streamflow data from Tamshiyacu hydrometric station ( $r = 0.57$ ,  $p < 0.05$ , periods 1984–2017) at the Amazon River (located in Iquitos, at 850 km from our study site) was comparable to the correlations with stations located in the vicinity of the study area.

Tree-ring width chronologies show good replication and intercorrelation among radii (Rbar); EPS mean values above 0.85 indicate that the internal variance in each chronology corresponds to a common signal (Table S1). The comparison between the reconstruction models and GPCP precipitation suggests high skills for reconstructing precipitation for the November–October period, accounting for ( $R^2_{adj}$ ) 68% (1883–2008, Model 1), 30% (1817–2007, Model 2), and 44% (1883–2010, Model 3) of the precipitation variability during the calibration period (Table 1). The (lower) standard errors of the estimate (Se) are consistent with the (higher) skills in the regression models. According to the Durbin-Watson test, the residuals of the regression models are not significantly autocorrelated (DW = 2). The three models successfully passed the verification process (positive RE and significant RMSEv), which implies significant predictive accuracy of tree-ring

**Figure 2.** Tree-ring based reconstruction. (a) Comparison between GPCP (blue) and tree-ring reconstructed (black) rainfall for the 1979–2010 period. The coefficient of determination ( $R^2$ ) and adjusted by degrees of freedom ( $R^2_{adj}$ ) show significant positive correlations between the GPCP precipitation and tree-ring precipitation reconstruction. (b) Reconstruction of the yearly (November–October) precipitation variations in the Amazonian Andes of Peru. This nested tree-ring based reconstruction covers the 1817–2010 period. Mean (1,930.9 mm, solid gray line), 90th (2,096.8 mm), and 10th (1,742.5 mm) percentiles (P90 and P10, dashed lines) are shown for reference in the reconstruction. The shaded area stands for the  $\pm 1$  root mean square error (RMSE), which estimates the uncertainty of the reconstructed series. A 20-year smoothing spline was used to emphasize the low frequency above (blue) and below (red) the mean. (c) Occurrence rate (in years) of severe dry (red) and wet (blue) events for the precipitation reconstruction over the Amazonian Andes of Peru for the last two centuries, calculated for the 10th and 90th percentile thresholds, respectively. Shaded areas represent 95% confidence intervals.

chronologies to infer past changes in precipitation. Additionally, the tree-ring chronologies' VIF, when used as predictors for the reconstructed period, had an average value of 1.23, indicating independence (low correlation) among chronologies.

4	1981 (2,229.33)	1879–1883 (2,058.76)	1980–1989 (1,993.11)
5	2010 (2,220.36)	1979–1983 (2,022.06)	1924–1933 (1,981.47)

*Note:* The precipitation for the 5- and 10-year periods was obtained using a moving average, selecting the highest and lowest events with no overlapping years (1-year overlap was allowed in the 10-year period).

The final nested reconstruction covers the periods 1817–2010 AD and shows important interannual to multidecadal variability throughout the past 194 years for precipitation (November–October,  $R^2_{adj} = 0.68$ ,  $p < 0.001$ ) over the Amazonian Andes of Peru (Figure 2a). The reconstruction presents several multidecadal periods of precipitation below and above the average (low-frequency variation in Figure 2b), but a steady drop in precipitation is observed during recent years (Figure S1), which is also reflected in the negative trend and persistent dry years in the instrumental and GPCP precipitation series (see Figure 1c). The analysis of drought and pluvial occurrences (Figure 2c) reveals that the recurrence of dry years was higher during the 1817–1870 period, with a return interval of about 7 years for droughts below the 10th percentile. A second jump in drought ( $<P10$ ) recurrence every 7–8 years is seen in recent decades, suggesting an increasing trend in drought occurrence from ~1975 to the present. On the contrary, the frequency of pluvials was high from 1880 and especially in the first decades of the 20th century (1910–1940). However, the recurrence of high rainfall is decreasing in recent decades as the frequency of drought events tends to be higher.

**Figure 3.** Oscillatory modes of variability in the precipitation reconstruction. (a) Spectral analysis of the reconstruction. Significant main modes are labeled above the 99% and 95% confidence band. (b–d) Significant oscillatory modes of precipitation variability estimated by Singular Spectral Analysis (SSA). (e) The continuous wavelet transform of our precipitation reconstruction using a Morlet adjustment. Thick black contours indicate spectral signals at 95% significance level using the red noise model. Areas outside the cone of influence are shown in a lighter shade.

The intervals of low and high precipitation were grouped into periods of 1, 5, and 10 years and ranked according to their severity from 1 to 5 (Table 2). Extreme 1-year droughts appear well distributed throughout the 20th century (1901, 1936, 1944, 1962, and 2008). Nevertheless, the years within the decade 2000–2009 rank first in the 1- (2008) and 5-year (2004–2008) period and second in the 10-year (2000–2009) period, indicating that the last decade has been the driest in the 194-year precipitation reconstruction. The period 1970–1979 also appears in the ranking as the top third (5 year) and fourth (10 year) of the driest years. On the other hand, three out of the five wettest single events recorded by the reconstruction appear during the last two decades in the years 1981, 1995, and 2010. The interval between 1915 and 1933 ranks several times as the wettest 5- (first, third, and fifth) and 10-year (first and fifth) periods, confirming that many of the highest pluvials occurred during the first half of the 20th century.

### 3.2. Interannual and Multidecadal Variability and Large-Scale Climatic Forcings

The spectral analysis MTM indicates that the precipitation reconstruction over the Amazonian Andes of Peru contains significant signals of variability at interannual to multidecadal scales over the past 194 years, with quasi-periodicities at 2.5, 5.1, and 41.6 years (Figure 3a). Using the SSA, we found that these quasi-cycles explain 8%, 8.4%, and 13.1% of the total variance, respectively (Figures 3b–3d). The wavelet analysis shows significant periodicities across the precipitation reconstruction with most significant oscillatory modes associated with interannual variability (2–7 years) during the 1940–2000 period, and a strong and significant multidecadal variability (40–60 years) between 1850 and 1975 (Figure 3e).

We explore possible relationships between our reconstruction and ENSO indices from different Pacific Ocean regions. Pearson  $r$  coefficients of  $-0.34$  were obtained between Niño 1 + 2 and Niño 3 regions for the periods 1950–2010 (critical  $r = \pm 0.252$ ; 95% confidence level). In addition, significant  $r$  Pearson coefficient of  $-0.31$  was obtained for the same period but using the Niño 3.4 region. Given the similar correlations, we performed further analyses with Niño 3.4 index. More details about correlations between our reconstruction and several ENSO indexes are summarized in Table S3.

Coherence spectral analyses indicate that the November–October precipitation reconstruction captures interannual to multidecadal variability, with significant values (Figure 4). These bandwidths con-

tain the largest proportion of the reconstructed variance as shown above.

The Pearson correlation field between SST and our reconstruction for the 1950–2010 period shows a clear ENSO-like pattern across the Pacific Ocean, with significant and negative correlation values between the precipitation reconstruction and SSTs in the tropical Pacific Region (Figure 5a). SST correlations display the typical west-east gradient along the Equator, reaching maximum values in the vicinities of the South American coasts of Colombia, Ecuador, and northern Peru (Tedeschi et al., 2013). Above- (below) average temperatures in the tropical Pacific Ocean (coherent with El Niño [La Niña], the warm [cool] phase of ENSO) result in below- (above) average precipitations in the tropical Andes of Peru (Garreaud et al., 2009; Sulca et al., 2018). Another important factor influencing rainfall is brought by the significant and negative correlations between our precipitation reconstruction and the tropical north Atlantic Ocean temperatures (Figure 5a), suggesting that other sources of variability such as the intertropical Atlantic SSTs may have

**Figure 4.** Cross-spectral coherence computed between the precipitation tree-ring reconstruction (TR rec) and Niño 3.4 SST (above) and AMO index (below). Horizontal lines indicate the 99 and 95% confidence intervals. Precipitation reconstruction and Niño 3.4 SST are in phase and highly coherent at a period between 2.5 and 3 years (above 99% also indicated by shading), while the precipitation reconstruction and AMO index are in phase at a period of ~37 years (approaching 95%, indicated by shading).

an important influence in the rainfall of the study region. On the other hand, the main moisture source over the Yungas montane forests is the tropical lowlands east of the Andes, as revealed by the OLR correlations over the Amazon Basin (Figure 5b). As OLR is used to distinguish areas of deep tropical convection (Liebmann & Smith, 1996), negative (positive) correlations indicate higher (lower) cloud cover, and thus precipitation, over the area.

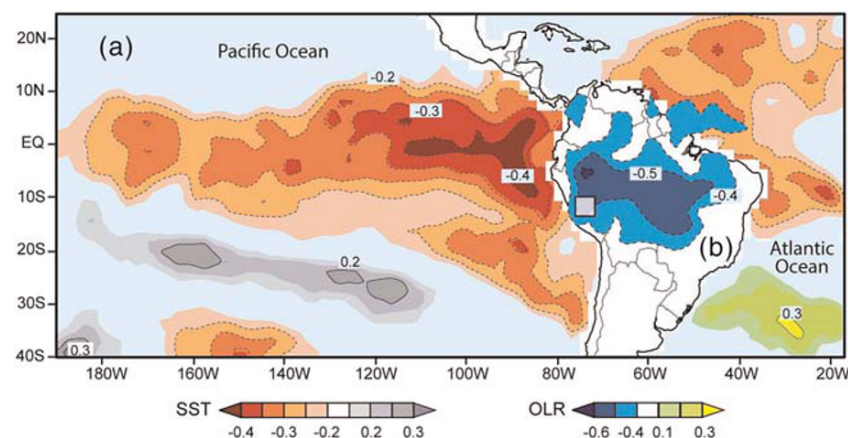

We evaluate the spatial correlation between the observed (GPCP) and reconstructed tropical Andes precipitation with gridded ( $0.5^\circ \times 0.5^\circ$ ) November–October precipitation from the University of Delaware data set (U. Del; Willmott & Matsuura, 2001) over tropical and subtropical South America ( $12^\circ\text{N}$ – $35^\circ\text{S}$ ; Figure 6). The two spatial correlation maps show significant positive correlations across the central tropical Andes in Peru, thus corroborating the spatially coherent signal of precipitation over the region, as obtained by comparing the GPCP precipitation with data from a network of climatic and hydro-metric stations (Figures 2a–2c). Furthermore, there are positive correlations across a large area in the Amazon Basin as well as over Bolivia and northern Argentina (distinct in Figure 6b). The maps also show negative correlations over the coasts of Ecuador and northern Peru, the Amazon lowlands in northeastern Peru, as well as eastern Brazil and southeastern South America, which correspond to the SACZ see-saw activity region (Diaz & Aceituno, 2003). It is worth noting that the correlation coefficients between the U. Del-gridded precipitation

and the GPCP observations (Figure 6a) show comparatively lower values than those for the precipitation reconstruction (Figure 6b) due to the different temporal window used for the correlations (32 vs. 61 years, respectively). Even though Figure 6b shows larger areas of spatial correlation, both maps are capturing the general circulation pattern of the monsoon precipitation over South America.

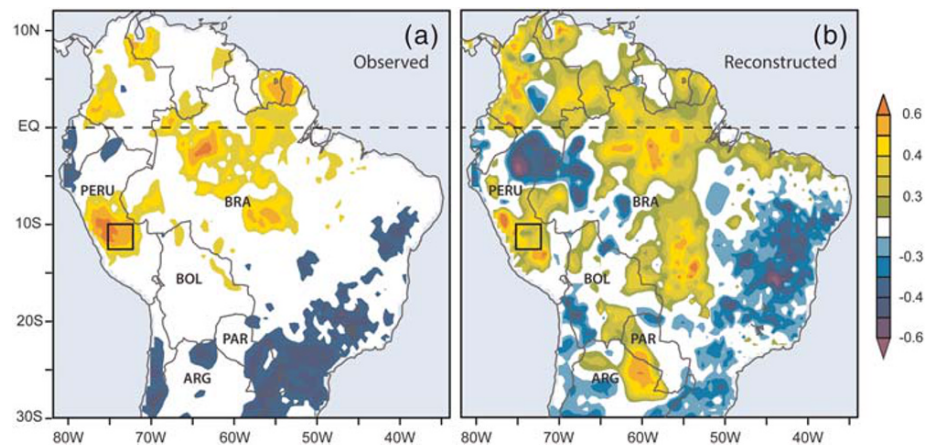

## 4. Discussion

### 4.1. A New Precipitation Reconstruction for the Tropical Andes

We report here the first annually resolved precipitation reconstruction for the tropical Andes of Peru based on growth rings of *C. odorata*, *C. nebulosa*, and *J. neotropica* tree species, extending the short instrumental

**Figure 5.** Spatial correlation field between annual (November–October) tree-ring precipitation reconstruction with (a)  $2.5^\circ \times 2.5^\circ$  gridded averaged November–October sea surface temperature (SST) over the equatorial Pacific and tropical Atlantic oceans for the 1950–2010 period and (b) outgoing longwave radiation (OLR) over South America during the 1979–2010 period. Significant correlations ( $p < 0.05$ ) are outlined for negative (dashed lines) and positive (solid lines) values. The reconstructed precipitation region is indicated by the square over Peru.

**Figure 6.** Spatial correlation field between the annual (November–October)  $0.5^{\circ} \times 0.5^{\circ}$  gridded precipitation data (University of Delaware, U. Del) over South America and (a) GPCP November–October series used for the reconstruction (1979–2010 correlation period), (b) the November–October tree-ring reconstructed precipitation (1950–2010 correlation period). Only significant correlations ( $p < 0.05$ ) are shown. The reconstructed precipitation region is indicated by the square over Peru. Countries acronyms are BRA = Brazil, BOL = Bolivia, PAR = Paraguay, and ARG = Argentina.

record (1979–2010) back to 1817. Our composite reconstruction, which covers the last 194 years (1817–2010) of hydroclimatic variability, is based on 120 tree-ring width series with measures of dendrochronological quality (Table S1) comparable to those reported for similar species in the subtropical Andes (Ferrero et al., 2015). The final nested precipitation reconstruction has good verification and calibration statistics. The most replicated model explains 68% of the total variance, which is higher than other precipitation reconstructions in tropical South America. Previous hydroclimatic reconstructions developed in northwestern Argentina (Ferrero et al., 2015), southern Ecuador (Pucha-Cofrep et al., 2015), southern Bolivia (López et al., 2017), eastern equatorial Brazil (Granato-Souza et al., 2018), and eastern Brazil (Pereira, 2018) typically accounted for 35–54% of precipitation variability during calibration periods. This new reconstruction extends the dendroclimatological studies from the subtropical Andes of Argentina into the montane tropical environments of South America.

The use of the GPCP precipitation product responds to the lack of instrumental data for the area except for a single station located in Satipo, with complete data only available starting in 1990. This data shortage constitutes one of the main limitations for the use of traditional precipitation reconstruction procedures. The use of the leave-one-out technique is especially useful for short instrumental data sets in palaeoclimatic studies (Barria et al., 2018). Despite this limitation, the GPCP-gridded data are significantly correlated to meteorological stations throughout the area and the gauge station located several hundred kilometers away in the Amazon River. Thus, the hydroclimatic signal displayed by GPCP precipitation-gridded product shows a spatial pattern representative of large tropical Andean Basins.

#### 4.2. Frequency of Drought and Pluvials

The precipitation reconstruction shows decadal to multidecadal variations with several below- and above-the-mean precipitation intervals (Figure 2b). The observed dry and wet periods identified in the reconstruction are in agreement with previous studies developed for the Amazon Basin. The earliest drought period registered in our reconstruction from 1817 to the 1870s has been described by Jenkins (2009) as occurring between 1817 and 1850 based on a 189-year *Cedrela* chronology (1817–2006) located in southeastern Peru (Madre de Dios Region). The rainfall reconstruction based on the Cascayunga Cave speleothems from northeast Peru ( $6^{\circ}05'S$ ,  $77^{\circ}13'W$ , 930 m) shows a steady decrease in rainfall values from the 1800s with a noticeable drop around the 1840s (Reuter et al., 2009). In addition, a sediment record from Lake Limón located in the western Amazon Basin of Peru ( $6^{\circ}43'S$ ,  $76^{\circ}14'W$ , 600 m) shows that rainfall at the beginning of the 19th century was below the mean until approximately 1875 (with heavy droughts around 1820 and 1840) (Parsons et al., 2018). After 1875, the precipitation signal in the lake record continues to increase, and authors describe a continuous wet period from 1900 to 1940–50 in their lake sediment records. This coincides with

the low-frequency patterns observed in our precipitation reconstruction with the period approximately 1920–1930 and 1950–1960 as the wettest recorded in our tree-ring records (see Table 2).

Frequency analyses of severe events over our precipitation reconstruction (Figure 2c) reveal that high precipitation events (above the 90th percentile) occurred from the 1880s to 1970, with a peak in the occurrence of very wet events from 1930 to 1950. On the other hand, severe low precipitation events (below the 10th percentile) were recurrent from 1817 to 1870 and again from 1980 to the present. This drying trend in recent decades is recorded during the years 2000–2009, as the top dry period in our precipitation reconstruction (Table 2). Marengo and Espinoza (2016) suggested that there is a general decrease in the precipitation trend in the Amazon Basin, probably related to the increase of interannual variability. The occurrence of precipitation events below the 10th percentile recorded in our reconstruction has increased from 7 to 8 years during the last two decades, but three events of very high precipitation have been registered in the last years (1981, 1995, and 2010; Table 1). This intensification in the interannual variability has been recorded across the Amazon, yet with different magnitudes and even opposite signs given the size of the basin and heterogeneous climate responses. For instance, Barichivich et al. (2018) found for the Amazon River that the frequency of severe floods over the 1903–2015 period has increased from one extreme flood every 20 years during the first half of the 20th century to one about every 4 years from the 2000s to the present.

### 4.3. Precipitation Reconstruction and Atmospheric Circulation Linkages

Most droughts recorded in our reconstruction and the region can be linked to El Niño episodes or tropical warm North Atlantic conditions (Jimenez et al., 2019; Marengo et al., 2016). For the Peruvian Amazon-Andes Region, Lavado Casimiro et al. (2013) demonstrated that rainfall is less abundant during El Niño (and more abundant during La Niña). Sulca et al. (2018) showed that during El Niño events, the dominant feature is the reduction in precipitation in the tropical Andes of Bolivia, Peru, and Ecuador. The dominant oscillatory modes in our tropical Andean precipitation reconstruction show major wavelengths at 2.5 and 5.1 years (16.4% of the total explained variance in precipitation) and are consistent with the classical ENSO band (2–8 years; Deser et al., 2010). We confirmed the high significance of this annual mode of variability with cross-spectral analysis between our tree-ring reconstruction and Niño 3.4 index (Figure 4). The amplitude of this component varies over the reconstruction with significant signal from 1940 onwards (Figure 3e). The annual spectral characteristics have been described for tree-ring hydroclimatic records in the Andes, where ENSO plays an active role in modulating local climate (e.g., Altiplano, Morales et al., 2012; northern coastal Peru, López et al., 2006; temperate-Mediterranean Chile, Christie et al., 2011) and these nonstationary periodicities have been previously reported in ENSO reconstructions (Li et al., 2013).

Pacific SST anomalies associated with ENSO play a primary role in modulating the interannual intensity of precipitation over the tropical Andes (Lavado Casimiro et al., 2013). Our precipitation reconstruction is significant and negatively correlated to SSTs, showing a clear ENSO-like pattern with higher correlation in the equatorial eastern Pacific Ocean (compatible with eastern ENSO; Figure 5a). Sulca et al. (2018) documented that reduced rainfall in the eastern Andean slopes of Peru is more associated with surface warming in the eastern equatorial Pacific and westerly wind anomalies. During summer, a high-pressure system (the Bolivian High; Silva Dias et al., 1983) allows the entrance of moist air influx from the Amazon Basin onto the central Andes, feeding convective storms and producing precipitation. However, this system is quite variable and tends to weaken in response to suppressed convective activity over the Pacific Ocean (i.e., related to El Niño) (Sulca et al., 2016). Sulca et al. (2018) also showed that warm ENSO phases in the eastern equatorial Pacific are negatively correlated with precipitation along the “rainfall hotspots” in the eastern Andean slopes of southern Peru (our study area), Bolivia, and adjacent Amazon plains. On the contrary, enhanced precipitation prevails along the coasts of Ecuador and northern Peru as well as in the northeastern Amazon of Peru. These results are expressed by the correlations between U. Del continental gridded precipitation, GPCP precipitation (Figure 6a), and our tree-ring precipitation reconstruction (Figure 6b) showing the same spatial patterns of precipitation related to El Niño events. The spatial correlation between OLR and the tree-ring reconstruction (Figure 5b) is higher over the monsoon core region where deep convection is established during the mature phase of the SAMS (Vuille et al., 2012) and also over the western Amazon Region where precipitation increases in the eastern slopes of the Andes (Espinoza-Villar, Ronchail, et al., 2009). The above is consistent with the spatial precipitation pattern over the Amazon and along the eastern Andes from Peru to

northern Argentina (as in Figure 6b) coinciding with the SALLJ region. This moisture transport is linked with an opposite sign anomaly (also observed by Sulca et al., 2016) over eastern South America and the adjacent Atlantic Ocean (as reflected by the positive OLR values in Figure 5b, and consequently reduced precipitation) associated with the SACZ activity, the other major feature of the South American monsoon.

Rainfall variability in the Andean-Amazon Region area, however, is not fully explained by ENSO events (Jimenez et al., 2019; Joetzjer et al., 2013; Yoon & Zeng, 2010). According to Zhou and Lau (2001), the second mode of summer rainfall variability over South America displays a significant signal over the Atlantic and varies at decadal time scale; Chiessi et al. (2009) showed with marine sediment records that Atlantic SST variations play a significant role in modulating multidecadal SAMS variability. The second oscillation which appears in our precipitation reconstruction is a long-term waveform centered at 41.6 years (Figure 3). Previous studies indicated that changes in the Atlantic SST variability reflect a low-frequency mode at 65–80 years, the AMO (Enfield et al., 2001). Cross-spectral coherence computed for our tree-ring reconstruction and AMO index (Trenberth & Shea, 2006) shows that both records are in phase at a period of ~37 years (Figure 4). The ~40-year mode in our tree-ring reconstruction is similar to the dominant mode of variability reported from a tree-ring AMO reconstruction bordering the North Atlantic (~42.7 year; Gray et al., 2004), and the Bosumtwi lake records used to reconstruct the Western African monsoon were related to AMO variations (33–42 year; Shanahan et al., 2009) (see our Figure S2).

SST fluctuations in the tropical Atlantic appear to be an important forcing for rainfall fluctuation in the upper Andean basins of the Amazon in Peru. Lavado Casimiro et al. (2013) showed that when the northern tropical Atlantic is warmer than the southern, the Amazon-Andes in Peru receive less water vapor than usual, resulting in reduced rainfall. Yoon and Zeng (2010) also showed that positive (negative) temperatures over the tropical North Atlantic (EQ to 20°N) are negatively (positively) correlated with interannual variability of Amazon Rainfall. This oceanic region coincides with the area displaying significant (and opposite) correlations with our precipitation reconstruction for a 50-year period (Figure 5a). A warm anomaly in the north Atlantic and a weak cold anomaly in the South Atlantic draw the rainfall belt northward, leading to subsidence (low precipitation) over the southern and western Amazon Basin (Cox et al., 2008; Marengo & Espinoza, 2016). Hua et al. (2019) also show for the period 1950–2017 that Amazon precipitation anomalies and negative correlation between the Atlantic north-south gradient are stronger when considering decadal to multidecadal scales ( $-0.87$ ,  $p < 0.01$ ), which at the time are highly correlated with the AMO. Moreover, Jones and Carvalho (2018) demonstrate that during 1900 and 2010, the AMO phases produce periods of high/low SALLJ activity on the eastern slopes of the Andes, linked to precipitation anomalies in decadal to multidecadal scales. Many prominent features in global climate multidecadal variability have been related to AMO (Knight et al., 2006); the multidecadal signal of ~40 years found in our high-resolution tree-ring reconstruction can contribute to the interpretation and understanding of the role of the tropical Atlantic and long-term modulations on the monsoon dynamics on the Andes and tropics of South America.

## 5. Conclusions

Tropical Andean forests provide water storage and can sustain the demand for water in broader regions (Bruijnzeel et al., 2011). The capacity to dampen flows and release water during dry seasons can provide a continuous supply to downstream areas (Immerzeel et al., 2019). The upper basin of the Peruvian Amazon is highly dependent on the precipitation concentrated during the spring-summer season. Intense precipitation events can cause flooding and landslides, but drought events can result in major loss of economic (i.e., agriculture) activities (Rodríguez-Morata et al., 2018; Young & León, 2009). The precipitation dynamics in the tropical Andes are changing due to rapid global warming and increasing human pressure on the environment. These changes not only affect biodiversity and forest conservation but also increasingly affect local population's demand for water. We developed a multicentury perspective for the precipitation variability in the tropical Andes-Amazon Region of South America, an area that lacks reliable instrumental data to evaluate long-term climatic variations. The new 194-year long tree-ring based precipitation reconstruction provides new information on the dynamics and behavior of the South American monsoon at high and low frequency. Dry and wet interannual and decadal periods, recorded in instrumental data and by proxy records developed for the region, were identified in our precipitation reconstruction. ENSO is a key modulator of Andes-Amazon climatic interannual variability, and our reconstruction also indicates that

conditions related to multidecadal changes in the Atlantic temperatures have modulated extended wet and dry periods of precipitation in the tropical Andes.

The hydroclimate information captured by our high-resolution precipitation reconstruction can identify the main large-scale climatic forcings that have influenced precipitation at interannual-to-multidecadal scales over the Andes-Amazon Region during the past two centuries. Our reconstruction is capturing the main features of the monsoon system dynamics over tropical and subtropical South America. The record showed here emphasizes the need for sampling long-lived tree specimens along the tropical Andes. The annual resolution of the growth rings and the high sensitivity to climate reflect with great detail the temporal variations and spatial patterns of instrumental series. This allows us to characterize climate on annual time scales for almost 200 years. The expansion of dendrochronological networks in the mountain tropics and the development of additional tree-ring derived proxies (i.e., stable oxygen and carbon isotopes) can help improve our understanding on the precipitation variability and South American monsoon dynamics along the Andes and neighboring regions. Historical land-surface changes in montane forests, recent large burning events in the Amazon, and their resulting effects on the hydrological cycle in the sub/tropical Andes regions are yet to be assessed.

## Data Availability Statement

Climatic and tree-ring data sets analyzed and/or generated in the study are available at <http://www.cr2.cl/datos-dendro-amazonas-peru/> and upon request from the authors (mferrero@mendoza-conicet.gob.ar; ere-quina@continental.edu.pe).
