Abstract

Modelling gas adsorption of porous materials is nowadays an undeniable necessary in order to complement experiment findings with the purpose to enrich our fundamental understanding of adsorption mechanisms as well as develop better performing materials for gas mixture separation. In this contribution, we explore the possibility to use first-principles molecular dynamics (FPMD) and grand canonical Monte Carlo (GCMC) simulations to target the gas adsorption of disordered nanoporous chalcogenides (*i.e.* chalcogels). This computational scheme allows us to take advantage of the ability of FPMD to accurately describe the structure and bonding of the disordered nature of chalcogels as well as the potential of GCMC to model the adsorption mechanisms of porous networks. We assess the versatility of such scheme by evaluating the role of pore size, chemical stoichiometry and composition for multiple chalcogenide-based systems on nitrogen adsorption isotherms.

Keywords: first-principles molecular dynamics, porous materials, chalcogel, gas adsorption, grand canonical Monte Carlo, chalcogenide glasses

1. Introduction

The development of porous materials for gas adsorption, separation and purification is central to many energy and environmental applications.[1] A great deal of progress has been made over the last decades in this field and many different porous materials have been studied for gas adsorption including metal-oxides [2, 3, 4, 5], zeolites [6, 7, 8, 9], porous carbon [10, 11, 12, 13], and metal-organic frameworks (MOFs).[14, 15] Keeping into consideration that the ideal sorbent material needs to show enhanced uptake capacity, high selectivity, easy recyclability, as well as very good structural and chemical stability, the development of porous materials able to satisfy all these requisites still represents a challenge. Porous gels [16, 17, 18, 19] and zeolitic chalcogenides [20, 21] have recently attracted increasing attention in the field of gas adsorption because of their high surface area and the soft Lewis base nature of chalcogen elements (S, Se, and Te).[22]. Unlike nanocrystalline chalcogenides, glassy chalcogels feature amorphous networks similar to those of amorphous silica. While their properties depend on the synthesis conditions, most chalcogels exhibit a high surface area owing to their mesoporous structure (pores from 2 to 50 nm) along with a smaller amount of micropores (< 2 nm) and macropores (> 50 nm).[16, 17, 18, 23, 24, 25] As a result, chalcogels are considered promising alternatives as adsorbent materials for gas transport and separation. However, despite the growing interest

Email address: guido.ori@ipcms.unistra.fr (Guido Ori*)

15 for this class of porous materials, the study of their adsorption properties is still limited.[26, 27, 28, 29] While ad-
16 sorption and transport in porous materials such as zeolites, porous carbon and MOF are relatively well understood,
17 the specific case of chalcogels remains unclear with many questions left unexplained such as the role of the surface
18 chalcogenide chemistry and the specific interactions playing at the gas/solid interface in the confined environment.
19 This arises from a general limitation of the experimental studies of gas adsorption of chalcogels as most methods are
20 unable to detect the features of this buried gas/solid interface. In this respect, molecular modelling has proven to be
21 an efficient technique to investigate the gas adsorption of such porous materials. In few recent works, we resorted
22 on a computational scheme based on first-principles molecular dynamics (FPMD) and grand canonical Monte Carlo
23 simulations (GCMC) to identify the microscopic mechanisms of N₂, CO₂, H₂ and CH₄ adsorption in a prototypical
24 chalcogel made of glassy GeS₂ (*g*-GeS₂ hereafter).[30, 31] With the present contribution we aim to widen this first
25 work and to assess the versatility of such computational scheme to gain insights on the role of pore size, chemical
26 stoichiometry and composition for multiple chalcogenide-based systems on nitrogen adsorption isotherms. Gas ad-
27 sorption of simple fluids such as N₂ at 77 K is a routine technique which allows characterizing the specific surface,
28 porous volume, and pore size distribution of microporous and mesoporous media. This contribution is organized
29 as follows. In a first section, the main advantages of employing FPMD and GCMC simulations within the field of
30 modelling chalcogels are presented. In a second section, as case studies, the role of pore size, chemical stoichiometry
31 and compositions are analyzed and discussed. We critically assess our results by invoking available experimental data
32 before drawing a final set of conclusions and perspectives.

33 **2. Computational methodology**

34 The computational scheme proposed here is based on the employment of FPMD simulations where the electronic
35 structure is described within the framework of the density functional theory (DFT) and it allows to accurately describe
36 the chemistry and bonding of amorphous chalcogenides and GCMC simulations to model the adsorption mechanisms
37 of porous chalcogels. In Figure 1 a schematic cartoon of the four main building blocks of this methodology is
38 presented:

- 39 1. Producing of a chalcogenide glass structural model in quantitative agreement with experimental findings;
- 40 2. Building and refinement of chalcogenide surface models at finite conditions;
- 41 3. Modelling gas adsorption mechanisms of chalcogel with defined porosity;
- 42 4. Detailed analysis of the gas/solid interface chemistry and computation of other properties.

43 Three out of the four building blocks resort to FPMD simulations in order to produce realistic and reliable structural
44 models of glassy chalcogenides as well as being able to accurately describe the chemical interactions involved at

45 the gas/solid interface and compute other electronic properties that might be of interest for specific cases. GCMC
46 simulations are used to model the gas adsorption and isotherms within the porous chalcogenide network.

47 *2.1. First-principles molecular dynamics: quantitative prediction of structure and bonding of bulk disordered chalcogenides and their surfaces*
48

49 In this section we tentatively summarize the reasons of first-principles molecular dynamics (FPMD)[34] combined with density functional theory (DFT) as the computational method of choice for the proper description of the
50 chemistry and structure of disordered chalcogenides. Empirical interatomic potentials, routinely employed in classical MD simulations, are found to generally fail in reproducing the correct chemical behavior for systems other than
51 those characterized by chemically ordered topologies (typical of oxide-based materials) as well as the presence of structural defects such as miss-coordinations and homopolar bonding. Thanks to a proper description of the local
52 electronic structure, FPMD allows instead to face the hurdle of describing the complex interplay between different bonding interactions particular of disordered chalcogenide-based materials, whether liquids or glasses (such as
53 ionocovalency[35] and metavalent bonding[36] among others). Typically, glassy phases are created by means of FPMD mimicking the melt-to-quench process used in the laboratory. Although employing a different time scale with
54 respect to the experiments, FPMD simulations allow nowadays to achieve a quantitative structural description of disordered chalcogenides. This performance, accurately reproducing experimental data, arises from a proper choice of the
55 FPMD computational scheme details such as the type of exchange-correlation (XC) functional, the role of dispersion forces (such as van der Waals (vdW)) and the size and length of the system and simulation trajectory, respectively. For
56 the class of Ge-X based chalcogenide glasses with X being the chalcogen counter-ion (S, Se or Te), the generalized gradient approximation (GGA) scheme together with the XC functional developed by Becke,[37] Yang, and Parr[38]

65 (BLYP) has been found to offer quantitative description (>96%) for multiple structural properties (such as neutron and
 66 X-ray structure factors, total and partial pair correlation functions). This capability arises from the ability of BLYP to
 67 enhance the valence electron cloud localization of the local atomic arrangements with respect to other XC (Perdew,
 68 Becke and Ernzerhof (PBE)[39, 40] for instance).[41] Table I shows the details of the systems considered in the present
 69 work and for which a quantitative agreement with experimental data was found over last few years. The specifics of
 70 the computational methodology employed for each system can be found in the references reported in Table I. The
 71 role of vdW interactions has also be taken into attentive account, especially if the interest is towards the study of the
 72 interactions of chalcogenide surfaces with other chemicals (such as gas or organic molecules). Multiple mathematical
 73 formalisms are available to describe the vdW interactions based on empirical corrections or on first-principles calcu-
 74 lations making use of the electronic structure provided by DFT. However, regarding the specific case of disordered
 75 chalcogenides, a thoughtful choice has to be undertaken with respect to vdW formalism used depending on the type
 76 of system and chalcogen under study.[35, 45, 46] Typically a glass model is obtained by means of FPMD simulations
 77 within about ~100-300 ps of thermal treatment plus few tens of ps of equilibration at the final finite temperature of
 78 interest. This time frame is often statistically adequate to obtain a realistic structural model of the chalcogenide glass
 79 of interest. Longer equilibration time can be eventually needed for the computation of other properties (electronic,
 80 vibrational and thermal). Once the bulk chalcogenide glass model is obtained, the corresponding surface model can
 81 be built by opening to a vacuum space the unit cell box along one direction and properly relax its structure at finite
 82 temperature. This thermal treatment is needed in order allow surface local atomic rearrangements and structurally
 83 relax the atoms at the surface. In so doing, the presence of dangling bonds is reduced to a minimum. Table II shows
 84 the local and average coordinations around the atomic species for the surface models of the chalcogenides targeted in
 85 this work. The reported values are evaluated by considering the whole systems and have been calculated including
 86 neighbors separated by a cutoff corresponding to the first minimum in the partial pair correlation functions. All the
 87 systems considered are mainly made of fourfold coordinated Ge and twofold coordinated X atoms. However, these
 88 surface models show an increase in Ge and X atoms under- and over-coordinations contents at the expenses of the

^a Atomic coordinations are calculated including neighbors separated by a cutoff corresponding to the first minimum of the corresponding partial pair correlation functions. ^b The atomic charges q are calculated by using the Qeq method developed by Rappé and Goddard et al. [47]. ^c Polarizability values are obtained from [48]. ^d Electronegativity values are obtained from [49].

89 fourfold and twofold coordinations with respect to the bulk counterparts. These results show that the surface mod-
90 els show a slightly lower chemical order than the bulk counterparts. It is important to highlight that the decrease of
91 the chemical order degree characterizes the external layers of the surface models (about ~ 7 -8 Å from the surface),
92 whereas in the inner-region the atom species keeps and/or recover coordination distributions typical of bulk models.
93 As an example, the inner-region region of g -GeSe₂ surface model shows a $\sim 73\%$ of Ge atoms fourfold coordinated
94 and $\sim 86\%$ of Se atoms twofold coordinated, which is inline with the contents found in the parent bulk model ($\sim 76\%$
95 and $\sim 93\%$, respectively). Regarding the analysis of chemical bonding, both the electron localization function (ELF)
96 and the maximally localized Wannier functions (MLWF) schemes are nowadays two widely used methodologies to
97 study the valence electron (de)localization and structure and infer on the type of chemical interactions involved in
98 amorphous chalcogenides. As an archetypal example, herein we report the typical information that can be extracted
99 resorting to the MLWF formalism, based on the notion of Wannier functions, the MLWF centers (WFCs) and their
100 spread. This scheme allows to seek further insight into the interplay between atomic structure and electronic proper-
101 ties with respect to the standard information based on the electronic density of states. Recently, we have employed
102 these quantities to rationalize the extent of covalent vs ionic nature of bonding for g -GeS₄, g -GeSe₄ and g -GeTe₄. This
103 has ben achieved by relying on the correspondence between the distances identified in the atom-WFCs pair correla-
104 tion functions ($g_{\alpha\beta}(r)$, with $\alpha = X$ and $\beta = \text{WFCs}$). The data ($g_{XW}(r)$ and WFCs spread) considered in the following
105 discussion can found be found in ref. [41] and [42]. In particular, three types of WFCs can be distinguished in this
106 series of binary glassy chalcogenides. The first type, labeled W_b , represents a clear fingerprint of Ge-X heteropolar

107 bonding and it is identified as the $g_{XW}(r)$ second peak found at about $\sim 0.9 \text{ \AA}$, $\sim 1 \text{ \AA}$ and $\sim 1.25 \text{ \AA}$ for $g\text{-GeS}_4$, $g\text{-GeSe}_4$
108 and $g\text{-GeTe}_4$, respectively. The second type, labeled W_h , refers to homopolar X-X bonding and it corresponds to the
109 typical $g_{XW}(r)$ third peak: W_h is found at about $\sim 1.02 \text{ \AA}$, $\sim 1.18 \text{ \AA}$ and $\sim 1.4 \text{ \AA}$ for $g\text{-GeS}_4$, $g\text{-GeSe}_4$ and $g\text{-GeTe}_4$,
110 respectively. The third type, labeled W_{lp} , refers to lone pair valence electrons not participating directly to chemical
111 bonds but remaining localized in the proximity of the X atoms. Given the above definitions, the locations of the W_b
112 centers with respect to the X atoms can be used to compare the covalency vs ionicity degree of bonding that character-
113 izes these glasses. The relative position of the $g_{XW}(r)$ second peak and the closer location to its origin allow to quantify
114 the greater ionic character of the Ge-X covalent bonds along the serie: $g\text{-GeS}_4 > g\text{-GeSe}_4 > g\text{-GeTe}_4$. This stems
115 from the fact that the centers of valence electronic localization (related to heterogeneous bonding) are systematically
116 closer to the S sites with respect to Ge sites than to the Se and Te sites, respectively. Furthermore, the inspection of
117 the electronic (de)localization degree (spread, ω) of the WFCs with respect to the X-WFCs distance allows to further
118 quantify the degree of polarity of the G-X bonding, which results following the serie Ge-S (higher polarity) > Ge-Se
119 > Ge-Te (lower polarity). These conclusions are found in sound agreement with the expected trends on the basis
120 of Pauling electronegativity scale and polarizability values (see Table II).[49, 48] In particular, the ω values and the
121 extension of its distribution with respect to X-WFCs distances allow to infer about the more softer (more polarizable,
122 i.e. higher polarizability) nature of Te atoms with respect to S and Se atoms.

123 Once the surface model of the amorphous chalcogenide system of interest is produced by means of FPMD simu-
124 lations, its optimized structure can be used to build a slit-like pore by introducing a proper vacuum space with respect
125 to the pore width of interest. However, before switching to GCMC simulations for the study of gas adsorption and
126 isotherms, a suitable set of atomic charges have to be assigned to the atoms of the host porous network. This step,
127 together with the refinement of the chalcogenide glass ' structure, represent the main challenge of the proposed com-
128 putational procedure. Indeed, classical potentials are often unable to describe deviations from chemically ordered
129 topologies occurring, for a given stoichiometry, in specific network structures (as glassy chalcogenides) made of in-
130 terconnected tetrahedra. In the present work, we tentatively propose a set of atomic partial charges dependent on the
131 local coordination. This approach is based on the exploitation of the charge equilibration method developed by Rappé
132 and Goddard. This method is derived from atomic ionization energies and electron affinity values in order to compute
133 partial atomic charges of the atoms with respect to covalent radii. Thanks to the fact that the charge on each atom is
134 distributed over a Slater orbital having the size of the atom, the advantage of the Qeq method is to predict charges as a
135 function of the local coordination environment.[47] This charge assignment results particularly suitable for the present
136 case since it is shown to provide a physical picture of the glassy chalcogenide surfaces by describing the charge dis-
137 tribution as a function of the chemical order. The chemical order for gassy chalcogenides is not only sensitive to the

138 composition but it can substantially differ from the perfect chemical order found in the crystalline parent phases. For
 139 instance, in the case of glassy g -GeSe₂, we recall the perfect chemical order corresponds to the absence of any under-
 140 or over-coordinated Ge or Se atoms. To be noted that the trend of partial charges obtained with the Qeq method are
 141 found to be in agreement with those obtained with the EReq method[50] as well as with the Bader method[51, 52]
 142 on the basis of charge densities computed by FPMD-DFT data. Whereas the Lowdin,[53] Mulliken,[54] and the
 143 electrostatic potential-based (ESP)[55] methods lead to a nonzero net charge or to charges nearly insensitive to the
 144 coordination number.[30] The Qeq (EReq) and Bader methods capture the effect of local coordination on the partial
 145 charges in chalcogenide materials. These methods provide reasonable partial charges for both the Ge and X atoms
 146 as their absolute charge increases with the coordination. However, the absolute charge values obtained by the Bader
 147 method are too large to be employed in classical simulations, conferring to the Ge and X atoms a nearly pure ionic
 148 character. Ori1 The charge-coordination correlation found in the Qeq(EReq) method seems more appropriate to be
 149 employed for classical simulations such as GCMC or classical MD, presuming the potential parameters are consis-
 150 tent. Table I shows the atomic partial charges obtained by means of Qeq method for the g -GeS₄, g -GeSe₄ and g -GeTe₄
 151 systems as well as g -GeSe₂ and g -GeSe₉. With this methods over-coordinated Ge (X) atoms possess a large positive
 152 (negative) charge with respect to that corresponding to stoichiometric coordination. This is directly related to their
 153 higher valence state which, in a formalism purely based on formal ionic charges [cations (Ge) and anions (X)], result
 154 in an increased charge localization. Likewise, the absolute charge value decreases descending along the element of
 155 the VI group of the periodic table for the counter-ion X ($q_S > q_{Se} > q_{Te}$). Along the Ge-Se serie, the absolute charge
 156 value for Ge sites increases with the Se:Ge ratio and it is counterbalanced by a decrease of the charge value of Se
 157 sites. Such method seems to be the best suited technique to describe changes in the valence (charge) state for different
 158 coordinations (e.g. structural order) as well as different chemical compositions and stoichiometry. However, it has to
 159 be underlined that it has not been demonstrated whether Qeq is as accurate as DFT-based methods reproducing QM
 160 energies nor that the predicted changes in polarization during dynamics agree with QM. Moreover, problem using
 161 this method could occur when high temperatures come into play or when extreme compositions are studied. With all
 162 these cautions in mind, the charges determined by Qeq method, in the presence of rationally physical situations, are
 163 reasonable and can be used to calculate the Coulomb interaction between atoms in (semi)empirical approaches.

164 2.2. Grand canonical Monte Carlo simulations: quantitative prediction of gas adsorption isotherms

165 Once a proper model of chalcogel pore is optimized by means of FPMD simulations, its structural model (i.e.
 166 atoms coordinates) and the corresponding charge atomic charge distribution (coordination dependent) can be em-
 167 ployed to perform GCMC simulations in order to model the gas adsorption isotherm. The GCMC technique is a
 168 stochastic method applicable to a system having a constant volume V (the pore with the adsorbed phase) in equilib-

169 rium with an infinite reservoir of molecules imposing a chemical potential μ for each species (N_2) and temperature
 170 T . The absolute adsorption isotherm is given by the ensemble average of each number of adsorbate molecule as a
 171 function of the fugacity f_{N_2} of the reservoir (the latter is determined from the chemical potential μ_{N_2}). For the adsor-
 172 bate, given the fugacities and temperatures considered in this work, the gas pressure P is assumed to be equal to the
 173 fugacity f_{N_2} (i.e. ideal gas assumption). We performed GCMC simulations of N_2 adsorption at $T=77$ K for chalcogel
 174 pores made of: $g\text{-GeS}_4$, $g\text{-GeSe}_4$ and $g\text{-GeTe}_4$ as well as $g\text{-GeSe}_2$ and $g\text{-GeSe}_9$. We model the N_2 adsorption isotherm
 175 between the 0.0 and the N_2 saturation pressure P_0 . Nitrogen adsorption at low temperature is a routine laboratory
 176 characterization technique of porous materials. For instance, the specific surface area of porous materials is usu-
 177 ally assessed from adsorption experiments. Nitrogen was described using the model of Potoff and Siepmann (Trappe
 178 forcefield).[56] In this model, each N atom of the rigid N_2 molecule is a center of repulsion and dispersion interactions
 179 via Lennard-Jones potential. In addition, each N atom bears a partial charge with $q_N = -0.482e$, charges interacting
 180 through Coulombic forces. At the center of the N-N bond a partial charge $q = +0.964e$ compensates the negative
 181 charge on the N atoms. Such charge distribution mimics the measured quadrupole moment of the N_2 molecule. All
 182 the interactions between the atoms of the N_2 molecules and the Ge and X atoms of the chalcogels were calculated by
 183 considering the intermolecular energy $U_{ij}(r)$ between two sites (i and j) as the sum of a Coulombic contribution and a
 184 pairwise-additive Lennard-Jones (LJ) 12-6 potential. In our simulations, the LJ cross interaction parameters (σ_{ij} , ϵ_{ij})
 185 between unlike sites are calculated using the Lorentz-Berthelot mixing rules. The LJ parameters (σ_{ij} , ϵ_{ij}) for the Ge
 186 and X of the chalcogels were taken from Ref. [57]. The dispersive interactions were neglected beyond a cutoff of 10\AA .
 187 The electrostatic interactions were computed using the Ewald summation technique (the parameters were chosen so
 188 that the relative accuracy in the Coulomb energy calculation is 10^{-5}). More details about the GCMC procedure and
 189 potential parameters employed in this study can be found in ref. [30].

190 2.3. Detailed analysis of the gas/solid interface chemistry and computation of other properties.

191 In order to refine the output configurations of the GCMC calculations of the systems made of N_2 adsorbed in the
 192 chalcogels' pores, FPMD simulations can be employed with the purpose to further optimize the systems structure
 193 and chemistry as well as compute other properties of interest. As an example, once the new chalcogels systems
 194 are obtained containing different contents of gas molecules, MLWFs can be further computed to investigate into the
 195 details the interactions involved between the gas molecules and the solid glassy surfaces. Furthermore, MLWFs can be
 196 also employed to compute molecular dipoles to measure the induced polarization due to the interaction with the glassy
 197 solid surface. This exploitation of MLWFs allows to obtain a deeper insight into the interactions between the adsorbed
 198 gas molecules and the chalcogenide surfaces. Even for the case of apolar gas molecules for which the dipole moment
 199 averaged over time is expected to be zero, the instantaneous molecular distortions can result in non-zero instantaneous

200 dipole moments (μ) and, in this respect, this analysis gives access to the local molecular polarization induced by the
201 solid surface. Recently, we investigated the case of CO₂ molecules adsorbed in a *g*-GeS₂ chalcogel slit-like pore.[58]
202 In this case, for the system made of a monolayer of CO₂ molecules physisorbed on a *g*-GeS₂ surface, the magnitude
203 of the induced μ_{CO_2} is found to be strongly dependent on the distance from the *g*-GeS₂ surface. Close to the solid
204 surface, the CO₂ molecules show a large μ_{CO_2} of about ~ 0.51 D, while departing from the surface μ_{CO_2} reaches values
205 close to those expected for the CO₂ in the gas phase (~ 0.1 D). The large variation of the dipole moments for the CO₂
206 molecules in contact with the solid surface can be explained by the high polarizability of both Ge and S atoms of the
207 *g*-GeS₂ surface. CO₂ molecules departing from the surface towards the empty space in the center of the pore restore
208 almost completely the μ_{CO_2} value typical of CO₂ molecules in the gas phase. Similarly, Karseemeijer *et al.* [60] and
209 Sun *et al.* [61] found values of μ_{CO_2} of about ~ 0.5 D for CO₂ molecules adsorbed on top of solid water. Interestingly,
210 our calculated dipole moments values are similar to those of induced μ_{CO_2} found for CO₂ molecules adsorbed in a
211 hydrated Ca-exchanged Montmorillonite (in the range ~ 0.4 - 1.0 D).[62] While the oxygen dipole moment coming from
212 the electronic polarization in glassy silica was found weakly dependent from the local melt composition.[63]

213 2.4. Models and methods details relevant to this work

214 The bulk structural models of the chalcogenide glasses studied in this work were obtained by means of FPMD
215 simulations following the typical melt-quenching technique. The details about the chalcogenide systems considered
216 here are reported in Table I. The electronic structure was described within DFT by using as generalized gradient
217 approximation (GGA) the Becke, Lee, Yang, and Parr (BLYP) exchange-correlation functional [37, 38] The BLYP
218 functional was combined with the empirical Grimme dispersion correction for van der Waals (vdW) interactions.[59]
219 This theoretical scheme has been successfully validated on a wide range of glassy chalcogenides. More specifics
220 about the methodology used to obtain the different chalcogenide glasses can be found in the references reported in
221 Table I. The surfaces models were initially built from the parent bulk models by removing the periodic boundary
222 conditions along the z direction. By inserting the slab having a thickness Δ_z in a simulation box of a size h_z , one
223 defines a slit pore of width $H = h_z - \Delta_z$ via the use of periodic boundary conditions. More precisely, we took the pore
224 width (H) as the distance between the mean positions of the chalcogen and Ge atoms on the two opposite surfaces.
225 We prepared systems with H in between 2 to 4 in order to obtain Ge _{x} Ch _{y} (with Ch:S,Se,Te) slit-like nanopores with
226 different widths. A selection of the output configurations obtained from the GCMC simulations were further refined
227 by means of FPMD simulations with applying a friction force on the atom dynamics (ion velocities scaled by a factor
228 0.95 at each step) in order to optimize the systems at $T = 0$ K. The surface models were then equilibrated by FPMD
229 at finite temperature and volume. The above calculations on clusters were performed with the CPMD code.

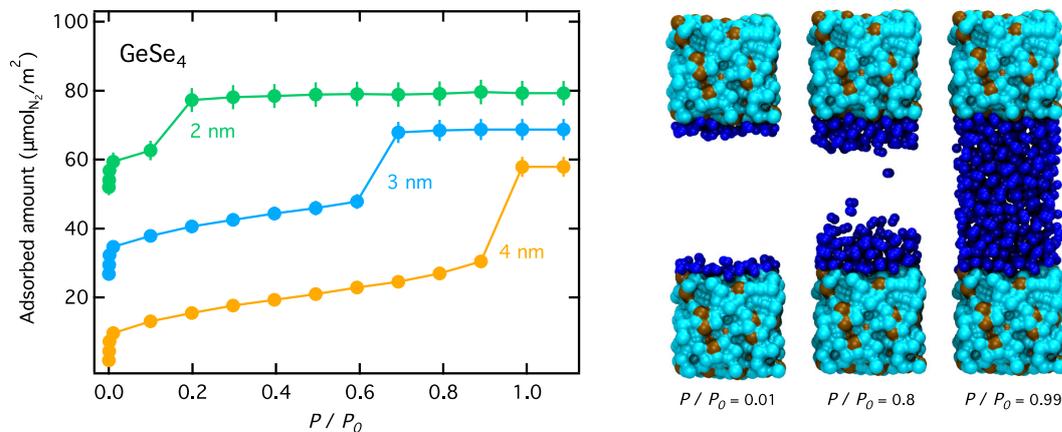

Figure 2: Left: N_2 adsorption isotherms at 77 K for porous g - $GeSe_4$ with slit-like pores of width H (indicated next to each adsorption isotherm). Adsorbed amounts are in $\mu\text{mol}/\text{m}^2$. For the sake of clarity, adsorption isotherms have been shifted up. Pressures are in relative units with respect to the bulk saturating pressure P_0 for N_2 at 77 K. Right: Typical molecular configurations for N_2 adsorbed in g - $GeSe_4$ pore with $H = 3.64$: (from left to right) $P/P_0 = 0.01$, $P/P_0 = 0.80$, and $P/P_0 = 0.99$. The ochre and cyan spheres are the Ge and Se atoms of the chalcogenide surfaces, respectively. The blue spheres are the atoms of the N_2 molecules.

3. Case studies

3.1. Pore size effect

Figure 2 shows the N_2 adsorption isotherm for g - $GeSe_4$ nanopores with $H = 2, 3$ and 4 nm computed at 77 K. The data obtained for the three pores confirm the typical behavior observed in the experiments of adsorption/condensation in solid nanopores. At low pressures, the adsorbed amount increases in a continuous fashion upon increasing the pressure with the N_2 forming an adsorbed film at the g - $GeSe_4$ pore surface. Beyond adsorption of the first layer, the slope of the adsorption isotherm decreases once the pore gets filled along the multilayer adsorption regime. Then, at a pressure lower than the bulk saturating vapor pressure P_0 , capillary condensation occurs. As expected on the basis of capillary condensation theories such as Derjaguin and Derjaguin-Broekhoff-De Boer model,[3, 5] the capillary condensation pressure increases with increasing the pore width H : the condensation pressures for the nanopores with $H = 2, 3$, and 4 nm are $\sim 0.10 P/P_0$, $\sim 0.59 P/P_0$, and $\sim 0.89 P/P_0$, respectively. Figure 2 also shows typical molecular configurations of N_2 molecules adsorbed at different relative pressures upon adsorption in the nanopore with $H = 4$ nm. Regardless of the pore width, the surface of g - $GeSe_4$ nanopores is covered with a homogeneous film at the onset of capillary condensation. A discontinuous transition (i.e., capillary condensation) between the partially filled and completely filled configurations occurs when the adsorbed film becomes unstable, in line the results found for g - GeS_2 and typical experimental data.[31] Note that for a proper quantitative comparison with experimental data this has to be normalized to the corrected Brunauer-Emmett-Teller (BET) [32] surface area. Generally, it is appropriate to correct the BET surface to account for the overestimate of the true geometrical surface areas by about 25-30%.[4, 33]

248 3.2. Chemical stoichiometry - Se:Ge ratio effect

249 Figure 3 shows the N_2 adsorption isotherm for nanopores with $H = 2$ nm computed at 77 K for Ge_xSe_y chalcogels
250 with different Se:Ge ratio $\phi_{Se/Ge}$: 2, 4 and 9 for $g-GeSe_2$, $g-GeSe_4$, and $g-GeSe_9$ respectively. The N_2 adsorbed amount
251 is normalized with respect to the pore surface area in order to take into account the different size of the simulated
252 system (see Table I for details). We recall that the pore surface areas considered in this work allows to rule out any
253 possible size effect, in accordance with the previous results obtained for the $g-GeS_2$ system. [31, 58] The data obtained
254 for the three systems show a similar trend that follows the typical behavior observed for adsorption/condensation
255 experiments in solid nanopores as discussed in the previous section. The onset of capillary condensation within
256 the pore occurs at similar relative pressure for systems with $\phi_{Se/Ge} = 2$ and 4 ($P/P_0 \sim 0.1$) whereas for the $\phi_{Se/Ge} =$
257 9 system it occurs at larger relative pressure ($P/P_0 \sim 0.2$). Figure 3 (inset) shows the comparison between the N_2
258 adsorption isotherms in the range $0.0 < P/P_0 < 0.25$ for the three systems. The non-negligible difference found
259 corresponds to a lower adsorbed amount of N_2 at low pressure ($< 0.15 P/P_0$) for the $g-GeSe_9$ system with respect to
260 $g-GeSe_2$ ($\sim -11\%$ and $\sim -9\%$ at $P/P_0 \sim 0.01$ and $P/P_0 \sim 0.1$ respectively). This result suggests a weaker interaction
261 between N_2 molecules and the Se atoms of the chalcogel surface with respect to the interaction between N_2 molecules
262 and the Ge atoms. The stronger interaction between N_2 and chalcogels with lower $\phi_{Se/Ge}$ arises from the interplay
263 between the electronegativity and electropositive charge of Ge atoms and its larger polarizability with respect to Se
264 ($\alpha_{Ge} \sim 42$ vs $\alpha_{Se} \sim 27$). [48]. The specific gas interactions with these surfaces is a key factor determining the behavior
265 of gas mixtures through porous structures. Our data is found in fair agreement with the experimental behavior for
266 adsorption/condensation obtained by Armatas et al. [18] for Ge_xSe_y chalcogels, where a system with a greater Se:Ge
267 ratio is found to promote lower N_2 adsorption at the same relative pressure ($\phi_{Se/Ge} \sim 0.44$ vs $\phi_{Se/Ge} \sim 0.21$).

268 3.3. Chemical composition - chalcogen effect

269 Figure 4 shows the N_2 adsorption isotherm for nanopores with $H = 3$ nm computed at 77 K for chalcogels made
270 of different chalcogen counter-ions: $g-GeS_4$, $g-GeSe_4$, and $g-GeTe_4$. The data obtained for the three systems show a
271 similar trend that follows the typical behavior observed for adsorption/condensation experiments in solid nanopores
272 as discussed in the previous section. The onset of capillary condensation within the pore occurs at similar relative
273 pressure for the sulfide and selenide systems ($P/P_0 \sim 0.6$) whereas for the telluride system it occurs at larger relative
274 pressure ($P/P_0 \sim 0.8$). Figure 3 (right panel) shows the comparison between the N_2 adsorption isotherms in the range
275 $0.0 < P/P_0 < 0.25$ for the three systems. At a given relative pressure, the amount of N_2 adsorbed on the chalcogel
276 surface is found to be strongly related to the nature of the chalcogen counter-ion and following the series $g-GeS_4 >$
277 $g-GeSe_4 > g-GeTe_4$. For example, at relative pressure of $P/P_0 \sim 0.3$, $g-GeSe_4$ and $g-GeTe_4$ show a lower adsorbed of

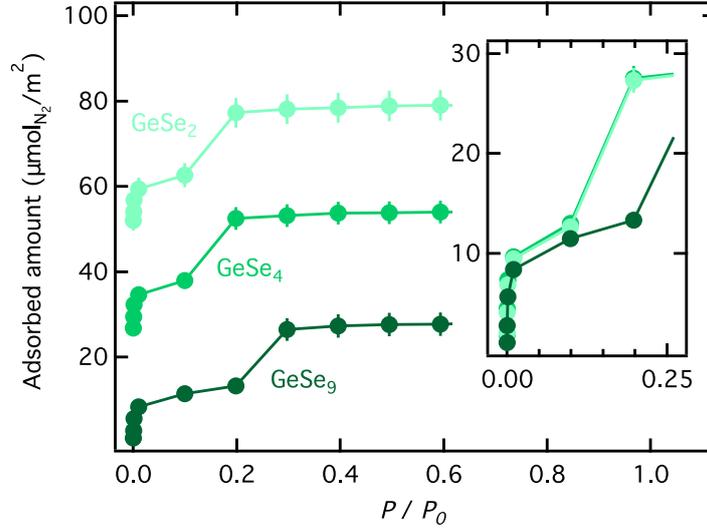

Figure 3: N_2 adsorption isotherms at 77 K for slit-like pores with $H = 2$ nm made of Ge_xSe_y chalcogels with different Se:Ge ratio $\phi_{\text{Se}/\text{Ge}} = 2, 4$ and 9 for $g\text{-GeSe}_2$, $g\text{-GeSe}_4$, and $g\text{-GeSe}_9$ respectively. For the sake of clarity, adsorption isotherms have been shifted up. Inset: zoom-in within the same $\mu\text{mol}_{\text{N}_2}/\text{m}^2$ scale at the low relative pressure P/P_0 range ($0.0 < P/P_0 < 0.25$).

278 N_2 with respect to $g\text{-GeSe}_4$ (-5.9% and -19.4%, respectively). This behavior can be ascribed to the interplay between
 279 the electronegativity, charge and polarizability of the chalcogels constituents elements. It remains to be investigated if
 280 the interactions of different gases (such as CO_2 , CH_4 , and H_2) with these porous glassy chalcogenides would follow
 281 the same trend.

282 4. Conclusions and perspectives

283 Realistic models of porous glassy chalcogenides were used to probe the viability of such a class of materials for
 284 adsorption applications. Using atomic-scale simulation based on first-principles molecular dynamics and grand canon-
 285 ical Monte Carlo simulations, we gained insights into the adsorption mechanisms for N_2 molecules. Both the effects of
 286 pore size and chalcogenide chemistry (composition and stoichiometry) were investigated in order to gain fundamen-
 287 tal understanding on the chalcogels gas adsorption properties and assess the versatility of computational modelling
 288 approach proposed. Our results are found to be in good agreement with available experimental data, confirming the
 289 ability of our methodology to produce realistic chalcogel models and predict their N_2 gas adsorption performance.
 290 Owing to their high polarizability, the isosteric heats of adsorption show that chalcogenide surfaces have a stronger
 291 interaction with CO_2 than with CH_4 or H_2 . As a result, large selectivities were observed towards CO_2 pointing to such
 292 materials as potential adsorbents for gas separation, such as land-gas separation or CO_2 capture/sequestration. We also
 293 showed that selectivities can be accurately described using the ideal adsorbed solution theory (IAST) which predicts
 294 coadsorption isotherms based on pure component adsorption isotherms. Such a reliable theory allows avoiding to

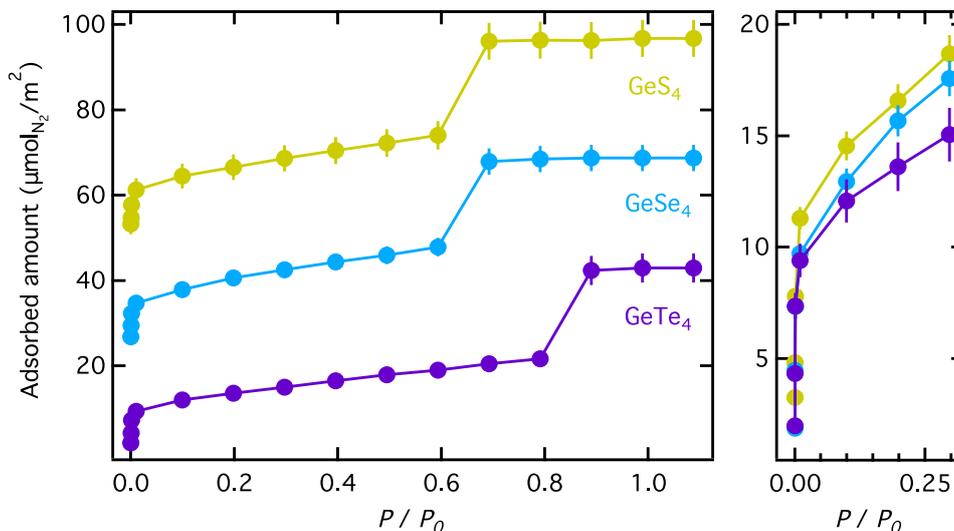

Figure 4: Left: N_2 adsorption isotherms at 77 K for slit-like pores with $H = 3$ nm made of chalcogels based on different chalcogen element: g - GeS_4 , g - $GeSe_4$, and g - $GeTe_4$ respectively. For the sake of clarity, adsorption isotherms have been shifted up. Right: zoom-in within the same $\mu\text{mol}_{N_2}/\text{m}^2$ scale at the low relative pressure P/P_0 range ($0.0 < P/P_0 < 0.25$).

295 measure coadsorption isotherms thereby considerably decreasing the cost and time needed to design efficient adsor-
 296 bents based on porous chalcogenides. The present work shows that glassy porous chalcogenides are a valuable class
 297 of materials for gas adsorption. While further work is needed to clarify gas adsorption for different gas probes, these
 298 results shed light on the adsorption mechanisms for porous chalcogenides. Such an approach can be used for *a priori*
 299 evaluation of their gas adsorption performances and pave the way for the design of chalcogenide-based adsorbents
 300 towards specific applications.
