Here we show that nonanuclear lanthanide complexes represent a new class of solution state UC molecules. For a composition of one Tb per eight Yb the nonanuclear complexes display a very efficient upconversion phenomenon with Tb luminescence in the visible region upon 980 nm NIR excitation of Yb. An unprecedented value of 1.0×10^{-7} was obtained for the UC efficiency at only 2.86 W/cm^2 , demonstrating these new molecular complexes to be up to 26 times more efficient than the best current molecular systems, the UC being observed down to a concentration of 10 nM.

While UC has been observed and studied for more than sixty years,¹ it is only in the last decade that researchers are playing with the coordination chemistry toolkit in an attempt to observe it at the molecular scale in solution.² The main difficulty of the molecular approach relies in the presence of organic matter constituting the ligands and the solvent molecules. The multistep mechanisms of UC require that the NIR intermediate excited state persists sufficiently long enough to enable the further climbing of the energy ladder. As the main source of non-radiative deactivation of excited states is attributed to energy transfer to the overtones of vibrational bands in the NIR,³ decreasing this quenching is of paramount importance in molecular UC systems. However, by combining a judicious choice of energy donors and acceptors, a few discrete coordination complexes have been revealed as UC molecular systems in the solid state,⁴ but also in diluted solutions.^{2,5-7}

In 1994, Auzel proposed the formation of “ion clusters” as being responsible for solid state cooperative UC processes observed in some doped glasses.⁸ Such clusters results from ion pairing at very short distances (less than 5 Å) and were later confirmed to be the origin of green cooperative UC luminescence of Tb observed in some doped Yb/Tb solids.⁹ We thus hypothesized that chemical engineering of equivalent

complexes might lead to the observation of the cooperative photosensitization process in discrete molecular entities in solution.

Among known lanthanide (Ln) complexes,¹⁰ a family based on β -diketonate ligands attracted our attention as a result of their straightforward synthesis,¹¹ versatility in nuclearity¹² and composition,¹³ and short inter-Ln distances.¹⁴ The simple case of acetylacetonate ligands forming nonanuclear complexes¹² particularly piqued our interest with the close proximity of up to nine Ln atoms in a very small volume and intermetallic distances shorter than 5 Å. Noteworthy, a controlled doping of such complexes might allow the formation of entities containing up to eight sensitizing ions for one emitting UC center, a situation considered to be optimum for maximizing energy transfer UC.¹⁵ Taking advantage of these prior works, we show that the structures obtained in the solid state retain their integrity in solution and that the chemical composition can be tuned to obtain mixed Yb/Tb nonanuclear complexes exhibiting outstanding UC properties in solution.

The nonanuclear complexes of general composition $[\text{Ln}_9\text{L}_{16}(\text{OH})_{10}](\text{OH})$ (L = Acac = acetylacetonate, yttrium (Y) will be integrated in the abbreviation of Ln for brevity) were obtained by adaptation of the literature procedures (Figure 1a).¹¹ Full synthetic details and characterization of the complexes can be found in the supplementary information. The solid state structure of the Ln_9 complexes¹² can be viewed as two pentanuclear square pyramids sharing the apical Ln atom, with a torsion angle of approximately 45° between the two pyramids, resulting in square anti-prismatic geometry at the central Ln (Figure 1a). The eight triangular faces of the pyramids are capped by μ_3 -OH groups linked to the three Ln at the edges of the triangles, while the four Ln atoms of the two square faces are connected by μ_4 -OH bonds. All Ln atoms

except the central one are linked to

two acetylacetonate ligands.

Scheme 1. a) Synthetic protocol for the preparation of the nonanuclear complexes. b) ES/MS spectra of the Y nonanuclear cluster showing a major peak at 2554.8901 and the expansion of this peak with the calculated isotopic distribution.

For the study in solution, the Y_9 complex was taken as a reference due to a) the chemical similarity of Y(III) with Ln(III) cations of the end of the Ln series (ionic radii of 1.027, 1.019 and 1.015 Å respectively for Dy(III) , Y(III) and Ho(III) for a coordination number of 8)¹⁶ and b) its diamagnetic nature allowing for an easy interpretation of NMR experiments. The complex was redissolved in CH_3OH and first studied by electrospray mass spectrometry (Figure 1b). The spectrum displays one major peak at 2554.89 m/z units corresponding to the monocharged $[\text{Y}_9\text{L}_{16}(\text{OH})_{10}]^+$ complex and minor peaks were observed attributed to doubly charged polyhydrated fragments having lost one YL_1 unit or one YL_2 unit and triply charged polyhydrated complexes missing one YL_3^- unit (Figure S1).

The $^1\text{H-NMR}$ spectrum of the Y cluster in CDCl_3 (Figure S2) presents time-averaged C_4 symmetry, with two sets of methyl groups (48H each) and two sets of CH (8H each) for the Acac ligands, and two broad singlets integrating for 8H and 2H corresponding to the two sets of OH bonds observed in the solid state structure (*vide supra*). The different NMR experiments (^{13}C , HSQC, HMQC, ROESY and DOSY Figure S2-7) pointed to the two sets of Acac ligands originating from two families of independent ligands, which were ascribed to eight Acac ligands capping the top and the bottom of the cluster (*exo* ligands, blue in Figure 1a) and eight Acac ligands positioned at the equatorial plane of the cluster (*endo* ligands, red in Figure 1a). Each of these

ligands can easily rotate to exchange the positions of the two methyl groups, but the exchange between the *exo* and *endo* positions is slow on the NMR time scale at 298 K. The 2D-DOSY NMR spectrum was particularly informative (Figure S7), as the average value of the diffusion coefficients at $4.37 \times 10^{-10} \text{ m}^2 \cdot \text{s}^{-1}$ represents a volume of $3270 \pm 150 \text{ \AA}^3$, in good agreement with the crystal structure of the complex in the solid state ($2847(1) \text{ \AA}^3$).

Figure 2. a) UV-Vis-NIR absorption spectrum (blue) b) normalized emission

Considering that the maximization of the number of sensitizing ions per emitting centers (activators) is expected

Figure 3. a) UC emission spectrum of the (D:D) complex in CD_3OD ($c = 2.0 \text{ mM}$, $P = 2.86 \text{ W cm}^{-2}$, $\lambda_{\text{exc}} = 980 \text{ nm}$). b) UC intensity as a function of the incident pump power density in a Log/Log scale (squares correspond to increasing pump intensities and red dots for decreasing ones). Blue dotted line represents the linear regression of the data. c) Temporal evolution of the UC emission at 542 nm upon $60 \mu\text{s}$ pulsed excitation at 980 nm for complexes of Yb_8Tb_1 (green) and Yb_9 (red) compositions

to optimize the UC process,¹⁵ we then prepared mixed complexes containing 8 Yb donors and one Tb acceptor by simply starting from a 1:8 Tb:Yb mixture. The complexes were obtained from CH_3OH and $\text{LnCl}_3 \cdot 6\text{H}_2\text{O}$, or from CD_3OD and $\text{LnCl}_3 \cdot 6\text{D}_2\text{O}$ starting salts, respectively referred to H:H or D:D. The solid-state infrared (IR) spectra of the novel complexes display a net shift of the $\mu_x\text{-OH(D)}$ vibrational band from 3316 cm^{-1} to 2439 cm^{-1} upon deuteration (Figure S8 for the IR spectra). Powder XRD of the H:H complex (Figure S9) clearly demonstrated that, in the solid state, the synthesized $[\text{Yb}_8\text{Tb}_1]$ cluster are isostructural to the reported $[\text{Tb}_9]$ ones.¹² TEM-EDX analysis were performed on 10 different points of monocrystals of H:H, giving a composition of $89.6 \pm 2.4\%$ of Yb and $10.4 \pm 2.4\%$ of Tb, in good agreement with the 89.1% of Yb and 10.9% of Tb, introduced in the synthesis. Alternatively, the Yb and Tb contents of the heteronuclear complexes were determined by ICP-AES measurements confirming the Yb_8Tb_1 composition with an estimated error of ± 0.1 atomic unit.

The UV-Vis-NIR absorption spectrum of the H:H complex in CH_3OH is presented in Figure 2 (Figure S10 for the D:D complex). It is composed of a broad absorption band in the UV region at 291 nm ($\epsilon = 14.8 \times 10^4 \text{ M}^{-1} \cdot \text{cm}^{-1}$), attributed to transitions centered on the Acac ligands.¹⁷ In the NIR, the spectrum displays a broad absorption band at 975 nm ($\epsilon = 46.9 \text{ M}^{-1} \cdot \text{cm}^{-1}$ in CH_3OH ; $\epsilon = 51.7 \text{ M}^{-1} \cdot \text{cm}^{-1}$ in CD_3OD) attributed to the ${}^2\text{F}_{7/2} \rightarrow {}^2\text{F}_{5/2}$ transition of Yb. At high concentrations, a very weak absorption band can be observed around 485 nm ($\epsilon = 0.055 \text{ M}^{-1} \cdot \text{cm}^{-1}$, Figure S10) attributed to the ${}^7\text{F}_6 \rightarrow {}^5\text{D}_4$ transition of Tb.

Upon excitation into the Acac absorption band (292 nm), the complexes display two sets of emission bands (Figure 2), those in the visible region corresponding to the ${}^5\text{D}_4 \rightarrow {}^7\text{F}_J$ ($J = 6$ to 3) transitions of Tb,¹⁸ ($\Phi_{\text{Tb}} = 1.5\%$ in CH_3OH), and a broad emission band peaking at 975 nm corresponding to the ${}^2\text{F}_{5/2} \rightarrow {}^2\text{F}_{7/2}$ transition of Yb ($\Phi_{\text{Yb}} = 0.08\%$). The corresponding luminescence lifetimes were 0.95 ms for Tb and $<1 \mu\text{s}$ for Yb in CH_3OH . For the D:D complex in CD_3OD , the lifetimes increase to $16.6 \mu\text{s}$ for Yb and 1.12 ms (95%) and $350 \mu\text{s}$ (5%) for Tb, indicating two different chemical environments. From previous site specific doping experiments,¹¹ the larger Tb ion is expected to be predominantly positioned at the central site of the

cluster and one might relate this to the longer lifetime value regarding the relative intensities of the two components. However, the excitation through the ligand absorption bands is expected to favor the emission from the cations positioned at the periphery of the cluster to which Acac ligands are directly bonded and the attribution of the lifetimes to the two different sites is still subject to doubts.

From the NIR absorption band of Yb and weighting the absorption coefficients by the number of Yb atoms (8), it was possible to calculate the radiative lifetime of Yb, τ_{rad} , according to the methodology described by Werts and coworkers.¹⁹ Full experimental description of the method is given in the supplementary information (Section S3). Values of τ_{rad} between 578 and $683 \mu\text{s}$ were obtained (Table S1) for the H:H and D:D complexes in CH_3OH or CD_3OD , affording a mean value of $639 \pm 28 \mu\text{s}$. The Yb lifetimes being too short to be measured with our setup in CH_3OH , only values in CD_3OD for the D:D complex were used (Table S1) to calculate a Yb centered luminescence quantum yield of 2.6% with a modest sensitization efficiency of 22% by excitation through the Acac ligands.

The most striking feature of the mixed cluster was observed when the D:D complex in CD_3OD was excited in the NIR absorption band of Yb at 980 nm (Figure 3a), resulting in a strong emission in the visible region with the typical spectral signature of the Tb emission.

The luminescence intensity was recorded as a function of the incident pump power density and the logarithmic representation (Figure 3b) presents a quasi linear profile with a slope of two, accrediting the two photon UC process.^{20,21}

Analysis of the temporal evolution of the UC intensity at 542 nm upon pulsed excitation (Figure 3c) evidences a first slow rise during the $60 \mu\text{s}$ pumping period, indicative of a cooperative photosensitization mechanism,^{7,21} followed by a bi-exponential decay ($\tau_1 = 170 \mu\text{s}$ (93%); $\tau_2 = 390 \mu\text{s}$ (7%)). The same experiment performed on the Yb_9 cluster resulted in the absence of the green emission, confirming that the emission arises from the Tb atoms.

The proposed mechanism (Figure 4) entails a first absorption of a photon by an Yb atom, leading to a $[\text{Yb}_7\text{Yb}^*\text{Tb}]$ species, the absorption of a second photon

forming the $[\text{Yb}_6\text{Yb}^*_2\text{Tb}_1]$ intermediate, cooperative energy transfer to Tb to form the $[\text{Yb}_8\text{Tb}_1^*]$ excited states which

decay to the ground state by emission of visible light.

Figure 4. Proposed cooperative photosensitization process UC mechanism.

The UC quantum yield (Φ_{UC}), calculated following published procedures,²² was determined to be 1×10^{-7} (@ 2.86 W.cm^{-2}). As Φ_{UC} is directly proportional to the power of the excitation source for a two-photon process,^{22a} and the calculation of the Φ_{UC} does not take into account the factor 2 sometimes used to account for the two-photon process,⁵ this value is 92 to 377 times larger than that of the best UC Er complexes ($1.95 \times 10^{-9} < \Phi_{UC} < 8 \times 10^{-9}$ @ 21 W.cm^{-2}),⁵ and 26 times larger than previous heteropolynuclear Yb/Tb UC complexes (1.4×10^{-8} @ 10.3 W.cm^{-2}).⁶ The importance of reducing excited-state deactivation by OH oscillators is exemplified by the 18-fold larger Φ_{UC} for the D:D cluster compared to its H:H congener (Table S1).

The sensitivity of the UC emission was investigated by decreasing the concentration of the solution down to the lowest observable emission. At micromolar concentrations, the Tb UC emission signal was still fully resolvable and the lower limit of detection with our setup at full power ($P = 10.3 \text{ W.cm}^{-2}$) was determined to be 10 nM (Figure S11).

In conclusion, the doping of Yb nonanuclear complexes by Tb ions afforded heteronuclear $[\text{Yb}_8\text{Tb}(\text{Acac})_{16}(\text{OH})_{10}(\text{OH})]$ complexes which display a cooperative UC photosensitization process demonstrated to be more than one order of magnitude more efficient than previous molecular or supramolecular UC probes,^{2,5-7} being observable at concentration as low as 10 nM. The tremendous potential of readily accessible β -diketonate ligands, coupled with the wide variety of Ln donor-acceptor dyads and the structural diversity of such complexes, opens avenues to even more efficient UC systems, with applications in luminescence bio-analytical applications.²³
