Abstract

It has been hypothesized that the human neurocognitive architecture may include a perceptual Ratio Processing System (RPS) that supports symbolic fraction understanding. In the present study, we aimed to provide further evidence for the existence of the RPS by exploring whether individuals with a range of math skills are indeed perceptually sensitive to non-symbolic ratio magnitudes. We also aimed to test to what extent the RPS may underlie symbolic fraction processing in those individuals. In a match-to-sample task, typical adults, elementary school children, and adults with dyscalculia were asked to match a non-symbolic ratio (i.e., target) to one of two non-symbolic ratios (i.e., the match and distractor). We found that all groups of participants were sensitive to the ratio between the match and the distractor, suggesting a common reliance on the RPS. This ratio sensitivity was also observed in another group of typical adults who had to choose which of two symbolic fractions match a non-symbolic ratio, indicating that the RPS may also contribute to symbolic fraction understanding. However, no ratio dependence was observed when participants had to choose which of two symbolic fractions match another symbolic fraction, suggesting that reliance on the RPS in symbolic fraction processing is limited and may not support exact fraction processing.

Keywords: *Ratio Processing System, Symbolic Fractions, Match to Sample task, Dyscalculia*

1. Introduction

Fractions have a key role to play in the holistic development of numerical concepts. From a life skills perspective, they are crucial for calculating discounts, managing medical dosage, cooking, banking, and in laying the foundation for careers in science, technology, engineering, and mathematics. From an educational perspective, they are central in mathematics curriculum at both elementary and secondary school level and have a strong predictive relationship with algebra and mathematics achievement later in life (Bailey, Hoard, Nugent, & Geary, 2012; Booth & Newton, 2012; Siegler et al., 2012). Although children receive fraction instruction beginning around 8 years of age, they continue to struggle with fractions in high school and even after college (Kloosterman, 2010; Stigler, Givvin, & Thompson, 2010; Van Hoof, Lijnen, Verschaffel, & Van Dooren, 2013). Attesting to the problem, mathematic educators and researchers worldwide have noted a pervasive lack of fraction understanding among students (Chan, Leu, & Chen, 2007; Ni, 2001; Yoshida & Sawano, 2002).

Why are fractions difficult?

Research in mathematics education and cognitive science has documented two main reasons that may explain why adults and children across countries face difficulties with fractions. The first reason is that accessing the holistic magnitude of symbolic fractions appears to be difficult for most individuals (Kallai & Tzelgov, 2009, 2012; Stafylidou & Vosniadou, 2004). Being able to estimate the magnitude of fractions is critical in the development of conceptual knowledge of fractions and predicts success in fraction computation and arithmetic (Siegler & Pyke, 2013; Siegler, Thompson, & Schneider, 2011). Unfortunately, the challenges to access and

1
2
3 process the holistic magnitude of fractions are all too common even in expert mathematicians
4
5 (Obersteiner, Van Dooren, Van Hoof, & Verschaffel, 2013).
6
7

8 Limited understanding of fraction magnitude is quite evident in children. For instance, a
9
10 study on 6th and 8th graders noted that one-third of the students solved fraction arithmetic
11
12 problems by handling numerators and denominators separately (Siegler & Pyke, 2013). In a one-
13
14 to-one instructional session, seven out of eight 6th graders responded 1/8 to be greater than 1/6
15
16 (Mack, 1990). It has also been observed that students are challenged by the concepts of
17
18 equivalence because they fail to understand that different symbolic fractions can represent the
19
20 same magnitude (e.g. 4/8 and 2/4) (Clarke & Roche, 2009). Additionally, studies on adult
21
22 participants suggest that the holistic magnitude of fractions can be accessed when componential
23
24 strategies relying on the separate processing of numerators and denominators fail (Meert,
25
26 Grégoire, & Noël, 2009, 2010; Meert, Grégoire, Seron, & Noël, 2012).
27
28
29
30
31

32 A second reason for the difficulty individuals face with fractions is that they often assume
33
34 that properties of whole numbers apply to all numbers (Siegler, Fazio, Bailey, & Zhou, 2013;
35
36 Vamvakoussi & Vosniadou, 2010). This so-called whole-number bias (Braithwaite & Siegler,
37
38 2017; Ni & Zhou, 2005) leads to the misapplication of whole-number concepts and procedures on
39
40 fractions. For instance, children might erroneously think that fractions, like whole numbers, have
41
42 unique successors, can be counted, can be represented by a single symbol, or increase in
43
44 magnitude if they are multiplied (Siegler et al., 2012). The whole-number bias often leads to
45
46 erroneous conclusions, such as those reached when performing arithmetic operations separately
47
48 on the numerators and denominators of the operands (e.g., $1/8 + 1/8 = 2/16$) (Mack, 1995; Stigler
49
50 et al., 2010). For example, when estimating the answer to a problem such as $12/13 + 7/8$, 76% of
51
52 13-year-olds choose either 19 or 21 (i.e., the addition of numerators and denominators separately)
53
54
55
56
57
58
59
60

1
2
3 (Carpenter, Kepner, Corbitt, Lindquist, & Reys, 1980). Importantly, this bias is difficult to
4
5 overcome. A qualitative study on 52 seventh graders demonstrated that students were persistent
6
7 in their way of reasoning about fractions. This indicates that the most frequent errors were not
8
9 random but rooted in deep misconceptions (González-Forte, Fernández, & Dooren, 2019).

10
11
12
13 Finally, other sources of difficulties with fractions have been noted by researchers on
14
15 math education. For example, these may stem from a limited understanding of part-whole
16
17 concepts (Pitkethly and Hunting 1996; Steffe and Olive 2010; Streefland 1991), the multiple
18
19 ways in which rational numbers can be represented (Kieren, 1981), as well as the variety of
20
21 procedures that are involved in fraction arithmetic (Siegler et al., 2013). For example, adding
22
23 fractions with common denominators (e.g., $2/6 + 3/6$) requires one to maintain the denominator
24
25 constant and add the numerator, whereas multiplying the same fractions (e.g., $2/6 \times 3/6$) requires
26
27 one to multiply both the numerator and denominator. Thus, the procedures used in fraction
28
29 arithmetic are varied and complex.

The Innate Constraint Account

40
41 Owing to the severity of challenges faced, some researchers have argued that the human
42
43 cognitive architecture is endowed with a foundational system that is exclusively designed to deal
44
45 with discrete quantities (Gelman & Meck, 1983; Leslie, Gelman, & Gallistel, 2008). This
46
47 Approximate Number System (ANS) is thought to be inherited from evolution because early
48
49 competence with discrete quantities can be observed in many animal species, including rats,
50
51 pigeons, monkeys, chimpanzees, and several infant studies (Boysen & Capaldi, 1993; Dehaene,
52
53 Dehaene-Lambertz, & Cohen, 1998a). In humans, the ANS is also thought to serve as a
54
55
56
57
58
59
60

1
2
3 foundation for symbolic, whole number concepts (Bailey, Hoard, Nugent, & Geary, 2012;
4 Dehaene & Cohen, 2007; Dehaene, Dehaene-Lambertz, & Cohen, 1998b; Feigenson, Dehaene, &
5 Spelke, 2004; Piazza, 2010) (but see De Smedt et al., 2013; Leibovich et al., 2017). As this
6
7 system is not designed to deal with the physical features of fractional and rational number
8
9 quantities, it has been theorized that it may pose constraints on acquiring rational number
10
11 concepts (Bonato, Fabbri, Umiltà, & Zorzi, 2007; Feigenson et al., 2004). According to this

Innate Constraint account, it is not surprising that acquiring elementary level skills in whole-
numbers is more efficient and easier as compared to fractions and rational numbers. Therefore,
the innate mechanism that is assumed to help children learn discrete number concepts may
impede and/or interfere with children's acquisition of fractional numbers.

The Ratio Processing System

54
55
56
57
58
59
60
However, a growing body of evidence is difficult to reconcile with the Innate Constraint
account. For instance, McCrink and Wynn (2007) observed that 6-month old infants, when
habituated to specific non-symbolic ratios, tend to look longer at novel ratios (differing by a
factor of two), indicating that infants as young as 6 months can process differences between non-
symbolic ratios. By the age of 4, children can also accurately perform addition and subtraction on
part-whole representations of fractions (Mix, Levine, & Huttenlocher, 1999). Moreover, studies
on adults have revealed that non-symbolic ratios are encoded by specific neuronal populations in
the parietal cortex and lateral prefrontal cortex (Jacob & Nieder, 2009a, 2009b). Research on
non-human primates also shows that trained monkeys can match non-symbolic ratios accurately
(Vallentin & Nieder, 2010). Taken together, these studies raise the possibility that there exists an
evolutionary old perceptual system for representing and processing non-symbolic ratios in the

1
2
3 human brain. This system, which has been termed the Ratio Processing System (RPS), is thus
4
5 also likely to be present relatively early in children's development (Lewis, Matthews, &
6
7 Hubbard, 2015).
8

9
10 Critically, some have argued that the RPS might provide a basis for processing symbolic
11
12 fraction magnitudes in humans (Lewis, Matthews, Hubbard, 2016). This is suggested by four
13
14 lines of evidence. First, individual differences in non-symbolic ratio processing relate to
15
16 individual differences in symbolic fraction processing in school-aged children (Möhring,
17
18 Newcombe, Levine, & Frick, 2016) and adults (Matthews, Lewis, & Hubbard, 2016). Second,
19
20 when adults compare the magnitude of symbolic fractions as well as the magnitude of non-
21
22 symbolic ratios (e.g., pairs of lines), their performance depends on the ratio between the
23
24 magnitudes (i.e., a Ratio of Ratios, RoR) (Hurst & Cordes, 2016; Matthews & Ziols, 2019) For
25
26 example, participants are faster and more accurate at comparing symbolic fractions and non-
27
28 symbolic ratios when the RoR is large (e.g., $2/6$ versus $1/9 = 3:1$) than when it is small (e.g., $4/5$
29
30 versus $2/3 = 6:5$) (Hurst & Cordes, 2016). This effect – also observed with whole numbers – is
31
32 generally thought to indicate that numerical magnitudes are ordered along a mental number line
33
34 (Moyer & Landauer, 1967). Accordingly, representations of magnitudes are more difficult to
35
36 distinguish when the distance between them decreases (i.e., a distance effect) and when the
37
38 overall magnitude increases (i.e. a size effect). This combined effect of distance and size results
39
40 in performance that varies with the ratio between magnitudes (in the case of fractions a RoR).
41
42 Third, a study has found that adults are faster at comparing symbolic fractions to non-symbolic
43
44 fractions (i.e., a mixed-format comparison) than symbolic fractions to symbolic fractions (i.e., a
45
46 within-format comparison) (Matthews & Chesney, 2015). This also suggests that a shared
47
48 magnitude code might be accessed intuitively when performing mixed-format comparisons
49
50 (Matthews & Chesney, 2015; Matthews, Chesney, & McNeil, 2014). Fourth, fMRI studies have
51
52
53
54
55
56
57
58
59
60

1
2
3 shown that processing both symbolic fractions and non-symbolic ratios rely on similar brain
4 regions in and around the intraparietal sulcus (Ischebeck et al., 2009; Jacob & Nieder, 2009a,
5 2009b; Mock et al., 2018, 2019). Therefore, both behavioural and neural evidence raise the
6 possibility that a perceptual sense of ratio might be involved in processing symbolic fractions.
7
8
9

10 11 12 13 14 *The current study*

15
16
17 The goal of the current study is twofold. First, we aimed to provide further evidence for
18 the universality of the RPS by exploring to what extent individuals with a range of math skills are
19 perceptually sensitive to non-symbolic ratio magnitudes. To this end, we used a match-to-sample
20 task in which participants were asked to match a non-symbolic ratio (a pair of lines) presented on
21 the left side of a screen (i.e., target) to one of two non-symbolic ratios presented on the right side
22 (i.e., the match and distractor) (see **Figure 1A**). Critically, the ratio between the match and the
23 distractor (i.e., the RoR) was systematically varied, such that it was small in some trials and large
24 in others. This task was adapted from a preliminary study by Matthews (2015), in which an RoR
25 effect (i.e., more accurate performance for large than small RoR) was found in both adults and 16
26 children from kindergarten. This suggests an early developing sensitivity to differences in non-
27 symbolic ratios, consistent with the RPS. In the present study, we aimed to replicate these
28 preliminary findings by testing individuals who are proficient in fraction processing (i.e., adults)
29 and individuals who are not (i.e., elementary-school children). We also aimed to test whether
30 adults with dyscalculia (i.e., a learning disability that severely affects the acquisition of math
31 skills; Price & Ansari, 2013, Iuculano, 2016) exhibit an RoR effect in that task. Indeed, it has
32 been argued that a main cause of dyscalculia is a deficit in processing approximate non-symbolic
33 numerosities (Mazzocco, Feigenson, & Halberda, 2011; Piazza et al., 2010). A major question,
34
35
36
37
38
39
40
41
42
43
44
45

58
59
60

1
2
3 however, is whether this deficit may extend to the RPS or if individuals with dyscalculia have a
4
5 relatively intact RPS despite poor calculation skills.
6

7
8 A second goal of the present study was to examine to what extent the RPS remains
9
10 involved when participants have to match symbolic fractions (rather than non-symbolic ratios) in
11
12 this match-to-sample task. In other words, we aimed to examine whether participants remain
13
14 sensitive to ratio magnitudes when those are expressed as symbols. Although it has been argued
15
16 that the RPS may contribute to symbolic fraction understanding (Lewis, Matthews, Hubbard,
17
18 2016), prior studies have largely relied on magnitude comparison tasks that only require
19
20 participants to access and estimate the approximate value of fractions. In contrast, a match-to-
21
22 sample task would involve asking participants to find which of two fractions is equivalent to a
23
24 target fraction, which may encourage them to access the exact values of the fractions (though
25
26 strategies based on approximation may still be involved to some extent). On the one hand, this
27
28 task might trigger explicit calculation strategies that rely on components of fractions (i.e.,
29
30 numerator and denominator) and have little to do with the RPS. On the other hand, if symbolic
31
32 fraction understanding is grounded in the RPS, participants may still intuitively access the RPS
33
34 even in such match-to-sample tasks. To test between these possibilities, we adapted the match-to-
35
36 sample task described above and designed a condition in which the pairs of lines were replaced
37
38 by symbolic fractions representing the same ratios (see **Figure 1B**). We reasoned that, if the RPS
39
40 contributes to the understanding of symbolic fractions in this task, there should be an RoR effect
41
42 similar to that obtained with non-symbolic ratios. In contrast, if the RPS does not contribute to
43
44 the understanding of symbolic fractions, performance should not depend on RoR.

2. Experiment 1

2.1. Methods

2.1.1. Participants

It has been argued that an effect size of $d = 0.4$ is a good estimate of the smallest effect size of interest in experimental psychology (Brybaert, 2019). Therefore, to be able to detect an effect of that size with 80% power in a within-subject comparison, we planned to recruit about 50 participants.

Forty-eight individuals from the University of Lyon volunteered to participate in this experiment. Data collection for the participants was carried out in two days. Six participants were excluded because of technological issues ($n=2$) and non-compliance with the instructions ($n=4$). The remaining forty-two participants ($M = 20.7$ years, range = 18-54, 31 females) were included in the analyses, for an achieved power of 72% (based on a hypothesized effect size of $d = 0.4$). As compensation, participants received a book or chocolate. The experiment was performed in accordance with the ethical standards established by the Declaration of Helsinki.

2.1.2. Materials

Participants completed a match-to-sample task in which they were asked to match a ratio presented on the left of the screen to one of two ratios presented on the right of the screen (one of which was equivalent to the ratio on the left). The task was adapted from Matthews (2015). In two separate blocks, ratios were presented either as symbolic fractions or as non-symbolic ratios (**Figure 1**).

2.1.2.1 Symbolic fractions

Symbolic fractions were composed of numerators and denominators ranging from 1 to 15 and were presented in a font size of 20 point in Times New Roman. In each trial, 3 fractions (target, match, distractor) were presented simultaneously. The target was presented on the left of the screen and the match and distractor were presented on the right (see **Figure 1**). The ratio between the fractions presented as match and distractor (i.e., a *Ratio of Ratios* or *RoR*) was varied such that it was large in half of the trials and small in the other half. Large RoR were of 3:1 and 2:1. Small RoR were of 4:3 and 6:5. For instance, for a 4:3 RoR, a $\frac{2}{3}$ match could be paired with a $\frac{4}{8}$ distractor. These ratios were chosen based on Matthews (2015). Specifically, they corresponded to the two largest and two smallest ratios from this preliminary study. For each RoR, forty unique fraction pairs were generated (see Appendix). Following previous studies (Meert, Gregoire, & Noel, 2010; Schneider & Siegler, 2010), we also generated an equal mixture of fractions where numerators of target and distractor were either the same or different. Critically, because there is often a relation between overall fraction magnitude and size of the numerator, we found the ratio between numerators of match and distractor to increase with that of the RoR. That is, small and large RoRs were associated with average ratios between numerators of match and distractor of 1.44 and 2.37 (respectively). This raises the possibility that participants might just compare the numerators of match and distractor to complete the task. To evaluate if this was the case, fraction pairs within small and large RoRs were further broken down into pairs for which the ratio between numerators of match and distractor was small (i.e., smaller than 1.44 for small RoRs and smaller than 2.37 for large RoRs) and pairs for which the ratio between numerators of match and distractor was relatively larger (i.e., larger than 1.44 for small RoRs and larger than

1
2
3 2.37 for large RoRs). This allowed us to explore the effects of RoR and effects of ratio between
4
5 numerators of match and distractor independently.
6
7

8 9 10 *2.1.2.2 Non-symbolic ratios*

11
12
13 Non-symbolic ratios were composed of pairs of line segments representing the same
14 ratios as those used in symbolic fractions. Individual line lengths ranged between 10px to 160px
15 approximately on an 800 x 994px full screen. This corresponded to a size between 0.2 cm and 3.2
16 cm (visual angle 0.19 - 3.05 degrees). As for symbolic fractions, the ratio between the non-
17 symbolic ratios presented as match and distractor was varied, such that it was large (i.e., 3:1 and
18 2:1) in half of the trials and small (4:3 and 6:5) in the other half. For each RoR, 40 non-symbolic
19 ratio pairs were generated. Since the ratio size determined the magnitude of the line lengths,
20 participants could not rely on individual line lengths and had to process the relationship between
21 the two lines. For instance, for line ratios such as those shown in **Figure 1**, all the stimuli (target,
22 match, and distractor) had different sizes of individual components. Further, a ratio of 2/4 when
23 matched to a ratio of 5/10 was composed of line segments of two/four and five/ten units of length
24 respectively where a single unit length of line segment was fixed in size. Because of this, the
25 individual components of the line ratios differed in size but the relationship between the ratios
26 stayed the same. In the following analyses, we consider the “numerator” of each pair of line to be
27 the shortest line of the pair.

51 *2.1.3. Procedure*

52
53 During the entire experiment, participants were seated approximately 60 cm from a 14’’
54 screen. All instructions were presented on the laptop screen in French. Participants could ask
55
56
57
58
59

RPS AND SYMBOLIC FRACTIONS

1
2
3 questions about the task after reading the instructions and receive additional instructions if they
4
5 needed to. Participants were told that they would see in each trial 3 ratios (one on the left side of
6
7 the screen and 2 on the right side) presented in either symbolic or non-symbolic format. For both
8
9 notations, they were instructed to match the ratio on the left (i.e., the target) to the equivalent
10
11 ratio on the right (i.e., the match) as accurately and quickly as possible. They could do so by
12
13 pressing the button 'H' if the upper stimulus was equivalent to the target and the button 'B' if the
14
15 lower stimulus was equivalent to the target (on a QWERTY keyboard). The 3 ratios were
16
17 presented for a duration of 3,000 ms. Participants could respond from the onset of stimuli until
18
19 the timeout at 6,000 ms.
20
21
22
23

24 Participants completed 1 block of non-symbolic ratios and 1 block of symbolic fractions.
25
26 Each block included 4 practice trials (with feedback) that were followed by 40 experimental
27
28 trials. Each block was made of 20 trials with a large RoR (i.e., 10 trials with a RoR of 3:1 and 10
29
30 trials with a RoR of 2:1) and 20 trials with a small RoR (i.e., 10 trials with a RoR of 4:3 and 10
31
32 trials with a RoR of 6:5). These trials were selected randomly from the triplets of fractions
33
34 generated for each RoR. The practice trials were constructed of easier RoR (4:1) and participants
35
36 had to reach 100% accuracy to be presented with experimental trials. Almost all participants were
37
38 able to complete the practice trials with 100% accuracy. Those who did not were given additional
39
40 instructions and were successful in completing the practice trials. Block order was
41
42 counterbalanced and trial order was randomized within blocks. Side of the presentation of the
43
44 match was counterbalanced with half of the match ratios on the top and the other half at the
45
46 bottom. The experiment was designed using JavaScript and HTML. The entire experiment lasted
47
48 between 10 and 15 min.

2.2. Results

Proportion correct was analysed in a repeated-measures ANOVA with the within-subject factors RoR (Large, Small), Notation (Line, Fraction), Ratio between numerators of match and distractor (Large, Small), and Numerator of the distractor (Identical to the target, Different from the target). All analyses were carried out in Jamovi (www.jamovi.org/). Main effects and interactions relevant to our hypotheses are presented below.

First, this ANOVA revealed a main effect of Notation ($F(1,41) = 16.36, p < 0.001, \eta^2_p = 0.285$) and a main effect RoR ($F(1,41) = 22.96, p < 0.001, \eta^2_p = 0.359$), which were qualified by an interaction between Notation and RoR ($F(1,41) = 49.79, p < 0.001, \eta^2_p = 0.548$). Bonferroni corrected t-tests revealed that participants were more accurate for large than small RoR when choosing between non-symbolic ratios ($p < 0.001$). However, there was no accuracy difference between large and small RoR when choosing between symbolic fractions ($p = 0.701$). This interaction between Notation and RoR was neither affected by Numerator of the distractor ($F(1,41) = 0.45, p = 0.505, \eta^2_p = 0.011$) nor by Ratio between numerators of match and distractor ($F(1,41) = 0.33, p = 0.567, \eta^2_p = 0.008$). Thus, RoR differently affected performance on non-symbolic and symbolic stimuli across all different trial types (see **Figure 2**).

Second, there was a significant interaction between Notation and Numerator of the distractor ($F(1,41) = 32.62, p < 0.001, \eta^2_p = 0.443$), revealing that participants were most accurate when the numerator of the distractor was different from the target for non-symbolic ratios ($p < 0.001$) whereas they were most accurate when numerators were identical across target and distractor for symbolic fractions ($p < 0.001$).

Third, the ANOVA revealed a main effect of Ratio between numerators of match and distractor ($F(1,41) = 5.53, p = 0.024, \eta^2_p = 0.119$), which was qualified by an interaction with

1
2
3 Notation ($F(1,41) = 40.26, p < 0.001, \eta^2_p = 0.495$). For non-symbolic ratios, participants were
4 more accurate when the ratio between numerators of match and distractor was large than small (p
5 < 0.001). For symbolic fractions, however, performance was not affected by the ratio between
6 numerators of match and distractor ($p = 0.378$).
7
8
9
10
11
12

13 Because frequentist statistics do not provide evidence for a null hypothesis, we turned to
14 Bayesian statistics (Morey et al., 2016; Lee and Wagenmakers, 2013) to estimate the strength of
15 evidence (i.e., the Bayes factor, BF) for a lack of difference between large and small RoR (H_0)
16 versus a higher accuracy for large than small RoR (H_1) in both symbolic and non-symbolic trials.
17 Following Jeffreys (1961), a $BF < 3$ was considered anecdotal evidence, a $3 < BF < 10$ was
18 considered substantial evidence, a $10 < BF < 30$ was considered strong evidence, a $30 < BF < 100$ was
19 considered very strong evidence and a $BF > 100$ was considered extreme evidence that our data
20 are more likely under the alternate than the null hypothesis (i.e., BF_{+0}) or under the null
21 hypothesis than the alternate hypothesis (i.e., BF_{0+}). Bayesian paired t-tests with default priors
22 (0.707) revealed strong evidence for H_0 versus H_1 in the case of symbolic fractions ($BF_{0+} =$
23 14.4). In contrast, there was extreme evidence for H_1 versus H_0 in the case of non-symbolic
24 ratios ($BF_{+0} > 100$). Therefore, while there was evidence that large RoR were more accurate than
25 small RoR for non-symbolic ratios, there was also evidence that it was not the case for symbolic
26 fractions.

47 *2.3. Discussion*

48
49 In this first experiment, we explored the extent to which typical adults are sensitive to
50 ratio magnitudes when they match either non-symbolic ratios or symbolic fractions. The findings
51 demonstrate a clear RoR effect for non-symbolic line ratios, with higher accuracy for large RoR
52
53
54
55
56
57
58
59
60

RPS AND SYMBOLIC FRACTIONS

1
2
3 than for small RoR. These findings replicate the preliminary results described in Matthews
4
5 (2015). They also suggest that adults are perceptually sensitive to ratio magnitudes, even when
6
7 they have to match (and not only compare, as in magnitude comparison tasks) non-symbolic
8
9 stimuli. This supports the claim that adults possess an RPS that may allow them to access a
10
11 perceptual sense of ratios, akin to the ANS for whole numerosities (Dehaene, 1997; Feigenson,
12
13 Dehaene, & Spelke, 2004; Gilmore, Attridge, De Smedt, & Inglis, 2014). Interestingly, our study
14
15 indicates that some componential strategies may also be involved in this task. For example, in
16
17 addition to the RoR effect, accuracy depended on whether numerators of target and distractor
18
19 (i.e., the shortest line of each pair) were identical or different. It also depended on the ratio
20
21 between numerators of match and distractor. This suggests that participants may have attended to
22
23 components of each pair of lines in addition to their overall ratio. This is broadly consistent with
24
25 previous findings that have shown that participants may rely on both holistic and componential
26
27 strategies when comparing fractions (though these studies mainly focused on symbolic fractions)
28
29 (Bonato et al., 2007; Faulkenberry & Pierce, 2011; Meert et al., 2010, 2012; Obersteiner et al.,
30
31 2013; Schneider & Siegler, 2010).
32
33
34
35
36

37
38 A novel aspect of our study is that we asked participants to match symbolic fractions in
39
40 addition to non-symbolic ratios. In sharp contrast to the results obtained with non-symbolic
41
42 ratios, our results revealed an absence of RoR effect for symbolic fractions. This suggests that
43
44 participants do not access a representation of fractional magnitudes when they have to match
45
46 symbolic fractions in this task. Rather, they are likely to use componential strategies, focusing on
47
48 the numerators and denominators separately. This is suggested by the fact that participants'
49
50 accuracy depended on whether the numerator of the target was identical or different from the
51
52 numerator of the distractor. Clearly, focusing on the numerator is an efficient strategy when the
53
54 numerator of the target is the same as the distractor because it indicates that these fractions are
55
56
57
58
59
60

1
2
3 not equivalent. However, the effectiveness of such a componential strategy is less obvious when
4
5 numerators differ between target and distractor. Yet, our results clearly indicate that performance
6
7 does not depend on RoR, suggesting that participants do not rely on fractional magnitudes to
8
9 complete the task.
10

11
12 Other strategies that participants are likely to rely on in Experiment 1 may involve
13
14 calculating (e.g., reducing a fraction to its simplest form) and their mastery may emerge after
15
16 years of practice in school. Therefore, reliance on these strategies might depend on degree of
17
18 familiarity with fractions as well as proficiency with arithmetic. Such strategies may also tax
19
20 working memory and therefore depend on working memory resources of participants. In other
21
22 words, it is possible that participants with limited practice with manipulating symbolic fractions,
23
24 limited arithmetic fluency, or limited working memory resources may rely on an intuitive sense
25
26 of fractional magnitudes to a greater extent than competent adults. To test this hypothesis, we
27
28 presented the same task to children who are beginning to learn about symbolic fractions in 4th and
29
30 5th grade. These children should, therefore, have more limited experience with the strategies used
31
32 to solve fraction problems than adults. They should also have lower arithmetic fluency and
33
34 working memory ability than adults (Cowan, 2016; De Brauwer, Verguts, & Fias, 2006; Imbo &
35
36 Vandierendonck, 2008). None of these factors may influence the RPS because it is thought to be
37
38 an evolutionarily old system that requires few cognitive resources and is early developing.
39
40 However, these factors may affect the extent to which children use strategies in the symbolic
41
42 version of the task. Therefore, we predicted that these children should rely (at least to some
43
44 extent) on the RPS to match symbolic fractions as well as non-symbolic ratios (i.e., they should
45
46 exhibit a sensitivity to ratio magnitudes when matching non-symbolic ratios and symbolic
47
48 fractions).

3. Experiment 2

3.1. Methods

3.1.1. Participants

Children are introduced to symbolic fractions during 4th grade in France. Thus, we recruited 40 4th and 5th graders from a private school in Lyon, France. The difference between large and small RoR for non-symbolic stimuli in Experiment 1 was very large (Cohen's $d = 1.43$). Therefore, this sample size, which would yield more than 99% power to detect an effect size of $d = 0.80$ in a within-subject comparison, was more than adequately powered to detect an effect of that size. Two children were excluded because of non-compliance with instructions. The remaining thirty-eight children ($M = 9.92$ years, range 9-11, 26 females), twenty-one 4th graders and seventeen 5th graders were included in the study. Data collection was done during one school day. The experiment was performed in accordance with the ethical standards established by the Declaration of Helsinki.

3.1.2. Materials and Procedure

Materials and procedures remained the same as in Experiment 1. However, children were given oral rather than written instructions about the task and were tested in groups of four.

3.2. Results

Proportion correct was analysed in a repeated-measures ANOVA with the factors RoR (Large, Small), Notation (Line, Fraction), Ratio between numerators of match and distractor (Large, Small), and Numerator of the distractor (Identical to the target, Different from the target).

First, the ANOVA revealed a main effect of RoR ($F(1,37) = 14.74, p < 0.001, \eta^2_p = 0.285$), which was qualified by an interaction between RoR and Notation ($F(1,37) = 39.76, p < 0.001, \eta^2_p = 0.518$). Bonferroni-corrected post hoc tests showed that children were more accurate for large than small RoR for non-symbolic ratios ($p < 0.001$). In contrast, there was no difference in accuracy between large and small RoR for symbolic fractions ($p = 1.000$). The interaction between Notation and RoR was neither affected by Numerator of the distractor ($F(1,37) = 0.56, p = 0.460, \eta^2_p = 0.015$) nor by Ratio between numerators of match and distractor ($F(1,37) = 0.55, p = 0.462, \eta^2_p = 0.015$). Thus, much like in typical adults, RoR differently affected performance on non-symbolic and symbolic stimuli across all different trial types in children (see **Figure 3**).

Second, the ANOVA revealed a main effect of Ratio between numerators of match and distractor ($F(1,37) = 11.42, p = 0.002, \eta^2_p = 0.236$). Although the interaction with Notation did not reach significance ($F(1,37) = 1.51, p = 0.227, \eta^2_p = 0.039$), follow-up Bonferroni tests indicated that the main effect of Ratio between numerators of match and distractor was driven by non-symbolic stimuli. For non-symbolic ratios, children were more accurate when the ratio between numerators of match and distractor was large than small ($p = 0.011$). For symbolic fractions, performance was not affected by the ratio between numerators of match and distractor ($p = 0.892$).

1
2
3 Bayesian paired t-tests with default priors (0.707) revealed extreme evidence for H1 (i.e.,
4 large RoR is associated with higher proportion correct than small RoR) versus H0 (i.e., no
5 difference between large and small RoR) when children had to choose between non-symbolic
6 ratios ($BF_{+0} > 100$). There was, however, moderate evidence for H0 versus H1 when children had
7 to choose between symbolic fractions ($BF_{0+} = 6.92$). Therefore, much like adults in Experiment
8 1, there was evidence with children that large RoR were more accurate than small RoR for non-
9 symbolic ratios. However, there was also evidence that it was not the case for symbolic fractions.

3.3. Discussion

24
25 In Experiment 2, we presented the symbolic and non-symbolic versions of the match-to-
26 sample task to children in 4th and 5th grade. Because children are introduced to symbolic fractions
27 in 4th grade in France, we reasoned that these participants may have less experience with
28 manipulating symbolic fractions than adults and lack practice with different strategies.
29 Accordingly, they may rely to a lesser extent on these strategies when matching symbolic
30 fractions (and might instead rely on a more intuitive sense of ratio magnitudes). Consistent with
31 the fact that these participants are less proficient with symbolic fractions than adults, children
32 matched symbolic fractions with a relatively low accuracy of about 54.6% (as opposed to 73.8%
33 on average for adults in Experiment 1). Accuracy was also comparable in trials in which the
34 numerator of the target fraction was similar to that of the distractor fraction (54.1%) and in trials
35 in which the numerator of the target fraction was different from that of the distractor fraction
36 (55.2%). This suggests that children struggled to perform this symbolic version of the task and
37 focus less systematically on numerators than adults did in Experiment 2 (similar to Zhang, Fang,
38 Gabriel, & Szűcs, 2014). Yet, the pattern of results is largely similar to Experiment 1.

1
2
3 First, children exhibited RoR effects when matching non-symbolic ratios, indicating that
4 children around the age of 10 are perceptually sensitive to ratio magnitudes. This is in line with
5 several prior studies also showing sensitivity to non-symbolic ratio magnitudes in children. For
6 example, in the preliminary study by Matthews (2005), sixteen pre-schoolers showed RoR effects
7 when matching non-symbolic ratios. In another study, six-month-old infants show similar
8 discrimination acuity for non-symbolic ratios as they do for non-symbolic numerosities in
9 magnitude discrimination tasks (McCrink & Wynn, 2007). Finally, studies on non-symbolic
10 proportional reasoning tasks employing continuous quantities (in which participants have to focus
11 on the relationship between the quantities because individual units cannot be counted) have
12 shown that children as young as 6 years old are successful in processing proportional information
13 across a wide range of non-symbolic formats (Boyer, Levine, & Huttenlocher, 2008; Hurst &
14 Cordes, 2018; Jeong, Levine, & Huttenlocher, 2007; Meert, Grégoire, Seron, & Noël, 2013).
15 Therefore, together with these studies, our data are consistent with the idea that the RPS is
16 relatively early developing.
17
18
19
20
21
22
23
24
25
26
27
28
29
30
31
32
33
34
35

36 Second, despite a level of accuracy relatively similar between the non-symbolic ratios and
37 the symbolic fractions (49.4% versus 54.6%), children's accuracy in the symbolic task was not
38 dependent upon the RoR. Therefore, contrary to our prediction, even children with a lack of
39 extensive experience with componential and other strategies do not appear to access
40 representations of magnitude when matching symbolic fractions. Of course, children are
41 beginning to learn about fractions in 4th grade, as indicated by relatively high error rates. It is thus
42 possible that they were not exposed to enough instruction on rational numbers to be able to
43 access the underlying ratio magnitudes. To test this possibility, we turned to adults with
44 dyscalculia.
45
46
47
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 Dyscalculia is a specific learning disability affecting the acquisition of numerical skills,
4
5 despite normal intelligence and educational opportunities. Research has shown that individuals
6
7 with developmental dyscalculia possess an impaired ANS as well as relatively poor working
8
9 memory ability (Geary, 2011; Iuculano, 2016; Mazzocco et al., 2011; Piazza et al., 2010). This,
10
11 in turn, is thought to significantly affect arithmetic learning. Clearly, adults with dyscalculia have
12
13 been exposed to extensive instruction on rational numbers in school. Yet, their impaired
14
15 calculation skills may prevent them from effectively using componential strategies when
16
17 matching symbolic fractions. Although this may translate into greater use of the RPS, it is also
18
19 possible that ANS impairments in individuals with dyscalculia may extend to the RPS. Therefore,
20
21 Experiment 3 investigated the sensitivity to ratio magnitudes of adults with dyscalculia who were
22
23 asked to match both non-symbolic ratios and symbolic fractions.

25
26
27
28
29
30

31 **4. Experiment 3**

32 4.1. Methods

33 4.1.1. Participants

34
35 Seventeen adult participants were recruited using advertisements in social media, the
36
37 university “mission-handicap”, and by word of mouth. Thirteen participants ($M = 23.3$ years,
38
39 *range* 19-27, 12 females) met the inclusion criteria based on clinical diagnosis and standardized
40
41 tests (described below), yielding 80% power to detect an effect size of $d = 0.85$ in a within-
42
43 subject comparison. Because the effect sizes associated with the difference in accuracy between
44
45 large and small RoR in Experiments 1 and 2 were larger than $d = 0.85$ (i.e., $d = 1.43$ and $d =$
46
47
48

2
3 1.08), we considered this sample size to be adequate. The experiment was performed in
4
5 accordance with the ethical standards established by the Declaration of Helsinki.
6
7
8
9

10 11 *4.1.2. Standardized Tests* 12 13

14 Adults were administered various tests to assess cognitive, numerical, and reading skills.
15
16 Using the WAIS-IV (Wechsler, 2008), verbal IQ was estimated using the verbal reasoning
17 subtest while spatial IQ was estimated using the matrix reasoning subtest. Math skills were
18 assessed using 2 subtests of the Woodcock-Johnson Test of Achievement (WJ-III) (Woodcock et
19 al., 2001): Math Fluency and Applied Problems. The Math Fluency sub-test is a timed test in
20 which the participants have to solve as many single-digit additions, subtraction, multiplication,
21 and division problems as they can within 3 min. The Applied Problems subtest is un-timed and
22 measures the ability to analyse basic numerical concepts and oral word problems. This test stops
23 after 6 consecutive errors or when the last item is reached. Reading fluency was assessed with
24 the Alouette-R test (Lefavrais, 1967), which is frequently used to test reading skills in French-
25 speaking countries. This test requires participants to read a 265-word text aloud in 3 minutes and
26 measures the number of words read, the time required, and the number of pronunciation errors to
27 evaluate the reading speed and efficiency, respectively. Because the test is standardized for
28 children and adolescents but not for adults, we used the guidelines of Cavalli et al. (2018) to
29 identify cut-off criteria for dyslexia (i.e., reading speed score above 8.7 and/or reading efficiency
30 score above 402.26)
31

16
17
18
19
20

21 *4.1.3. Materials and Procedures*

22
23
24 Materials and procedures remained the same as in Experiment 1 with one exception.
25 Because the sample size was smaller than in Experiment 1, we presented participants in
26 Experiment 3 with twice more trials to improve individual estimates of performance. That is,
27 after completing 4 practice trials in each block, participants evaluated 80 experimental trials.
28 Therefore, there was a total of 160 trials (i.e., 80 non-symbolic ratios and 80 symbolic fractions).
29 The whole experiment lasted about 20 minutes.

39
40

41 *4.2. Results*

42
43
44 As for Experiment 1 and Experiment 2, proportion correct was analysed in a repeated-
45 measures ANOVA with RoR (Large, Small), Notation (Line, Fraction), Ratio between
46 numerators of match and distractor (Large, Small), and Numerator of the distractor (Identical to
47 the target, Different from the target) as within-subject factors.

51
52
53
54
55
56
57
58
59
60

1
2
3 First, this ANOVA revealed an interaction between Notation and RoR ($F(1,12) = 35.04$,
4 $p < 0.001$, $\eta^2_p = 0.745$). Bonferroni corrected t-tests revealed that participants were more accurate
5 for large than small RoR when choosing between non-symbolic ratios ($p < 0.001$). However,
6 there was no accuracy difference between large and small RoR when choosing between symbolic
7 fractions ($p = 0.106$). This interaction between Notation and RoR was neither affected by
8 Numerator of the distractor ($F(1,12) = 0.36$, $p = 0.557$, $\eta^2_p = 0.029$) nor by Ratio between
9 numerators of match and distractor ($F(1,12) = 1.47$, $p = 0.248$, $\eta^2_p = 0.109$). Thus, as in
10 Experiment 1 and 2, RoR differently affected performance on non-symbolic and symbolic stimuli
11 across all different trial types in adults with dyscalculia (see **Figure 4**).

56
57
58
59
60
Second, there was a significant interaction between Notation and Numerator of the
distractor ($F(1,12) = 20.09$, $p < 0.001$, $\eta^2_p = 0.626$), revealing that participants were most
accurate when the numerator of the distractor was different from the target for non-symbolic
ratios ($p = 0.017$) whereas this factor was not affecting accuracy for symbolic fractions ($p =$
1.000).

Third, the ANOVA revealed a main effect of Ratio between numerators of match and
distractor ($F(1,12) = 22.17$, $p < 0.001$, $\eta^2_p = 0.649$), which was qualified by an interaction with
Notation ($F(1,12) = 11.47$, $p = 0.005$, $\eta^2_p = 0.489$). For non-symbolic ratios, participants were
more accurate when the ratio between numerators of match and distractor was large than small (p
< 0.001). For symbolic fractions, however, performance was not affected by the ratio between
numerators of match and distractor ($p = 0.522$).

Bayesian paired t-tests with default priors (0.707) revealed extreme evidence for H1 (i.e.,
large RoR is associated with higher proportion correct than small RoR) versus H0 (i.e., no
difference between large and small RoR) when participants had to choose between non-symbolic

1
2
3 ratios ($BF_{+0} > 100$). There was moderate evidence for H0 versus H1 when participants had to
4
5 choose between symbolic fractions ($BF_{0+} = 10.89$). Thus, adults with dyscalculia displayed
6
7 higher accuracy for large than small RoR for non-symbolic ratios, but not for symbolic fractions.
8
9

10 11 12 13 14 *4.3. Discussion*

15
16
17 Results of Experiment 3 show that adults with dyscalculia exhibit a pattern of responses
18
19 very similar to that of children in Experiment 2. First, overall accuracy was low on both non-
20
21 symbolic ratios (54%) and symbolic fractions (62.6%), suggesting that participants completed the
22
23 tasks with some difficulty. Second, despite this relatively low accuracy, there was a clear RoR
24
25 effect with non-symbolic ratios. This suggests that adults with dyscalculia have a perceptual
26
27 sensitivity to ratio magnitudes, much like normal adults in Experiment 1 and children in
28
29 Experiment 2. This is noteworthy because it presents evidence that adults with dyscalculia may
30
31 have access to a relatively intact RPS. Interestingly, prior research on number acuity has revealed
32
33 an impaired ANS in individuals with dyscalculia (Mazzocco et al., 2011; Piazza et al., 2010 for a
34
35 contrasting view see Iuculano, Tang, Hall, & Butterworth, 2008). To our knowledge, the present
36
37 study is the first to examine the intuitive, perceptual ability to process non-symbolic ratios in this
38
39 population. Our findings raise the possibility that the RPS may be relatively independent from the
40
41 ANS and spared in dyscalculia. Note, however, that these results come from a relatively small
42
43 sample size (despite moderate to large effect size, $\eta^2_p = 0.346$) and that future studies would need
44
45 to confirm this claim by gathering concomitant measures of both ANS and RPS in individuals
46
47 with dyscalculia.

Third, we expected to observe a RoR effect for symbolic fractions, due to less automatized calculative abilities and lower working memory capacity in adults with dyscalculia. However, performance on symbolic fractions was not affected by RoR, indicating that adults with dyscalculia do not access a representation of ratio magnitudes when they match symbolic fractions.

Overall, results of Experiment 3 are similar to the results of Experiment 1 and Experiment 2 in that participants do not naturally appear to use the RPS to match symbolic fractions in this task, independently of their level of math skills. This, however, may not mean that they *cannot* use the RPS when processing symbolic fractions. For example, accessing the RPS may be necessary if participants are forced to estimate the ratio that underlie a symbolic fraction. To explore this hypothesis, we designed a mixed-format version of the match-to-sample task in which another sample of adults were asked to choose which of two symbolic fractions corresponds to a non-symbolic ratio (see **Figure 5**). In such a task, participants are forced to *estimate* (rather than precisely determine) which symbolic fraction is the best match for the non-symbolic ratio. We expected that such a mixed-format task would require participants to access fractional magnitudes in a way that previous symbolic versions of the task did not.

5. Experiment 4

5.1. Participants

Thirty-three participants ($M = 20.5$ years, range 18-25, 25 females) from the University of Lyon 2 volunteered to participate in the study. All of them were included in the analyses. This yields 80% power to detect an effect size of $d = 0.50$ (which would be much smaller than the

1
2
3 effect reported for the difference between large and small RoR in non-symbolic stimuli in the
4
5 previous experiments). The experiment was performed in accordance with the ethical standards
6
7 established by the Declaration of Helsinki.
8
9

10 11 12 13 14 5.1.1. *Materials and Procedures*

15
16 The procedure remained the same as in the experiments above. However, stimuli for the
17
18 match-to-sample task were modified. For this task, non-symbolic ratios were presented on the left
19
20 side of the screen and symbolic fractions were presented on the right side of the screen (see
21
22 **Figure 5**). Participants were asked to match the non-symbolic ratio on the left with the correct
23
24 symbolic fraction on the right. Participants completed one block with 4 practice trials (with
25
26 feedback) followed by 80 experimental trials (consisting of 20 trials per RoR). The entire
27
28 experiment lasted for about 10 minutes.
29
30
31
32
33
34

35 5.2 *Results*

36
37 Proportion correct was analysed in a repeated-measures ANOVA with the factor RoR
38
39 (Large, Small). The analysis revealed a main effect of RoR ($F(1,32) = 63.9, p < 0.001, \eta^2_p =$
40
41 0.666), indicating that participants were more accurate for large RoR than small RoR (see **Figure**
42
43 **6**).
44
45
46
47

48 In line with the results above, a Bayesian paired t-test with default priors (0.707) revealed
49
50 extreme evidence for H1 (i.e., large RoR are associated with higher proportion correct than small
51
52 RoR) versus H0 (i.e., no difference between large and small RoR) across all trials of the
53
54
55
56
57
58
59
60

1
2
3 experiment ($BF_{+0} > 100$). Therefore, there was evidence for a difference in accuracy between
4
5 large and small RoR.
6
7
8
9

10 11 *5.3. Discussion*

12
13 Results of Experiment 4 clearly show an RoR effect in this mixed-format version of the
14 match-to-sample task, indicating that adult participants do access fractional magnitudes to
15 complete this task. This demonstrates that the lack of RoR effect in symbolic fractions in
16 Experiments 1 to 3 may not necessarily reflect an inability to use the RPS to process symbolic
17 fractions. Rather, it suggests that participants do not naturally access this non-symbolic
18 representation when they are asked to match symbolic fractions and are most likely reverting to
19 componential strategies. Yet, it is interesting to note that overall accuracy in Experiment 4 is
20 reliably above chance (66%, $t(32) = 7.48, p < 0.001, d = 1.30$), suggesting that strategies relying
21 on an intuitive understanding of fractional magnitudes may be relatively efficient. The results of
22 the four experiments are discussed in detail below.
23

38
39
40

41 **6. General Discussion**

42
43 In the above experiments, we aimed to test the hypothesis that participants are sensitive to
44 ratio magnitudes when they match non-symbolic ratios as well as symbolic fractions, thereby
45 providing further evidence for the existence of the RPS and its potential role in symbolic fraction
46 processing. Using a version of a match-to-sample task developed by Matthew (2015), we asked
47 participants to choose which of two non-symbolic ratios or symbolic fractions corresponded to a
48 given non-symbolic ratio or fraction. Our results indicate that adults have a perceptual sensitivity
49
50

52
53
54
55
56
57
58
59
60

RPS AND SYMBOLIC FRACTIONS

1
2
3 to ratios when these are presented in a non-symbolic format. This sensitivity does not appear to
4
5 be affected by the level of math skill because it was also largely present in individuals with lower
6
7 math abilities (i.e., children in 4th and 5th grade and adults with dyscalculia). Furthermore, this
8
9 sensitivity was observed when symbolic fractions had to be matched with a non-symbolic ratio,
10
11 suggesting that the RPS may contribute to symbolic fraction processing in some situations.
12
13 However, performance did not depend on the RoR when symbolic fractions had to be matched
14
15 with other symbolic fractions.
16

18
19
20
21
22
23

A perceptual route to process the approximate magnitude of fractions

24
25
26 Over our first 3 experiments, the results clearly indicate that participants' performance is
27
28 affected by the RoR when they match non-symbolic ratios. Therefore, our results add to the
29
30 growing evidence that the human cognitive architecture provides a perceptual route to process
31
32 approximate magnitudes of fractions when represented by non-symbolic ratios (Fazio, Bailey,
33
34 Thompson, & Siegler, 2014; Matthews & Chesney, 2015; Matthews & Lewis, 2017). For
35
36 instance, Matthew (2015) noticed that pre-schoolers may already possess some perceptual
37
38 sensitivity towards non-symbolic ratios and that the accuracy of some high achieving pre-
39
40 schoolers might match adult levels (Matthews, 2015; Matthews & Ziols, 2019). Furthermore, this
41
42 sensitivity has been shown to be present across species, age groups, and even in societies that
43
44 lack formal mathematic education (Jacob et al., 2012; Jeong et al., 2007; Kalra et al., 2020;
45
46 McCrink et al., 2013; McCrink & Wynn, 2007; Meert et al., 2012, 2013; Sophian, 2000). Thus,
47
48 this evidence points towards the RPS being an early developing, evolutionarily ancient system
49
50 (Lewis, Matthews, & Hubbard, 2016).
51
52
53
54
55
56
57
58
59
60

1
2
3 We also observed that performance of 4th and 5th graders on the non-symbolic ratio
4 comparison task in Experiment 2 was much lower than that of adults in Experiment 1 (contrary to
5 the preliminary study by Matthews, 2015). This might be due to the fact that the RPS might still
6 be developing in children and/or that formal mathematical experience might influence RPS
7 acuity. This would be relatively consistent with research on the ANS, which shows that formal
8 mathematical experience typically improves ANS acuity (Halberda et al., 2008; Pica, 2004).
9 Similarly, even though the RPS might be an evolutionarily ancient system present early on in
10 developmental years, its acuity might be dependent on both the quantity and quality of
11 mathematical experience and the age.
12
13
14
15
16
17
18
19
20
21
22
23

24 Finally, we found clear RoR effects for non-symbolic line ratios in adults with
25 dyscalculia. Dyscalculia is a complex, multifaceted neurodevelopmental disorder that hinders
26 acquisition of mathematical concepts despite normal intelligence (Iuculano, 2016). Much of the
27 research on dyscalculia has focused on whether and how the disability affects the processing of
28 whole number magnitudes. Some researchers have identified ANS deficits to be a potential
29 source of dyscalculia (Butterworth, 2005, 2010; Mazzocco et al., 2011; for a contrasting view, see
30 De Smedt & Gilmore, 2011; Iuculano et al., 2008, Rousselle & Noel, 2007). To our knowledge
31 no research on perceptual sensitivity of relational magnitudes in adults with dyscalculia exists.
32 Our results in adults with dyscalculia highlight two important points. First, the fact that
33 performance of adults with dyscalculia depends on RoR in our non-symbolic task suggests that
34 these individuals possess the perceptual ability to process ratios. This naturally suggests a spare
35 RPS in adults with dyscalculia. Second, performance of adults with dyscalculia in this task was
36 much lower than that of typical adults, which could be attributed either to the quality of
37 mathematical experience or a slower development of the RPS system. Nonetheless, our findings
38 raise the intriguing possibility that even though adults with dyscalculia may experience

RPS AND SYMBOLIC FRACTIONS

1
2
3 difficulties with whole number concepts, they might still be able to leverage the RPS to learn
4 fractions. One can speculate that this ability to process relational magnitudes between numbers
5 might even be utilized to teach whole number concepts (Lewis, Matthews, Hubbard, 2016).
6
7 Future studies on larger sample size and across different age groups will further help develop a
8 comprehensive picture of the development of the RPS in individuals with dyscalculia. This
9 knowledge might aid in current efforts to develop identification criteria and screeners for
10 dyscalculia in children (Rodrigues & Jordan, 2019) and adults.

20

A limited role for the RPS in symbolic fraction processing

21
22 Results of Experiment 4 suggests RPS involvement in symbolic fraction processing.
23 Specifically, we found that typical adults exhibit the signature RoR effect when they have to
24 choose between two symbolic fractions to match a non-symbolic ratio. Our results are in line
25 with a prior study done on cross-format comparisons revealing distance effects across different
26 formats (dot arrays, circle areas, symbolic fractions) indicating magnitude abstraction (Matthews
27 & Chesney, 2015). It is noteworthy to mention that several other studies on fraction magnitude
28 comparison tasks have also demonstrated a link between perceptual sensitivity to non-symbolic
29 ratios and symbolic fraction processing (Matthews, Chesney, & McNeil, 2014). Furthermore, it
30 has been argued that the cross-format comparison tasks are key to understanding a shared system
31 for non-symbolic and symbolic magnitudes as they rely on the abstract nature of magnitude
32 between the different notations (Matthews & Chesney, 2015).

38
39
40
41
42
43
44
45
46
47
48

49 However, we did not find any RoR effect when participants had to choose which of two
50 symbolic fractions matched another symbolic fraction. This was true for adults (Experiment 1),
51 children from 4th and 5th grade (Experiment 2), and adults with dyscalculia (Experiment 3). Thus,
52 participants do not appear to access ratio magnitudes when performing this matching task. On the
53
54
55
56
57
58
59
60

1
2
3 one hand, these findings are consistent with a body of literature showing that accessing the
4 holistic magnitude of fractions is challenging for typical adults (Kallai & Tzelgov, 2009, 2012;
5 Stafylidou & Vosniadou, 2004). On the other hand, they somewhat conflict with prior studies that
6 suggest that the RPS contribute to symbolic fraction processing. For example, in contrast to our
7 findings, studies have found that performance on fraction comparison tasks is influenced by
8 linear or RoR distance (Kalra et al., 2020; Matthews & Chesney, 2015; Schneider & Siegler,
9 2010).

10
11
12
13
14
15
16
17
18
19 Interestingly, this difference between our results and those prior findings does not seem to
20 stem from a clear difference in timing of response. For example, average response time was of
21 2,284 ms for adults in Experiment 1, which is only slightly higher than the average response time
22 of 1,995 ms found in the fraction comparison task designed by (Matthews & Chesney, 2015)
23 (consider also that 3 fractions are displayed simultaneously in a match-to-sample task, compared
24 to only 2 fractions in a comparison task). It is also unlikely that our participants may have chosen
25 not to rely on fractional magnitude because they used another analogical strategy involving a
26 comparison of the size of components of fractions. Indeed, in contrast to what was found for non-
27 symbolic ratios (see below), the ratio between numerators of match and distractor did not
28 influence performance on symbolic fractions. Thus, differences between our findings and that of
29 previous studies are more likely due to differences in the processes involved in magnitude
30 comparison versus match-to-sample tasks. In magnitude comparison tasks, participants are asked
31 to compare the relative sizes of two fractions (e.g., assess which fraction is larger). This task can
32 arguably be done without accessing the exact value of each fraction. Thus, magnitude comparison
33 tasks are likely to encourage participants to simply estimate approximate magnitudes (which
34 might promote strategies relying on analogical processing). In our match-to-sample task,
35 however, we asked participants to find which of two fractions corresponded to a target fraction.

RPS AND SYMBOLIC FRACTIONS

1
2
3 Although we acknowledge that it is possible to complete this task by approximating ratios, we
4 speculate that such an equivalence task more likely prompts participants to access the exact rather
5 than the approximate value of fractions. Therefore, although children, typical adults, and adults
6 with dyscalculia may rely on an intuitive sense of ratios to process non-symbolic ratio
7 magnitudes, our findings raise the possibility that this sense may only drive performance in tasks
8 that encourage subjects to approximate ratios.

19 *The role of componential strategies in symbolic fraction and non-symbolic ratio processing*

20
21 Overall, our study clearly highlights an influence of components of fractions in typical
22 adults. Interestingly, this influence was not limited to symbolic fractions but was also observed in
23 non-symbolic line ratios. For example, in addition to RoR, accuracy in the non-symbolic task
24 depended upon (i) whether the numerator (i.e., smallest of the lines) of the target was the same as
25 the numerator of the distractor and (ii) whether the ratio between the numerators of the match and
26 distractor was small or large. For symbolic fractions, accuracy was also higher when numerators
27 were identical between match and distractor, indicating that participants might have used
28 common components to process magnitudes. This influence of components on fraction
29 processing is consistent with previous reports. For instance, experts have been shown to make use
30 of componential strategies when they are efficient to solve fraction problems (Obersteiner et al.,
31 2013). Drawing on concepts from the *Dynamic Strategy Choice* account (Alibali & Sidney,
32 2015), we argue that the specific task feature of common numerator might have led participants
33 to utilize a simple and effective “compare the denominator” strategy. It is also possible that the
34 use of such a strategy with symbolic fractions might have influenced the adults to utilize a similar
35 strategy for non-symbolic formats (in addition to the RPS). Note that it is also possible that the
36 use of trials in which the numerator of the target was identical to that of the distractor might have
37
38
39
40
41
42
43
44

51
52
53
54
55
56
57
58
59
60

1
2
3 also encouraged participants to use componential strategies, even on other trials in which the
4
5 numerator of the target was different than that of the distractor. Although this equal mixture of
6
7 trials was chosen to present participants with a variety of fractions, future studies might
8
9 investigate to what extent the use of componential strategies may depend on different types of
10
11 fractions on such match-to-sample tasks.
12
13

14
15 This ability to utilize and form new strategies to solve problems may also develop with
16
17 age and mathematical experience, consistent with the fact that the identity of the numerator (i.e.,
18
19 same or different across target and distractor) influenced performance in adults (Experiment 1)
20
21 but not in children (Experiment 2). These results are similar to a study done by Zhang &
22
23 Colleagues, 2014, whereby based on accuracy rates the authors noted that adults are better
24
25 equipped to adopt componential processing strategies than children. Finally, an important
26
27 question regarding the role of formal education in shaping perceptual abilities was raised by
28
29 Lewis, Matthews, & Hubbard, 2015 in their chapter. We believe our results might have shed
30
31 some light on this phenomenon. The finding that processing non-symbolic line ratios may rely on
32
33 componential strategies might suggest that formal education and years of experience could be
34
35 responsible for the transfer of these efficient strategies from symbolic fractions to non-symbolic
36
37 line ratios thus, playing a role in shaping perceptual abilities.
38
39
40
41
42
43

44 *Symbolic fraction knowledge in adults with dyscalculia*

45

46
47 A couple of prior studies have investigated fraction knowledge in children with
48
49 dyscalculia. These studies point to the difficulties encountered by children with dyscalculia when
50
51 processing symbolic fractions. For example, it has been shown that children with dyscalculia fail
52
53 to order fractions, estimate the sum of two fractions, and identify equivalent fractions (Mazzocco
54
55 & Devlin, 2008; Hansen, Jordan, & Rodrigues, 2015). In a study by Siegler & Pyke, 2013 and
56
57
58
59

1
2
3 Bailey et al., 2015, understanding magnitudes of fractions and performing arithmetic
4
5 computations were shown to be challenging for children with dyscalculia. Another study showed
6
7 that children with dyscalculia also persist to view visual models of fractions as concrete
8
9 representations until Grade 8, which misguides them on Arabic fraction representations
10
11 (Mazzocco, Myers, Lewis, Hanich, & Murphy, 2013). To our knowledge no studies to date have
12
13 examined the difficulties and strategies used by adults with dyscalculia when performing fraction
14
15 tasks. Exploring how symbolic fractions are processed by adults with dyscalculia might aid in
16
17 understanding the misconceptions and challenges faced by them on fraction tasks. Our results
18
19 show that the performance of adults with dyscalculia was lower for both symbolic and non-
20
21 symbolic tasks as compared to typical adults. Further, effective effortful strategies like
22
23 componential processing were not utilized by adults with dyscalculia which might have been one
24
25 of the reasons for a lower accuracy score. This indicates that adults with dyscalculia struggle with
26
27 equivalent fractions and are unable to utilize componential processing strategies effectively as
28
29 compared to typical adults.
30
31
32
33
34
35
36
37

38 **7. Conclusion**

39
40 The aim of this research was twofold; first, to examine perceptual sensitivity towards non-
41
42 symbolic ratio magnitudes in participants with varying levels of math skills and second, to
43
44 investigate the extent to which the perceptual ability is utilized for symbolic fraction processing.
45
46 We found evidence for perceptual sensitivity towards non-symbolic ratio magnitudes in all
47
48 groups of participants, irrespective of their age or level of math skill. A clear pattern that also
49
50 emerged in our study was that children and adults with and without dyscalculia do not rely on the
51
52 RPS when they have to find equivalent symbolic fractions (Experiments 1 to 3). However, they
53
54 do rely on the RPS when the ratios behind symbolic fractions have to be estimated (Experiment
55
56
57
58
59
60

1
2
3 4). Together these findings add to growing evidence for an intuitive, perceptual sensitivity for
4 non-symbolic relational magnitudes. They also indicate that the role of the RPS in symbolic
5 fraction processing is limited to tasks in which participants have to approximate the value of a
6
7
8
9
10 fraction.

Figure Legends

Figure 1. Match-to-sample task. (A) In each non-symbolic trial, participants had to match the pair of line segments on the left of the screen to the equivalent pair of line segments on the right of the screen. (B) In each symbolic trial, participants had to match the fraction on the left of the screen to the equivalent fraction on the right of the screen.

Figure 2. Results of Experiment 1 (typical adults). (A) Proportion correct as a function of Notation and RoR for trials in which the numerator of the target was *identical* to the numerator of the distractor and in which the ratio between numerators of match and distractor was small. (B) Proportion correct as a function of Notation and RoR for trials in which the numerator of the target was *identical* from the numerator of the distractor and in which the ratio between numerators of match and distractor was large. (C) Proportion correct as a function of Notation and RoR for trials in which the numerator of the target was *different* from the numerator of the distractor and in which the ratio between numerators of match and distractor was small. (D) Proportion correct as a function of Notation and RoR for trials in which the numerator of the target was *different* from the numerator of the distractor and in which the ratio between numerators of match and distractor was large. The bars here represent standard errors.

Figure 3. Results of Experiment 2 (children).
