27 ABSTRACT

28 While evidence that telomere length is associated with health and mortality in humans and birds
29 is accumulating, a large body of research is currently seeking to identify factors that modulate
30 telomere dynamics. We tested the hypothesis that high levels of glucocorticoids in individuals
31 under environmental stress should accelerate telomere shortening in two wild populations of
32 roe deer (*Capreolus capreolus*) living in different ecological contexts. From two consecutive
33 annual sampling sessions, we found that individuals with faster rates of telomere shortening
34 had higher concentrations of fecal glucocorticoid metabolites, suggesting a functional link
35 between glucocorticoid levels and telomere attrition rate. This relationship was consistent for
36 both sexes and populations. This finding paves the way for further studies of the fitness
37 consequences of exposure to environmental stressors in wild vertebrates.

43

44 **1. Introduction**

45 Telomeres are non-coding and repetitive DNA sequences located at the extremity of eukaryotic
46 linear chromosomes. The shortening of telomere sequences observed in somatic cells over the
47 lifetime of most species is expected to be associated with the aetiology of age-related diseases
48 and an increased risk of mortality (see Blackburn et al. 2015; Wilbourn et al. 2018 for evidence
49 in humans and birds). Therefore, identifying ecological factors modulating telomere dynamics
50 has become an important challenge (Blackburn et al., 2015; Monaghan et al., 2018). In
51 vertebrates, including humans (Epel et al., 2004), it has been repeatedly suggested that
52 environmental stressors (e.g. exposure to predators, food shortage, psychosocial stress) should
53 accelerate telomere attrition rate (Epel et al., 2004; Haussmann and Marchetto, 2010;
54 Monaghan, 2014). In agreement with this prediction, a recent meta-analysis based on 109
55 studies investigating the association between environmental stressors and telomere length
56 across vertebrates revealed that individuals facing stressful conditions have, on average, shorter
57 telomeres (Chatelain et al. 2020). This relationship was particularly pronounced in birds and
58 mammals, and was consistent irrespective of the type of stressor considered (Chatelain et al.
59 2020). From a mechanistic point of view, environmental stressors have been suggested to
60 modulate telomere dynamics through stimulation of the hypothalamic-pituitary-adrenal axis,
61 triggering the release of glucocorticoids into the bloodstream by the adrenal gland cortex
62 (reviewed in Haussmann and Marchetto 2010). Chronically elevated glucocorticoids are
63 thought to accelerate telomere shortening through diverse physiological pathways (Haussmann
64 and Marchetto, 2010), especially through increased oxidative stress (Angelier et al., 2018; Gil
65 et al., 2019; Reichert and Stier, 2017).

66 In the wild, most of our knowledge about the influence of glucocorticoids on telomere
67 length or dynamics comes from avian studies (Angelier et al., 2018). These studies have
68 revealed that, in most cases, high levels of plasma corticosterone are associated with short

69 telomeres. This is well illustrated in black-legged kittiwakes (*Rissa tridactyla*) where
70 individuals carrying a corticosterone implant during the reproductive season experienced more
71 marked telomere shortening than control individuals (Schultner et al., 2014) and in black-
72 browed albatross (*Thalassarche melanophrys*) where a negative association was found between
73 baseline corticosterone levels and telomere length in both sexes (Angelier et al., 2019).
74 Interestingly, some studies have reported no association between glucocorticoid level and
75 telomere length, or even a positive relationship in some cases (reviewed in Angelier et al. 2018),
76 and empirical studies have suggested that the direction of the association might be influenced
77 by both environmental conditions and sex (Bauch et al., 2016; Jiang et al., 2019; Young et al.,
78 2016). Our knowledge is much more limited in mammals, although a few experiments on
79 laboratory rodents suggest that stressful environments can induce shorter telomeres (Ilmonen
80 et al., 2008). Overall, our current understanding of the link between physiological markers of
81 stress and telomere dynamics remains limited, especially in wild mammals. In this study, we
82 tested whether individuals with high glucocorticoid levels had shorter telomeres and a faster
83 year-to-year telomere attrition rate in both sexes of two free-ranging populations of roe deer
84 (*Capreolus capreolus*) living in environments that differ markedly in terms of habitat quality.
85 We predicted that the relationship between glucocorticoid level and telomere loss should be
86 steeper in the roe deer population facing marked resource limitation (Chizé) than in the
87 population living in a more productive environment (Trois-Fontaines). We also predicted that
88 this relationship should be steeper in males, as they might experience a higher baseline stress
89 level than females (Carbillet et al., 2019). A stronger impact of glucocorticoids on telomere
90 shortening in males compared to females could explain, at least to some extent, why male roe
91 deer have a shorter lifespan compared to females (e.g. Garratt et al., 2015).

92

93

94

95 **2. Material and Methods**

96 *2.1. Study population and sample collection*

97 We studied two populations of roe deer living in enclosed forests. Trois-Fontaines forest (TF -
98 1,360 ha), located in north-eastern France (48°43'N, 4°55'E), has rich soils and provides high
99 quality habitat for roe deer. In contrast, Chizé forest (CH - 2,614 ha), located in western France
100 (46°05'N, 0°25'W), has a low productivity due to poor soils and frequent summer droughts,
101 providing a less suitable habitat for roe deer (Pettorelli et al., 2006). For the last 40 years, 10-
102 12 days of capture have been organized each winter as part of a long-term Capture-Mark-
103 Recapture program (Gaillard et al., 1993). During winter, the diet composition is very similar
104 at both study sites (mostly brambles, *Rubus* sp. and ivy, *Hedera helix*, see Tixier and Duncan
105 1996) and should not generate differences in faecal composition between populations which
106 otherwise may cause a bias in FGM measurements (see below). In two consecutive years (2016
107 and 2017), blood samples were collected between January and February, minimizing potential
108 confounding variation in stress levels due to individual reproductive state (Cheynel et al., 2017).
109 Indeed, at this time of the year, nearly all females are in the very early phase of gestation, while
110 males have not yet established their mating territories (Andersen et al., 1998). Upon capture,
111 individuals are sexed, weighed (\pm 50g) and a basic clinical examination is performed. We
112 collected blood samples (up to 1mL/kg) from the jugular vein. We sampled only individuals of
113 known age, which have been captured during the first year of life. Within 30 min of sampling,
114 whole blood was spun at 2000 g for 10 min and the plasma layer drawn off and replaced with
115 the same quantity of 0.9% w/v NaCl solution and spun again. The intermediate buffy coat layer,
116 comprising mainly leukocytes, was collected in a 1.5-mL Eppendorf tube and immediately
117 frozen at -80 °C in a portable freezer (Telstar SF 8025) until further use.

118

119 2.2. *Telomere assays*

120 Relative telomere length (hereafter RTL) was measured by quantitative PCR as previously
121 described for these populations (Wilbourn et al., 2017). Genomic DNA was extracted from
122 white blood cells using the Macherey-Nagel NucleoSpin® Blood QuickPure kit. DNA yield
123 and purity was quantified using a Nanodrop ND-1000 spectrophotometer (Thermo Scientific,
124 Wilmington DE, USA) and DNA integrity was assessed by running 200 ng total DNA on a
125 0.5% agarose gel and DNA bands scored on a scale of 1-5 by visual examination. Samples
126 passed QC with a DNA yield of ≥ 20 ng/ μ l, an acceptable purity absorption range of 1.7 - 2.0
127 for the 260/280 nm ratio and > 1.8 for the 260/230 nm ratio, and a DNA integrity score of either
128 1 or 2 (Seeker et al., 2016). We measured relative leukocyte telomere length (RTL) using a
129 real-time quantitative PCR method (qPCR; Cawthon 2002) which has previously been
130 optimized and validated in sheep and cattle (Seeker et al., 2016) and previously used in roe deer
131 (Wilbourn et al., 2017). This method measures the total amount of telomeric sequence present
132 in a DNA sample relative to the amount of a non-variable copy number reference gene (beta-
133 2-microglobulin (B2M)). B2M was previously identified as an appropriate reference gene for
134 use in qPCR studies of telomere length in sheep (Fairlie et al., 2016) and cattle (Seeker et al.,
135 2018, 2016). The selection was based on comparison of panels of candidate genes supplied as
136 part of the GeNorm kit by Primerdesign (12 candidate reference genes for sheep, 6 for cattle).
137 B2M showed a consistent amplification profile, clean melting curve and stable qPCR results in
138 preliminary analyses with roe deer samples, and was therefore deemed to be a suitable reference
139 gene for our study (Wilbourn et al., 2017). For telomere reactions, we used the following HPLC
140 purified primers, Tel 1b (5'-CGG TTT GTT TGG GTT TGG GTT TGG GTT TGG GTT TGG
141 GTT-3') and Tel 2b (5'-GGC TTG CCT TAC CCT TAC CCT TAC CCT TAC CCT TAC
142 CCT-3') (from Epel et al. 2004). For B2M reactions, primers were supplied by Primer Design
143 (Catalogue number: HK-SY-Sh-900, Southampton, UK).

144 Using an automated liquid handling robot (Freedom Evo-2 150; Tecan), we were able
145 to load both the DNA samples and qPCR master mix in 384 well plates, allowing us to run both
146 telomeric and B2M reactions in separate wells, but on a single plate. A separate master mix for
147 each primer set was prepared containing 5 μ l LightCycler 480SYBR Green I Master Mix (Cat
148 # 04887352001, Roche, West Sussex, UK), 0.5 μ l B2M (300nm) primer or 0.6 μ l each telomeric
149 primer (900nm), and 1 ng of sample DNA per individual PCR reaction. DNA was amplified in
150 10 μ l reactions. Each plate included a non-treated control (water; NTC) for each amplicon, a
151 calibrator sample (1ng) on each row to account for plate to plate variation and robot pipetting
152 error, as well as a five step 1:4 serial dilution starting at 20ng/ μ l to inspect visually the qPCR
153 curves. The calibrator sample was DNA that had been extracted from a large quantity of blood
154 obtained from a single wild roe deer. In this case, the calibrator was extracted using the Qiagen
155 DNeasy Blood and Tissue kit (Cat# 69581. Manchester. UK), pooled and quality controlled in
156 the same way as our DNA samples of interest. All samples, calibrators and NTC's were run in
157 triplicate and all qPCR were performed using a Roche LC480 instrument using the following
158 reaction protocol: 10min at 95°C (enzyme activation), followed by 50 cycles of 15s at 95°C
159 (denaturation) and 30s at 58°C (primer annealing), then 30s at 72°C (signal acquisition).
160 Melting curve protocol was 1 min at 95°C, followed by 30s at 58°C, then 0.11°C/s to 95°C
161 followed by 10s at 40°C.

162 We used the LinRegPCR software package (version 2016.0) (Ruijter et al., 2009) to
163 correct for baseline fluorescence, to set a window of linearity for each amplicon group and to
164 calculate well-specific reaction efficiencies and C_q values (Fairlie et al., 2016). A constant
165 fluorescence threshold was set within the window of linearity for each amplicon group,
166 calculated using the average C_q across all three plates. The threshold values used were 0.304
167 and 0.394, and the average efficiency across all plates was 1.89 for both the B2M and telomere
168 amplicon groups. Samples were excluded from further analysis if the coefficient of variation

169 (CV) across triplicate Cq values for either amplicon was > 5%, or if at least one of their triplicate
170 reactions had an efficiency that was 5% higher or lower than the mean efficiency across all
171 wells on that plate for the respective amplicon. Overall, thirteen samples failed quality control
172 at either the DNA extraction or qPCR stage and were excluded from the study. We calculated
173 relative telomere length (RTL) for each sample following (Pfaffl, 2001) as follows:

$$174 \text{ RTL} = (\text{ETEL}(\text{CqTEL}[\text{Calibrator}] - \text{CqTEL}[\text{Sample}])) / (\text{EB2M} (\text{CqB2M}[\text{Calibrator}] - \\ 175 \text{CqB2M}[\text{Sample}]))$$

176 where ETEL and EB2M are the mean reaction efficiencies for the respective amplicon group
177 across all samples on a given plate; CqTEL[Calibrator] and CqB2M[Calibrator] are the average
178 Cqs for the relevant amplicon across all calibrator samples on the plate; and CqTEL[Sample]
179 and CqB2M[Sample] are the average of the triplicate Cqs for the sample for each amplicon.

180 Data on RTL change between years were available for 43 individuals (Chizé: 12
181 females, 6 males; Trois Fontaines: 13 females, 12 males, see Table 1 for sample sizes).

182

183 2.3. *Glucocorticoid assays*

184 Glucocorticoid levels were assessed by measuring fecal glucocorticoid metabolites (hereafter
185 FGMs). In roe deer, FGM levels represent an integrated measure of adrenocortical activity
186 about half a day prior to capture (Dehnhard et al., 2001; Palme, 2019). Feces were collected
187 rectally and frozen immediately at -80°C until assayed (except in 2016 at TF when samples
188 were stored at -20°C). FGMs were extracted following a methanol-based procedure and assayed
189 using a group-specific 11-oxoetiocholanolone enzyme immunoassay (EIA) as previously
190 described and validated for roe deer (Möstl et al., 2002; Zbyryt et al., 2017). To determine the
191 amount of glucocorticoid metabolites in feces of roe deer from the 2016 and 2017 field seasons,
192 we sampled 500 ± 5 mg of each homogenized fecal sample that we vortexed for 30 min with 5
193 ml of 80% methanol before being centrifuged (15 min at 2500 g) (Palme et al., 2013). We

194 determined the amount of FGMs (with a 3 α , 11-oxo structure) in an aliquot of the supernatant
195 (after a further 1+9 dilution with assay buffer). Measurements were carried out in duplicate
196 (intra- and inter-assay coefficients of variation were <10% and <15%, respectively) and results
197 expressed as nanograms per gram of wet feces. To ensure that there were no differences in the
198 moisture content of feces between populations that could bias our FGM measurements, we
199 measured the moisture content of 60 randomly selected fecal samples (30 per population). In
200 each sample, the moisture content was calculated by subtracting dry mass (after total
201 dehydration in an oven at 60°C for 120 hours) from wet mass. The weighing was carried out to
202 the nearest 0.1 mg on an electronic scale and the result was expressed as % of wet mass. The
203 results did not reveal any difference in feces moisture content between sites (mean moisture
204 content \pm SD: 43 \pm 7% vs. 44 \pm 11% at Chizé and Trois Fontaines, respectively).

205 Overall, FGM concentrations were similar in Chizé and Trois Fontaines (Chizé:
206 973.98ng/g, 95% CI [716.55;1231.42]; Trois Fontaines: 800.59ng/g, 95% CI [649.60;951.47]).
207 One male from the TF population had an extremely low non-physiological (and unexplained)
208 FGM level in 2017 (8 ng/g, see Fig. S1) and was removed from the analyses. Individual
209 concentrations of FGMs in 2016 and 2017 were correlated ($r = 0.42$, $p = 0.02$, $n = 30$, Fig. 1).
210 However, this relationship was strongly influenced by a single male in Chizé, which had the
211 highest level of FGMs in the dataset in both 2016 and 2017. Once this individual was removed,
212 individual concentrations of FGMs in 2016 and 2017 were no longer correlated ($r = 0.18$, $p =$
213 0.34 , $n = 29$), but the repeatability of FGM concentrations (i.e. ratio of among-individual
214 variance to total variance, Nakagawa and Schielzeth, 2010) between 2016 and 2017 was 0.35,
215 which is within the range generally observed for glucocorticoids in vertebrates (Taff et al.,
216 2018) and more specifically in roe deer (Carbillet et al., 2020).

217

218 *2.4. Statistical analyses*

219 We performed a set of analyses seeking to test whether either raw RTL values (in 2016 and
220 2017) or the change in RTL between years (RTLc, computed as the difference in RTL values
221 between 2016 and 2017 for a given individual) were related to glucocorticoid levels. We first
222 analyzed the relationship between FGMs on RTL within each year. As both habitat and sex
223 have been suggested to mediate the relationship between FGMs and telomere length in wild
224 animals (Angelier et al., 2018), we included possible additive or interactive effects of sex and
225 population. Finally, we included age to control for possible age-dependence of telomere length
226 (Wilbourn et al., 2017), and body mass (log-transformed) to control for possible growth-
227 mediated covariation between body mass and telomere length (Monaghan and Ozanne, 2018)
228 as covariates (see Tables S1, S2 Appendix A for the full set of models).

229 To test for a link between FGMs and RTLc, we analyzed the relationship between RTLc
230 and FGM levels (log-transformed) measured in 2016 and 2017 (e.g. Table S4). In addition to
231 the effects of FGMs measured in 2016 or 2017, we tested the influence of the mean FGM level
232 (log-transformed) as a proxy of the mean baseline stress level experienced during two
233 consecutive winters on RTLc. We followed the same model selection procedure as the one
234 described above using RTL as the response variable. We thus included log-transformed body
235 mass (using body mass measured in 2016, 2017 or mean body mass for models with FGMs in
236 2016, FGM in 2017 and mean FGMs, respectively) and age as potential covariates. We also
237 included possible additive or interactive effects of sex and population on RTLc (see Table S3
238 for a full list of models).

239 We repeated the analyses excluding individuals sampled in their first year of life (i.e. at
240 about eight months of age, Tables S2 and S4), because telomere attrition may be faster during
241 early life compared to adulthood (Fairlie et al., 2016), and including the birth cohort (2003 to
242 2015) as a random effect (Table S5) to control for non-independence among animals born in
243 the same year using linear mixed effects models (using the R-package lme4). In all cases, results

244 were qualitatively unchanged (Tables S2, S4 and S5). Model selection was based on the Akaike
245 Information Criterion (AIC) and we retained the model with the lowest AIC, except when the
246 difference in AIC (ΔAIC) between two competing models was less than 2, in which case we
247 retained the simplest model (Burnham and Anderson 2002).

248

249 **3. Results**

250 Within years, we detected no association between FGMs and RTL (Table S1, $\beta \pm SE = -0.04 \pm$
251 0.07 , $n = 38$ in 2016; $\beta = -0.11 \pm 0.08$ in 2017, $n = 32$; Fig. 2). The repeatability of RTL values
252 was 0.24, while we observed a decrease in telomere length between 2016 and 2017 in 51.2%
253 (22 out of 43) of individuals (Fig. 3). Our model selection procedure revealed that high average
254 FGM levels in 2016 and 2017 were associated with a stronger decrease in RTL between these
255 two consecutive years (Table S3, $\beta = -0.23 \pm 0.11$, $n = 30$, Fig. 4a). Likewise, FGM levels of roe
256 deer captured in 2017 were negatively associated with RTLc ($\beta = -0.20 \pm 0.09$, $n = 32$, Fig. 4b).
257 Population, sex and body mass had no detectable influence on RTLc. The level of FGMs
258 measured in 2016 was not related to RTLc (the constant model was selected, Table S3, Fig 4c).
259 Finally, our results were not impacted by individual differences in the number of days elapsed
260 between the 2016 and 2017 capture sessions (Table 2).

261

262 **4. Discussion**

263 Previous reports in birds have revealed that high levels of glucocorticoids are associated with
264 shorter telomeres in nestlings (e.g. Pegan et al., 2019; Powolny et al., 2020) and among adults
265 (see Angelier et al., 2018 for a review; but see Cerchiara et al., 2017 for a counter-example in
266 Magellanic penguins, *Spheniscus magellanicus*). In our study, we did not observe any within-
267 year association between relative telomere length and FGM level in roe deer. While substantial
268 inter-individual differences in telomere dynamics occur in wild vertebrates (Fairlie et al., 2016;

269 Spurgin et al., 2018), the large variation in telomere length observed among juveniles
270 (Wilbourn et al., 2017) might explain these results if, to some extent, telomere length in
271 adulthood can be predicted by telomere length during early-life. However, we found that high
272 average FGM levels in two consecutive winters predicted the rate of telomere attrition in both
273 roe deer populations. Here, it is noteworthy that, between 2016 and 2017, telomere length
274 increased with age in 48.8% of individuals, in line with a few recent reports of within-individual
275 elongation of telomere length in wild populations of vertebrates (e.g. Soay sheep, *Ovis aries*,
276 Fairlie et al., 2016; edible dormouse, *Glis glis*, Hoelzl et al., 2016; Seychelles warbler,
277 *Acrocephalus sechellensis* Spurgin et al., 2018). While measurement error could contribute to
278 such an apparent elongation of telomere length (Steenstrup et al., 2013), we cannot totally ruled
279 out that this pattern might have a biological foundation (Bateson and Nettle, 2017). For
280 instance, this pattern could arise from year-to-year changes in the leukocyte formula of
281 individuals (Spurgin et al., 2018), which has already been observed in roe deer (Cheynel et al.,
282 2017). In addition, the elongation of telomeres with increasing age could result from a possible
283 expression of telomerase (Blackburn et al., 2015). Currently, our knowledge on telomerase
284 activity in cervids is both limited and unclear (no expression in the fibroblasts of two Muntjac
285 species, *Muntiacus muntjak* and *Muntiacus reevesi*, see Gomes et al., 2011; expression in the
286 antlers of sika deer, *Cervus nippon*, see Sun et al., 2010) so that complementary analyses are
287 thus required to disentangle these different scenarios that challenge the common view of an
288 inevitable telomere loss over the life course. In roe deer, repeatability in telomere length was
289 relatively high (i.e. 0.24) compared to previous published values (e.g. 0.068 in Seychelles
290 warbler, *Acrocephalus sechellensis*, but see Bichet et al., 2020), which might be due to the fact
291 that our measurements were performed in two consecutive years, so that a lower rate of change
292 is expected compared to measurements taken across a longer time span.

293 Our findings indicate that the relationship between glucocorticoid levels and telomere
294 dynamics is not sex-specific in roe deer. This contrasts with the relationship between baseline
295 corticosterone levels and telomere length (measured in two consecutive years) reported in males
296 only in a study in common terns (*Sterna hirundo*) (Bauch et al., 2016). In terns, corticosterone
297 levels reflect male, but not female, reproductive expenditure (Bauch et al., 2016) and males
298 allocate three times more effort to chick feeding than females (Wiggins and Morris, 1987),
299 which may explain these sex-specific responses of telomere attrition. In roe deer, males grow
300 antlers each year and actively defend mating territories, while female reproductive allocation is
301 high, because they generally give birth to twins that have fast post-natal growth rates (Andersen
302 et al., 1998). Given that the overall reproductive effort is high in both males and females and
303 that this species is weakly dimorphic in size, this is consistent with the lack of sex differences
304 in telomere dynamics that we report. From this, it appears particularly important to accurately
305 assess how reproductive expenditure differs between males and females and to consider how
306 the stress response following increased reproductive effort might differ between the sexes when
307 investigating the possible sex-specific effects of stress on telomere dynamics.

308 In recent years, a few studies in birds have investigated whether the relationship between
309 telomere length and corticosterone level can be modulated by environmental conditions. A
310 comparison of nestlings from two populations of Thorn-tailed Rayadito (*Aphrastura*
311 *spinicauda*) located at different latitudes and thus exposed to different climatic conditions
312 revealed that individuals living at high latitude have higher levels of baseline corticosterone
313 and somewhat shorter telomeres than individuals living at low latitude (Quirici et al., 2016).
314 However, the negative association found between telomere length and baseline corticosterone
315 level was broadly similar across the two populations (Quirici et al., 2016). On the contrary, a
316 comparison of three colonies of thick-billed murre (*Uria lomvia*) revealed a much more
317 contrasted picture (Young et al., 2016). While no relationship between telomere length and

318 baseline corticosterone levels was found in individuals living in habitat of medium quality, the
319 relationship was negative in the high quality habitat but, surprisingly, positive in the low quality
320 habitat, emphasizing the complex role played by the environment in mediating these
321 relationships (Young et al., 2016). One possible approach to decipher these relationships is to
322 focus on telomere loss rather than telomere length to control for inter-individual differences in
323 telomere length (Quirici et al., 2016). In the present study, we found that the slope of the
324 relationship between telomere length and glucocorticoid level did not differ between our two
325 populations of roe deer living in contrasting environments. Since glucocorticoid levels also did
326 not differ between the two populations, we can hypothesize that an adaptive down-regulation
327 of the stress response in Chizé, where the roe deer experience the harshest environmental
328 conditions (see Le Saout et al. 2016 for similar observations in black-tailed deer, *Odocoileus*
329 *hemionus sitkensis*) might lead to a similar pattern of telomere loss as a function of
330 physiological stress in both habitats. Note, however, that we cannot rule out that the absence of
331 sex- or population-specific variation in our study might be due to low statistical power.

332 In vertebrates, the release of glucocorticoids is the last stage in a cascade of
333 physiological responses initiated by environmental stressors (Hausmann and Marchetto,
334 2010). While these pathways are well described (Boonstra, 2013), the physiological
335 mechanisms linking high levels of glucocorticoids to a faster pace of telomere attrition - as we
336 report here - are yet to be identified in wild vertebrate populations. Studies performed to date
337 have focused on the alteration of the redox homeostasis (Angelier et al., 2018; Hausmann et
338 al., 2012) and on the modulation of the mitochondrial metabolism (Casagrande et al., 2020;
339 Casagrande and Hau, 2019) by glucocorticoids. In addition, in vitro experiments have shown
340 that high levels of glucocorticoids reduce the activity of telomerase, the main enzyme
341 responsible for preserving chromosome length through telomeric DNA synthesis, in human
342 leukocytes (Choi et al., 2008). However, modulation of telomerase activity by stress is a

343 complex phenomenon that depends not only on glucocorticoid level, but also on the magnitude
344 of stress reactivity and recovery (Beery et al., 2012; Epel et al., 2010). Moreover, the relative
345 influence of this third pathway remains unknown in large herbivores, as our knowledge on
346 telomerase activity is particularly limited within this taxa (Gomes et al., 2011). Future work
347 should seek to integrate multiple measures of oxidative damage and antioxidant defenses with
348 measures of mitochondrial and telomerase activity in leukocytes to decipher the physiological
349 connections linking environmental stressors and telomere dynamics.

350 Overall, our study highlights that the level of stress (as measured by FGM levels)
351 influences telomere dynamics, even over a short time scale, which could potentially generate
352 substantial individual differences in telomere length in late adulthood. As short telomeres are
353 associated with poor health (Beirne et al., 2014), and thereby greater mortality risk in
354 populations of vertebrates in the wild (Bichet et al., 2020; Wilbourn et al., 2018), we suggest
355 that telomere dynamics might mediate the long-term survival cost of repeated exposure to
356 environmental stressors.

357

358 **Declaration of Competing Interest**

359 No conflict of interest.

360

361 **Acknowledgements**

362

363 We thank all the OFB staff, in particular Claude Warnant, Gilles Capron, Florian Chaudat and
364 the field volunteers for organizing the roe deer captures. We thank Edith Klobetz-Rassam for
365 FGM analysis. Lastly, we are grateful to two anonymous reviewers for helpful comments.

366

367 **Authors' contributions**

368

369 JFL & EGF conceived and designed the study. JFL, BR, LC, JMG, AJMH, HV, FD, JD, SP,
370 MP, EGF performed fieldwork. BR, CR and LC extracted DNA. RP, JC, BR ran FGM assays.
371 HF, RW, SLU and DN ran telomere assays. JFL performed the statistical analysis, wrote the

372 first draft of the paper and then received input from all other co-authors. All authors approved
373 the final version of the manuscript and agree to be held accountable for the content therein.
374

375 **Funding**

376
377 J.F.L., J.M.G., E.G.F., B.R. and L.C. were supported by a grant from the Agence Nationale de
378 la Recherche (ANR-15-CE32-0002-01). This work was performed within the framework of the
379 LABEX ECOFECT (ANR-11-LABX-0048), within the program ‘Investissements d’Avenir’
380 (ANR-11-IDEX-0007) operated by the French National Research Agency (ANR). D.H.N. and
381 H.F. were supported by a BBSRC grant no. (BB/L020769/1).
382

383 **Ethics**

384
385 The protocol of capture and blood sampling under the authority of the Office Français de la
386 Biodiversité (OFB) was approved by the Director of Food, Agriculture and Forest (Prefectoral
387 order 2009–14 from Paris). The land manager of both sites, the Office National des Forêts
388 (ONF), permitted the study of the populations (Partnership Convention ONCFS-ONF dated
389 2005-12-23). All experiments were performed in accordance with guidelines and regulations of
390 the Ethical Committee of Lyon 1 University (project DR2014-09, June 5, 2014).
391

Both populations	14 (age: 2-8)	18 (age: 2-14)	32 (age: 2-14)	Both populations	14 (age: 2-8)	16 (age: 2-14)	30 (age: 2-14)

569

570 **Table 2:** Parameter estimates of the selected model describing the change in RTL as a function
 571 of concentration in fecal glucocorticoid metabolites (FGMs) measured in 2017, n=32 (A) or the
 572 mean concentration (across 2016 and 2017) in fecal glucocorticoid metabolites (FGMs), n=30
 573 (B) with the number of days elapsed between the two capture events entered as a covariate.
 574

(A)	Estimate	SE	t	<i>p</i>
Intercept	-0.64	1.21	-0.53	0.60
FGMs (2017)	-0.24	0.09	-2.61	0.01
Number of days between captures	0.01	0.00	1.92	0.07

(B)	Estimate	SE	t	<i>p</i>
Intercept	-0.12	1.44	-0.08	0.94
Mean FGMs	-0.24	0.11	-2.15	0.04
Number of days between captures	0.00	0.00	1.35	0.19

579 **CAPTION FOR FIGURES:**

580

581 **Fig. 1:** Relationship between the concentration of fecal glucocorticoid metabolites (FGMs)
582 measured in 2017 (ng/g, log-transformed) and the FGM concentration measured in 2016 (ng/g,
583 log-transformed). Individual FGM concentrations in 2016 and 2017 were correlated ($r = 0.42$,
584 $p = 0.02$, $n = 30$), with a repeatability of 0.22. This relationship was strongly influenced by a
585 single male in Chizé with the highest FGMs in both 2016 and 2017. After removing this
586 individual the relationship was no longer statistically significant: $r = 0.18$, $p = 0.34$, $n = 29$,
587 repeatability of 0.32). Males in Chizé are in dark blue, females in Chizé are in light blue, males
588 in Trois-Fontaines are in dark red and females in Trois-Fontaines are in light red.

589

590 **Fig. 2:** Relationship between RTL and fecal glucocorticoid metabolite concentration (FGMs,
591 (ng/g, log-transformed) using samples collected in 2016 (a) and 2017 (b).

592

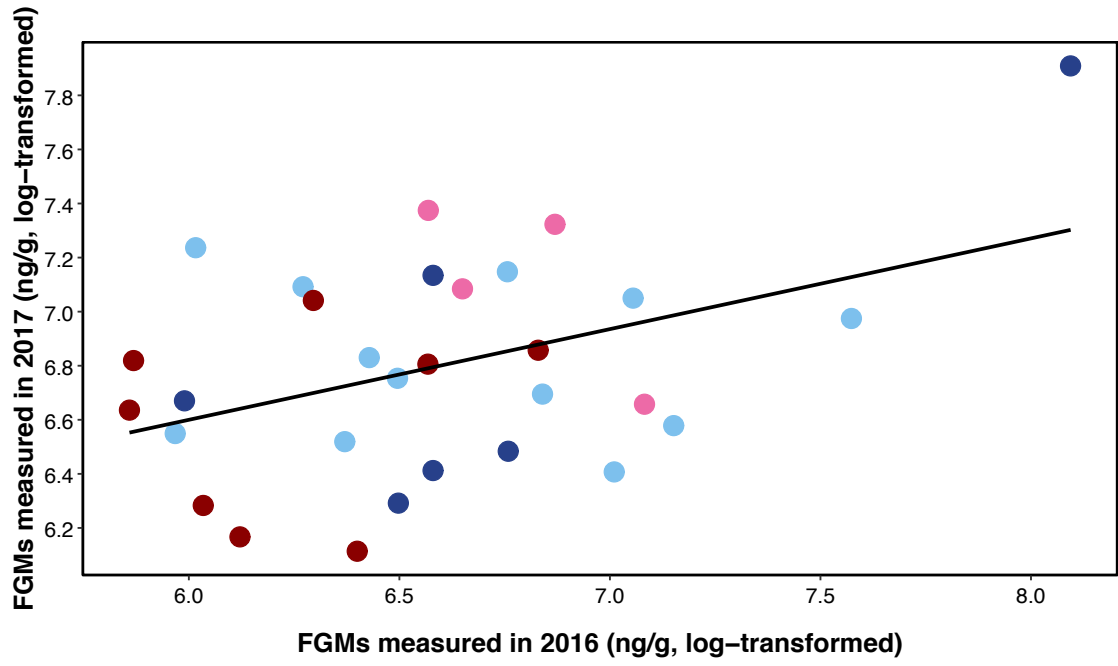

593 **Fig. 3:** Within-individual change in RTL across the two consecutive years of our study (2016
594 and 2016) ($n = 43$).

595

596 **Fig. 4:** Relationship between the within-individual difference in RTL between 2017 and 2016
597 and the individual mean FGM over both years (a), 2017 (b) and 2016 (c). Males in Chizé are in
598 dark blue, females in Chizé are in light blue, males in Trois-Fontaines are in dark red and
599 females in Trois-Fontaines are in light red.
