ABSTRACT

17 The relationship between the large-scale intraseasonal variability, synoptic
18 wind regimes and the local daily variability of precipitation over the main is-
19 land of New Caledonia (southwest tropical Pacific) is investigated with a focus
20 on the austral summer wet season (November to April). The average diurnal
21 cycle of precipitation over the island is characterized by a sharp afternoon
22 maximum around 4 pm, with significant differences between the windward
23 east coast, the leeward west coast, and the mountain range. The afternoon
24 peak is related to the afternoon sea breeze circulation and to the diurnal cycle
25 of convection over land. In general, its magnitude follows the same evolution
26 as the daily mean. In agreement with past studies, a clear modulation of the
27 Madden-Julian Oscillation (MJO) on both the diurnal cycle of precipitation
28 and the probability of occurrence of four robust wind regimes can be identi-
29 fied in the New Caledonia region during the wet season. From the evidence
30 that there is a qualitative correspondence between the effects of both the MJO
31 phases and the wind regimes on features in the diurnal cycle of precipitation,
32 a simple model is proposed to inspect the MJO forcing mediated by wind
33 regimes on the diurnal variability of rain. The complete decomposition of the
34 MJO impact shows that the modulation of diurnal cycle by the MJO relies
35 on complex interactions between the MJO and synoptic winds that involve
36 both large-scale MJO convective anomalies and MJO-induced modification
37 of wind patterns.

38 **1. Introduction**

39 New Caledonia is a group of islands composing one of the largest and most populated territories
40 in the tropical South Pacific. Located between 18°S and 23°S, 163°E and 169°E, about 1,500 km
41 east of Australia, it is made up of a long and narrow main island (the Grande Terre or Mainland)
42 and other smaller islands. The main island is roughly 400 km long, 50 km wide and features a
43 central mountain range averaging 800 m in altitude, with the two highest peaks reaching around
44 1,600 m. On a climatological average, New Caledonia is swept by the South Pacific southeasterly
45 trade winds that are almost parallel to the 45° orientation of the Grande Terre (Lefèvre et al. 2010),
46 as shown in Figure 1. Although winter temperatures frequently drop below 10°C, it experiences a
47 tropical climate with an average temperature of 18°C or higher every month of the year. The annual
48 cycle of rainfall can be decomposed into a warm, wet season from November to April, peaking in
49 the austral summer, and a dry, cold season from May to October. Rainfall is a paramount matter in
50 New Caledonia. At the end of the dry season, agricultural activities and drinking water resources
51 are particularly vulnerable to drought hazards on the West Coast plains. Subsequent rainy spells
52 often come as a relief in the fight against wildfires considered as the main cause of degradation
53 of primary forests and their unique ecosystem (Barbero et al. 2011). Reducing New Caledonia's
54 vulnerability to heavy precipitating events is also a major concern as some inhabited areas are
55 exposed to landslides and flash-floodings (Gouvernement de la Nouvelle-Calédonie 2016).

56 Heavy rainfall generally occurs on short time scales ranging from a few hours to a few days.
57 Within these time scales, the diurnal cycle is expected to play an important role as it influences the
58 timing of rainfall initiation or intensification. In the tropics, the diurnal cycle of convection and
59 corresponding wind patterns control the timing of diurnal precipitation peaks (Mori et al. 2004).
60 Over the open ocean, a precipitation maximum is generally reported at night or in the early morn-

ing (Yang and Smith 2006; Kikuchi and Wang 2008), resulting from convective instability created by nocturnal longwave radiative cooling in the middle and upper troposphere. Over islands, studies in the Maritime Continent and the Western Pacific have shown that provided the land surface is large enough, tropical islands are rainier than the open ocean and exhibit a diurnal cycle with a precipitation peak in the afternoon due to local forcings (Saito et al. 2001; Yang and Smith 2006; Kikuchi and Wang 2008; Vincent and Lane 2016). The main forcing is the sea breeze (Kikuchi and Wang 2008; Cronin et al. 2015). Owing to the smaller heat capacity of land surfaces compared to the ocean, the magnitude of the warming and cooling of the island with the day-night cycle is much larger than that of the ocean. A sea breeze develops in the afternoon when the land is warmer than the ocean and reverses into a land breeze at night when the land cools. Using an idealized model experiment of a flat, circular, low heat-capacity island, Cronin et al. (2015) have proposed a mechanism involving this land/sea breeze cycle to explain the specific features of rainfall on tropical islands. The convergence at the sea-breeze front is responsible for the formation of low-level convective clouds around noon, before these shallow clouds develop into deeper precipitating convective cells in the afternoon that eventually merge together and converge at the center of the island, triggering heavy rainfall in the late afternoon or early evening. Evidence of this process over real islands in the Maritime Continent is also shown in Qian (2008). Owing to the heavy afternoon rainfall, the island experiences heavier rainfall than the surrounding ocean. However, the size of the island and its orography also influence the rainfall pattern: according to Sobel et al. (2011), the larger the island, the more rainfall and for large islands, mountains increase precipitation. Indeed, in the case of mountainous islands, orographic effects can lead to further enhancement of the afternoon peak in the diurnal cycle. First, a mountain range tends to regularly experience afternoon cumulus formation because of the elevated surface heating, and is therefore a favorable place of its own for a strong diurnal cycle. Second, its interaction with the sea breeze is

85 likely to intensify cumulus formation in the afternoon through orographic lifting (Yang and Chen
86 2008; Vincent and Lane 2016). As for New Caledonia, Lefèvre et al. (2010) showed that the main
87 island exhibits a strong diurnal cycle in the wind that is related to a diurnal cycle in surface heat-
88 ing. They also highlighted an asymmetric sea-breeze pattern between the windward and leeward
89 sides. Consequently, precipitation on the island is also expected to exhibit an asymmetric pattern
90 in average rainfall, that has already been documented (Atlas Climatique de la Nouvelle-Calédonie
91 2008), and a diurnal cycle that will be the purpose of this study.

92 At longer time scales, the climate in New Caledonia is influenced by large-scale meteorological
93 patterns located both in the tropics and the mid-latitudes of the Southern Hemisphere. Mid-latitude
94 highs and lows, and especially the Kermadec high, control the orientation of the prevailing trade
95 winds, while tropical influences impact New Caledonia through the seasonal variations in the
96 location of the South Pacific Convergence Zone (SPCZ, Griffiths et al. 2003). Being located to
97 the south of the mean position of the SPCZ, New Caledonia's weather is impacted by the frequent
98 southward shifts of the SPCZ in the wet season, which bring increased precipitation (Lefort 2005;
99 Moron et al. 2016). Global modes of variability then modulate these climatological processes.
100 At the inter-annual time scale, El Nino Southern Oscillation (ENSO) influences the orientation of
101 the SPCZ (Vincent et al. 2011; Salinger et al. 2014) and the probability of occurrence of tropical
102 cyclones, that is increased in La Nina phase and decreased in El Nino phase (Leroy and Wheeler
103 2008). At the subseasonal time scale, the Madden-Julian Oscillation (MJO, Madden and Julian
104 1971) impacts wind patterns (Lefort 2005; Lefèvre et al. 2010), while it is also responsible for
105 shifts in the SPCZ (Matthews 2012; Moron et al. 2016) and changes in the probability of observing
106 a tropical cyclone (Leroy and Wheeler 2008). As a result, Leroy (2006) highlights an impact of
107 the MJO on New Caledonia rainfall, and Moron et al. (2016) also show a modulation of rainfall

108 by the subseasonal variability, although they need to use a tailor-made OLR-based intraseasonal
109 index centered on New Caledonia to demonstrate it.

110 Moreover, the MJO not only impacts the daily rainfall but also the diurnal cycle around islands,
111 as documented by several studies based on observations (Chen and Houze 1997; Sui et al. 1997;
112 Tian et al. 2006; Suzuki 2009; Hidayat and Kizu 2009; Rauniyar and Walsh 2011; Oh et al. 2012;
113 Kanamori et al. 2013; Peatman et al. 2014) and model simulations (Birch et al. 2016; Vincent and
114 Lane 2017). These studies analyze the direct relationship between the MJO phase and the diurnal
115 cycle of precipitation or convection with composite or case study analysis. Most of them focus
116 on the Maritime Continent area. Their conclusions vary depending on mesoscale phenomena such
117 as orographic effects and sea breeze, specific to the location under study. But they all highlight
118 the differentiated impacts of MJO variability on the diurnal cycle between land and ocean. In
119 particular, through the analysis of TRMM data, Peatman et al. (2014) come to the conclusion that,
120 in the Maritime Continent, 80% of the modulation of the precipitation by the MJO over land result
121 from MJO-induced changes of the amplitude of the diurnal cycle.

122 Finally, synoptic variability also influences daily rainfall and diurnal cycle over islands. Wind
123 regimes enable to classify the synoptic atmospheric circulation around the area of interest into
124 a few specific and recurrent patterns. They can be related to the large-scale, intraseasonal MJO
125 variability by considering how the MJO modulates their probability of occurrence. They can
126 also be related to the island mesoscale effects that are responsible for variations in the diurnal
127 cycle. Wind regimes were used to study the diurnal cycle, for instance by Qian et al. (2013)
128 over Borneo, by Moron et al. (2015) over the whole Maritime Continent, and more recently by
129 Hopuare et al. (2018) over the Pacific island of Tahiti. In New Caledonia, Lefort (2005) and Leroy
130 (2006) have shown that atmospheric conditions could be classified into a small number of regimes.
131 Lefèvre et al. (2010) have also highlighted the link between wind regimes and the phases of the

132 MJO. With a 6-state classification performed on daily New Caledonia rainfall, Moron et al. (2016)
133 have even managed to explain the relationships between the local precipitation and the large-
134 scale atmospheric dynamics at various time scales. However, the link between the subseasonal
135 variability and the diurnal cycle of precipitation in New Caledonia has not been investigated so far
136 and the present study intends to fill this gap.

137 The following section documents the influence of the MJO and wind regimes on the diurnal
138 cycle of rainfall over the main island of New Caledonia during the wet season, and investigates
139 the relationship between wind regimes and MJO. Section 2 introduces the data and methodology
140 used in this article. Section 3 is devoted to the change in diurnal cycle with synoptic and large-
141 scale circulation. It first presents the influence of the MJO on rainfall and its diurnal cycle in New
142 Caledonia, and that of wind regimes on the spatial variations of the diurnal cycle over the island,
143 independently from the MJO's influence. Section 4 investigates the link between the MJO and the
144 wind regimes and its impacts on the diurnal cycle. Finally, the main conclusions of the study are
145 presented in Section 5.

146 **2. Data and methodology**

147 *a. Data*

148 As this study is carried out for the wet season, only the months from November to April will be
149 considered in all datasets.

150 1) LARGE-SCALE DATA

151 Since the diurnal cycle of precipitation involves interactions between the large-scale atmospheric
152 dynamics and the island's specific topography, surface wind is presumably the best field to deter-
153 mine wind regimes and investigate the dynamical signal of the MJO as seen by the island. For

154 this purpose, the daily averaged 10-m winds from the ERA-Interim reanalysis (Dee et al. 2011)
155 are used at 1° resolution over a small domain encompassing New Caledonia (161°E - 170°E , 25°S -
156 17°S). The period considered is January 1, 1979-December 31, 2017 (39 years). ERA-Interim
157 10-m winds are also considered at a lower resolution of 2° on a large tropical domain (50°E -
158 240°E , 30°S - 0°) in order to represent the circulation anomalies associated to the MJO, along with
159 OLR anomalies computed from the daily averaged OLR from NOAA's polar-orbiting satellites
160 (Liebmann and Smith 1996).

161 2) NEW CALEDONIA RAINFALL DATA

162 A comprehensive study of the diurnal cycle of precipitation requires to use high-frequency rain-
163 fall data, ideally with an hourly or shorter time step. This work relies on the Météo-France hourly
164 rain gauge data for 28 stations scattered all over the main island of New Caledonia. These sta-
165 tions were chosen among the available stations according to three criteria: they provided hourly
166 rain rates, they had a sufficiently long record over the year and they were deemed reliable by the
167 Météo-France climatological services in New Caledonia. These stations are listed in Table A1
168 and shown on the map in Figure 2. We deliberately choose to focus this study on the main island
169 owing to the smaller sizes and the very different topographic profiles of the other islands, which
170 make them likely to exhibit a diurnal cycle that would be governed by different mechanisms. The
171 period of available data is station-dependent and some stations present periods of missing values.
172 In order to include as much data as possible, the period considered is January 1, 1991-December
173 31, 2017 (27 years), 1991 being the year when the first hourly records started.

174 3) MJO INDEX

175 Wheeler and Hendon (2004) have defined a set of two indices to represent the propagation of the
176 MJO and classify every day with significant MJO activity into one of the eight phases representing
177 the location of the convective envelope. These two Real-time Multivariate MJO indices (RMM1
178 and RMM2) are computed operationally at the Australian Bureau of Meteorology (BoM) from
179 NOAA OLR data (as a proxy for cloud amount) and NCEP2 reanalysis zonal winds at lower (850
180 hPa) and upper (200 hPa) levels of the atmosphere. In this study, the indices' values were retrieved
181 directly from the BoM website for the period from January 1, 1979 to December 31, 2017. The
182 (RMM1, RMM2) phase space is separated into eight quadrants and the location of a point indicates
183 the MJO phase. In this phase space, a canonical MJO event will be represented with a counter-
184 clockwise trajectory, the phase for each day going from 1 to 8. Note that when the amplitude of
185 the MJO, i.e. the norm of the (RMM1,RMM2) vector, is less than 1, the MJO is considered to be
186 weak (no MJO event) and the classification of the days into phases is no longer relevant.

187 *b. Wind regime classification*

188 Wind regime classification aims at sorting out the regional wind maps around New Caledonia
189 (i.e. in the selected 161°E-170°E, 25°S-17°S domain) into a few specific and distinct circulation
190 patterns. For this purpose, we use the same method as Lefèvre et al. (2010), Moron et al. (2015)
191 and Hopuare et al. (2018), which is based on a k-means clustering algorithm. Zonal and meridional
192 components of the daily-mean 10-m wind data at the 90 grid points in the domain were used
193 for each day of the wet season. Standardized anomalies were computed at each grid point by
194 subtracting the long-term mean and dividing by the corresponding standard deviation. Principal
195 Component Analysis was performed to filter out the smallest scales of spatial variability and the
196 first two principal components, accounting for 69% of the total variance, were retained. The

197 7,069 days of the 39 wet seasons were partitioned in this two dimensional space using the k-
198 means clustering algorithm with Euclidean distance. The optimal number of clusters was chosen
199 using a Classifiability Index as described by Michelangeli et al. (1995). The k-means clustering
200 algorithm takes the user-provided k number of clusters to choose k initial centroids (the seeds) at
201 random among the points to classify. The clusters are created by gathering each point to its closest
202 cluster, and a new centroid is computed for each cluster. This step is repeated until the algorithm
203 converges (i.e. no more changes in the clusters with the next iteration). The Classifiability Index
204 is computed for each number of clusters k . For a given k , N different partitions are computed. The
205 similarity between two partitions is taken as the largest of the k correlations (in the initial wind
206 field space) between the pairs of corresponding centroids. The Classifiability Index is the average
207 of the similarities in $\frac{N(N-1)}{2}$ possible pairs of partitions. In this study, the Classifiability Index was
208 calculated for a number of clusters k from 2 to 10 and $N = 50$. The closer the Classifiability Index
209 is to 1, the less the partition depends on the random initial seeds and the more robust it is.

210 *c. Quantifying the difference between two diurnal cycles*

211 A diurnal cycle of precipitation is an array of 24 values, one for each hour of the day. To quantify
212 the difference between two diurnal cycles, we define a distance between the diurnal cycles \mathbf{r}_1 and
213 \mathbf{r}_2 as the Euclidean norm of $\mathbf{r}_1 - \mathbf{r}_2$

$$\|\mathbf{r}_1 - \mathbf{r}_2\| = \sqrt{\langle \mathbf{r}_1 - \mathbf{r}_2 | \mathbf{r}_1 - \mathbf{r}_2 \rangle} = \sqrt{\sum_{t=1}^{24} [\mathbf{r}_1(t) - \mathbf{r}_2(t)]^2}, \quad (1)$$

214 that is constructed from the scalar product. The smaller the distance, the more similar \mathbf{r}_1 and \mathbf{r}_2 .
215 For more convenience, the squared distance $\|\mathbf{r}_1 - \mathbf{r}_2\|^2$, rather than the distance itself, will be used
216 as a metric in the following sections to compare the diurnal cycle within the MJO phases and the
217 wind regimes to the long-term mean diurnal cycle. The significance of the distance between the

218 average diurnal cycle of a given MJO phase (resp. wind regime) to the long-term mean diurnal
 219 cycle is assessed through bootstrapping. If n is the number of days in the MJO phase (resp. wind
 220 regime) and N_t the total number of days, 10,000 average diurnal cycles for random subsets of n
 221 days among the total N_t are constructed and the corresponding 10,000 distances to the long-term
 222 mean diurnal cycle are computed. The distance in the MJO phase (resp. wind regime) is significant
 223 if it is higher than the 95th percentile of the distribution of distances determined from the 10,000
 224 random draws.

225 Moreover, the diurnal cycles \mathbf{r}_1 and \mathbf{r}_2 can also be decomposed into the sum of their daily mean
 226 and the diurnal cycle of the anomalies relative to this daily mean. For instance,

$$\mathbf{r}_1 = r_1^m + \mathbf{r}_1^d, \quad (2)$$

227 where r_1^m is the daily mean and \mathbf{r}_1^d the anomalies of the diurnal cycle relative to r_1^m . The squared
 228 distance $\|\mathbf{r}_1 - \mathbf{r}_2\|^2$ can therefore be written as:

$$\|\mathbf{r}_1 - \mathbf{r}_2\|^2 = 24(r_1^m - r_2^m)^2 + \|\mathbf{r}_1^d - \mathbf{r}_2^d\|^2. \quad (3)$$

229 The first term on the right-hand side of Equation (3) represents the contribution of the difference
 230 in daily means, and the second term is the contribution of the difference in diurnal variability.

231 *d. Spatial classification of rain gauge stations*

232 A classification of the 28 rain gauge stations was performed in order to distinguish several ge-
 233 ographical zones which exhibit significantly different diurnal cycles of rainfall. Similar to any
 234 clustering problem, such a classification requires the definition of an accurate metric of the dif-
 235 ference between the items being classified (i.e. rain gauge stations). Our main purpose in this
 236 study is to illustrate, for each geographical zone, the influence of the wind regime on the diurnal

237 cycle. For each station, we computed the smoothed composite diurnal cycle for each wind regime
 238 by averaging hourly rainfall over the days belonging to that regime and filtering out all harmonics
 239 with periods below 8 hours. Given that four wind regimes (see Section 3) were finally retained,
 240 each station is characterized by 96 parameters corresponding to the 24 hourly rain rate values of
 241 its smoothed composite diurnal cycle in each of the four regimes. The metric used to quantify
 242 the difference between two stations was the square-rooted sum of the squared differences in this
 243 96-parameter space. This metric is relevant for this case as it takes into account both the average
 244 rainfall at the station and the diurnal variation: if two stations receive similar rainfall on average,
 245 they will be close to each other but they will be even closer if, for instance, they also have similar
 246 diurnal peak. The clustering algorithm used for this classification is hierarchical clustering. At
 247 each step, the two closest clusters according to Ward's minimum variance method were merged
 248 together. The optimal number of clusters could be determined thanks to the dendrogram to ensure
 249 that the clusters were well separated from each other.

250 *e. Statistical testing of the influence of MJO on the frequency of wind regimes*

251 In order to assess the statistical link between the MJO and the wind regimes, a contingency table
 252 showing the classification of wet-season days both into MJO phases and into wind regimes was
 253 built. The contingency table was submitted to a chi-square test (Wilks 2006) for each column
 254 representing a given wind regime. The null hypothesis states that the frequency of occurrence of
 255 the regimes does not depend on the MJO phase, which gives an expected distribution of the wind
 256 regimes that is similar to the overall distribution. The observed distribution is compared to the
 257 expected distribution under the null hypothesis through the chi-square indicator:

$$\chi^2 = \sum_{\phi=1}^{N_{\Phi}=9} \sum_{i=1}^{N_w} \frac{(O_{\phi i} - E_{\phi i})^2}{E_{\phi i}} . \quad (4)$$

258 MJO phases are indicated with the subscript ϕ and wind regimes are indicated with the subscript
 259 i . $O_{\phi i}$ is the observed number of days in wind regime i and MJO phase ϕ , while $E_{\phi i}$ is the
 260 corresponding number of days that would be expected if the proportion of days in regime i among
 261 the days in MJO phase ϕ were the same as the overall proportion of days in regime i among all
 262 days. N_w the number of wind regimes and $N_{\Phi} = 9$ the number of MJO phases (including weak
 263 MJO). Given the null hypothesis described above, the expected value $E_{\phi i}$ is given by

$$E_{\phi i} = \frac{N_{days}(\phi) \times N_{days}(i)}{N_t} . \quad (5)$$

264 N_t is the total number of wet season days in this study from 1979 to 2017 (i.e. $N_t = 7069$), while
 265 $N_{days}(\phi)$ (resp. $N_{days}(i)$) is the number of days in MJO phase ϕ (resp. wind regime i).

266 The χ^2 indicator was computed separately for each regime. Under the null hypothesis, it follows
 267 a chi-square distribution with $n-1=8$ degrees of freedom. The p-value gives the probability that the
 268 observed distribution of the given regime within the MJO phase could be obtained at random. The
 269 null hypothesis is rejected at the 95% confidence level if the p-value is less than 0.05. If the chi-
 270 square test allows to reject the null hypothesis, the contribution of each phase in this rejection can
 271 be assessed through the use of Pearson's residuals:

$$R_{\phi i} = \frac{O_{\phi i} - E_{\phi i}}{\sqrt{E_{\phi i}}} . \quad (6)$$

272 Because they are generally assumed to follow a normal distribution with mean 0 and standard
 273 deviation 1, the Pearson's residuals with values less than -2 or greater than +2 are considered to
 274 indicate the phases for which the deviation from the expected distribution of the wind regimes
 275 under the null hypothesis is significant. These phases are the largest contributors to the rejec-
 276 tion of the chi-square null hypothesis. Given their regime-phase symmetry, Pearson's residuals
 277 similarly indicate if a regime is significantly more or less frequent within a phase. The over-

278 or under-representation at the 95% level of a given regime within a MJO phase was also tested
 279 with bootstrapping. This method leads to conclusions that are identical to the Pearson's residuals
 280 approach.

281 *f. Impact of the interaction between the MJO and wind regimes on the diurnal cycle of precipita-*
 282 *tion*

283 In order to understand how the interaction between the MJO and wind regimes impacts the
 284 diurnal cycle, a method is proposed based on two simple but opposite models.

285 In this section, all diurnal cycle anomalies relative to the average diurnal cycle will be noted
 286 with a \prime , e.g

$$\mathbf{r}'_{\phi} = \mathbf{r}_{\phi} - \bar{\mathbf{r}}, \quad (7)$$

287 with \mathbf{r}'_{ϕ} the diurnal cycle anomaly in MJO phase ϕ and $\bar{\mathbf{r}}$ the average diurnal cycle. MJO phases
 288 are indicated with the subscript ϕ and wind regimes are indicated with the subscript i .

289 By definition, the diurnal cycle anomaly in MJO phase ϕ is the mean of the diurnal cycle anoma-
 290 lies of each regime in MJO phase ϕ , weighted by the frequencies of the regimes in the phase:

$$\mathbf{r}'_{\phi} = \sum_{i=1}^{N_w} f_{i\phi} \mathbf{r}'_{i\phi}. \quad (8)$$

291 Let's re-write Equation (8) as:

$$\mathbf{r}'_{\phi} = \sum_{i=1}^{N_w} [f_i + (f_{i\phi} - f_i)] [\mathbf{r}'_i + (\mathbf{r}'_{i\phi} - \mathbf{r}'_i)], \quad (9)$$

292 where we have introduced the perturbation of regime frequencies ($f_{i\phi} - f_i$) in MJO phase ϕ ,
 293 and the deviations ($\mathbf{r}'_{i\phi} - \mathbf{r}'_i$) of the regime diurnal cycle in that MJO phase from the mean regime
 294 diurnal cycle. The expansion of (9) yields:

$$\mathbf{r}'_{\phi} = \sum_{i=1}^{N_w} f_{i\phi} \mathbf{r}'_i + \sum_{i=1}^{N_w} f_i \mathbf{r}'_{i\phi} - \sum_{i=1}^{N_w} f_i \mathbf{r}'_i + \sum_{i=1}^{N_w} (f_{i\phi} - f_i) (\mathbf{r}'_{i\phi} - \mathbf{r}'_i). \quad (10)$$

295 By definition, $\sum_{i=1}^{N_w} f_i = 1$ and $\sum_{i=1}^{N_w} f_i \mathbf{r}_i = \bar{\mathbf{r}}$, which leads to $\sum_{i=1}^{N_w} f_i \mathbf{r}'_i = 0$.

296 Therefore, an exact decomposition of the diurnal cycle anomaly \mathbf{r}'_{ϕ} in MJO phase ϕ is:

$$\mathbf{r}'_{\phi} = \sum_{i=1}^{N_w} f_{i\phi} \mathbf{r}'_i + \sum_{i=1}^{N_w} f_i \mathbf{r}'_{i\phi} + \sum_{i=1}^{N_w} (f_{i\phi} - f_i) (\mathbf{r}'_{i\phi} - \mathbf{r}'_i). \quad (11)$$

297 In Equation (11), the third sum on the right-hand side is a non-linear, second-order residual term.
 298 The first term on the right-hand side of this equation is the contribution of the modification of the
 299 frequencies of occurrence of wind regimes. A simple model (Model 1) would be to assume that
 300 this term is dominant, as in the qualitative analysis carried out in previous studies on other regions
 301 (Ichikawa and Yasunari 2008; Hopuare et al. 2018). In this simple model,

$$\mathbf{r}'_{\phi} \simeq \sum_{i=1}^{N_w} f_{i\phi} \mathbf{r}'_i, \quad (12)$$

302 which corresponds to assuming that the characteristics of the regimes (wind direction and in-
 303 tensity, and characteristic precipitation patterns on the islands) are the same in all phases of the
 304 MJO.

305 An opposite model (Model 2) would be to assume that the first term on the right-hand side of
 306 Equation (11) is negligible, and that the second term, which is the contribution of regime change,
 307 is dominant:

$$\mathbf{r}'_{\phi} \simeq \sum_{i=1}^{N_w} f_i \mathbf{r}'_{i\phi} = \sum_{i=1}^{N_w} f_i (\mathbf{r}_{i\phi} - \mathbf{r}_i) . \quad (13)$$

308 This corresponds to considering that the characteristics of the regimes change between phases of
 309 the MJO, but the frequency of these regimes do not change. Equation (13) also shows that the de-
 310 viations of the diurnal cycle $\mathbf{r}_{i\phi}$ can be taken from the long-term mean $\bar{\mathbf{r}}$ or from the characteristic
 311 diurnal cycle of each regime \mathbf{r}_i .

312 We can expect the observed diurnal cycles to follow a pattern somewhat in between the two
 313 extreme simple models 1 and 2, and we can actually determine which model is closest to the
 314 observations.

315 The squared distances to the long-term mean diurnal cycle can be expressed as:

$$\|\mathbf{r}'_{\phi}\|^2 = \langle \mathbf{r}'_{\phi} | \mathbf{r}'_{\phi} \rangle . \quad (14)$$

316 According to Equation (11), this can be decomposed as:

$$\|\mathbf{r}'_{\phi}\|^2 = \sum_{i=1}^{N_w} f_{i\phi} \langle \mathbf{r}'_{\phi} | \mathbf{r}'_i \rangle + \sum_{i=1}^{N_w} f_i \langle \mathbf{r}'_{\phi} | \mathbf{r}'_{i\phi} \rangle + \sum_{i=1}^{N_w} (f_{i\phi} - f_i) \langle \mathbf{r}'_{\phi} | \mathbf{r}'_{i\phi} - \mathbf{r}'_i \rangle , \quad (15)$$

317 and, according to Equation (13), it can be re-written:

$$\|\mathbf{r}'_{\phi}\|^2 = \sum_{i=1}^{N_w} f_{i\phi} \langle \mathbf{r}'_{\phi} | \mathbf{r}'_i \rangle + \sum_{i=1}^{N_w} f_i \langle \mathbf{r}'_{\phi} | \mathbf{r}_{i\phi} - \mathbf{r}_i \rangle + \mathbf{s} . \quad (16)$$

318 This decomposition into $2 \times N_w + 1$ terms, which are scalar products of anomalous diurnal cycles
 319 against the anomalous diurnal cycle of the MJO phase, represents the contributions of all phenom-
 320 ena responsible for the change in the diurnal cycle within the MJO phase. The first term on the
 321 right-hand side of Equation (16) represents the difference to the long-term mean diurnal cycle ac-
 322 counted for by the change in frequency of each of the N_w regimes, following Model 1. The second

323 term on the right-hand side of Equation (16) terms represents the difference to the long-term mean
324 diurnal cycle accounted for by the change in the diurnal cycle of the regime within the MJO phase
325 relative to the average diurnal cycle of the regime, according to Model 2. s is the second-order
326 residual term.

327 **3. Influence of large-scale dynamics on the diurnal cycle of rainfall**

328 *a. Climatology of rainfall in New Caledonia*

329 The average daily rainfall received in the wet season by the 28 selected rain gauge stations is
330 represented in Figure 2. The rainiest stations are all along the east coast and at specific locations
331 inland that correspond to mountain peaks or passes. Stations along the west coast are compara-
332 tively drier. This east-west contrast is usually explained by two factors. First, with the presence
333 of the central mountain range and the easterly-southeasterly climatological direction of the trade
334 winds (illustrated in Figure 1), orographic lifting on the windward side combined with foehn effect
335 on the lee side drive a wetter climate along the east coast and a drier climate along the west coast
336 (Atlas Climatique de la Nouvelle-Calédonie 2008). Second, rainfall in New Caledonia can also be
337 triggered by the advection of warm and moist tropical air masses by northerly and easterly winds
338 that therefore preferentially hit the east coast (Moron et al. 2016).

339 The diurnal cycle of observed rainfall is represented in Figure 3 for both the warm, wet
340 (November-April) and the cool, dry (May-October) seasons, averaged over all stations shown in
341 Figure 2. While there is a strong diurnal cycle in the warm season, with a marked afternoon peak
342 at 4 pm and a secondary peak at night, rainfall in the dry season shows very little diurnal variation.
343 As detailed in Section 1, sea breeze and orographic effects are likely to explain the afternoon maxi-
344 mum in warm convection, and therefore in precipitation, over land (Cronin et al. 2015). Nighttime

345 convection over the open ocean and advection of precipitating clouds by large-scale winds can
346 presumably account for the secondary, nocturnal maximum. During the dry season, the sea sur-
347 face temperature is lower and the troposphere is much drier than in the warm season: these inhibit
348 deep convection, resulting in lower precipitation rates. The diurnal solar forcing is also smaller
349 in that season, so it creates weaker land/sea surface temperature gradient and sea breeze, which
350 is rarely strong enough to break through the convective inhibition. The diurnal cycle is therefore
351 considered to be one major player to explain differences in rainfall rates between wet and dry
352 season.

353 *b. Impact of the MJO on the diurnal cycle of rainfall in New Caledonia*

354 The influence of the MJO on the mean precipitation in New Caledonia (averaged over the 28
355 stations) is displayed in Figure 4a, along with the 95% confidence interval determined from a
356 bootstrap procedure (for each phase, 10,000 draws of the days in the phase are performed with
357 replacement). Daily mean rainfall variation oscillates with the MJO, following the propagation of
358 the MJO convective envelope. Phases 4, 5 and 6 are the rainiest phases, and in particular, they are
359 significantly rainier at the 95% confidence level than phases 1 and 2 which are the driest phases.
360 This is in agreement with the MJO-induced OLR anomalies over New Caledonia as shown in
361 Figure 5: the largest negative OLR anomalies over New Caledonia, associated with intensified
362 convection, are found in phases 4, 5 and 6, while the largest positive OLR anomalies, associated
363 with suppressed convection, correspond to phases 1 and 2. Figure 5 also shows that New Caledonia
364 is located at the southern edge of the strong, equatorial MJO signal and it experiences convection
365 anomalies in advance compared to the equatorial band. Positive or negative MJO-induced con-
366 vection anomalies extend southeastward from the heart of the equatorial convective patch. For
367 instance, New Caledonia experiences intensified convection when the equatorial convective enve-

368 lope is located over the Maritime Continent (phase 5), while it experiences reduced convection
369 when the equatorial convective envelope is roughly north of New Caledonia (phase 7).

370 The influence of the MJO on the diurnal cycle is summarized in Figure 4b which shows the
371 evolution of the diurnal amplitude with the MJO phase, along with its 95% bootstrap confidence
372 interval. The diurnal amplitude is defined as the difference between the maximum and the mini-
373 mum of the composite diurnal cycle of each MJO phase. The impact of the MJO on the diurnal
374 amplitude is less clear than that on average precipitation considering the error bars are larger, but it
375 also exhibits noteworthy features. The diurnal amplitude is largest for phase 4 to 6, which means
376 that the diurnal cycle tends to peak approximately one phase in advance compared to the mean
377 rainfall (phase 4 vs phase 5). This is reminiscent of Peatman et al. (2014)'s results, which docu-
378 mented a peak in diurnal amplitude with a one-phase lead before the arrival of the MJO envelope
379 over the Maritime Continent. As for the time of the daily rainfall maximum, no significant mod-
380 ulation by the phase of the MJO has been observed (not shown). The change in the timing of the
381 afternoon peak in relation with the MJO will therefore not be further investigated in this study.

382 The squared distance between the long-term mean diurnal cycle $\bar{\mathbf{r}}$ (as represented in Figure 3)
383 and the composite diurnal cycle \mathbf{r}_ϕ for a given MJO phase ϕ is defined in Section 2c. Figure 6
384 shows these squared distances for each MJO phase as a fraction of the squared norm $\|\bar{\mathbf{r}}\|^2$ of the
385 long-term mean diurnal cycle. The distances that are significant at the 95% confidence level (see
386 Section 2c) are indicated with asterisks above. The MJO phases for which the average diurnal
387 cycle over all stations in New Caledonia is the most modified are phases 1, 2, 5, 6 and, to a lesser
388 extent, 4. This is consistent with the results on Figure 4: phases 1 and 2 are the driest phases with
389 little diurnal variability, while phases 4, 5 and 6 are the wettest phases with an enhanced diurnal
390 peak. The same analysis for separate geographical zones (not shown) highlights similar impacts
391 with only minor changes.

392 Following Equation (3), the modifications of the diurnal cycle in Figure 6 are also split into a
393 contribution from the change in daily mean (in dark grey) and a contribution from the change in
394 the hourly anomalies relative to the daily mean (in light grey). The modification of the diurnal
395 cycle by the MJO appears to be primarily driven by the modification of the daily mean, while
396 the modification of the diurnal variability only plays a secondary role. This is consistent with
397 the results in Figure 4 in which the impact of the MJO is clearer on the daily mean than on the
398 diurnal amplitude. However, this decomposition neglects the influence of the diurnal cycle on
399 the mean and the contribution from the diurnal anomalies should be considered a lower bound of
400 the contribution from the diurnal cycle. The contribution of the diurnal variability is noteworthy
401 for the five MJO phases when the deviation from the long-term mean diurnal cycle is particularly
402 significant, e.g in phase 4.

403 *c. Identification of wind regimes*

404 The surface wind anomalies associated with the MJO propagation (Figure 5) suggest an influ-
405 ence of the MJO on the circulation around New Caledonia. This is an incentive to investigate how
406 the effect of the MJO on the diurnal cycle of rainfall over New Caledonia is mediated through the
407 synoptic wind regimes, as in Leroy (2006), Lefèvre et al. (2010) and Moron et al. (2015). The
408 wind regimes were determined using ERA-Interim 10-m winds as explained in Section 2b. The
409 computation of the classifiability index for 2 to 10 clusters is illustrated in Figure 7. Given the
410 excellent classifiability for 4 clusters which is also a reasonable number of wind regimes, 4 wind
411 regimes were retained. This number is consistent with the previous findings of Leroy (2006) and
412 Lefèvre et al. (2010), although the classifications were carried out on different datasets.

413 The composite wind maps for each regime are represented in Figure 8. These regimes can be
414 described as follows, in order of increasing average wind speed:

- 415 ● Northerly regime: the flow crossing the island is slowed down on the windward side, while
416 the wind flowing to the west remains slightly stronger. It is the least frequent regime (14.3%
417 of wet-season days) and has the weakest wind speed.
- 418 ● Southerly regime: the flow comes south-southeasterly and is stronger south of the island than
419 north of it. It has a frequency of 19.3% of wet-season days.
- 420 ● Easterly regime: the flow is straight from the East and slows down slightly in the island's
421 wake. It is one of the two most common regime, with a frequency of 33.2%.
- 422 ● Trade wind regime: the flow is very regular, almost along the main axis of the island. This
423 flow is very similar to, although faster than, the seasonal mean. It is the other most common
424 regime (33.2% of wet-season days) and it has the strongest wind speed.

425 Since wind regimes are supposed to represent recurrent patterns that may last for a few days,
426 the probabilities of transition between regimes are also important additional information about
427 their behavior. Table 1 displays these probabilities. The only transition that is significantly more
428 probable than a random draw at the 95% confidence level is the transition from the northerly to the
429 southerly regime. This corresponds to the eastward propagation of a cyclonic perturbation over
430 the island. All other probabilities that are significantly more probable than a random draw are
431 the probabilities of persistence of each regime. All other transitions are less likely than a random
432 draw.

433 *d. Influence of the wind regimes on rainfall and its diurnal cycle*

434 1) SPATIALLY-AVERAGED INFLUENCE

435 Figure 9a displays the diurnal cycle for each regime, averaged over all 28 stations. In terms
436 of average rainfall, the northerly regime is by far the wettest, the easterly and southerly regimes

437 exhibit a similar, intermediate behavior, and the trade wind regime is the driest. The northerly
438 regime can be interpreted as a southward shift of the SPCZ identified in previous studies (Lefort
439 2005; Leroy 2006). It corresponds to the arrival of warm, moist air from the equatorial band
440 resulting in precipitation over the island. The difference in rainfall averages between wind regimes
441 generally coincides with a difference in amplitude of the diurnal cycle. The afternoon peak in the
442 northerly regime is larger in amplitude than that of the easterly and southerly regime, while the
443 trade wind regime exhibits an even flatter cycle. Another interesting feature for the northerly
444 regime is the secondary maximum during the night. This secondary peak is presumably due to the
445 advection of precipitating cloud from the equatorial oceanic regions. Similar to the MJO phases
446 (Figure 6), the distance between the average diurnal cycle for each regime and the long-term mean
447 diurnal cycle is illustrated in Figure 9b. The two regimes for which there is a significant difference
448 are the northerly and the trade regimes, that is to say the more extreme (wettest and driest) ones,
449 in agreement with Figure 9a.

450 2) SPATIAL CLASSIFICATION OF RAIN-GAUGE STATIONS

451 The presence of a mountain range and the asymmetry in the island's mean rainfall pattern (see
452 Figure 2) suggests that the influence of the wind regimes on the diurnal cycle might not be the same
453 for all stations. This matter is investigated by dividing the island into distinct geographical zones
454 following the procedure of spatial clustering detailed in Section 2d. The resulting dendrogram is
455 represented in Figure 10a. It shows that a classification into 3 geographical clusters is relevant
456 in order to obtain distinct, well-separated clusters. The location of the stations in the 3 clusters
457 is represented in Figure 10b. The clustering algorithm separates the stations into geographically-
458 consistent zones: the mountain range (Range), the east coast (East) and the west coast (West). The
459 mountain stations of the Range can be identified by their altitude since they are higher than any

460 other station in East or West. The smoothed, average diurnal cycles for each cluster are represented
461 in Figure 11. The mountain range and the east coast are both wetter than the west coast, as could
462 be expected from Figure 1. In terms of diurnal variability, the west coast and the mountain range
463 exhibit a similar behavior with an afternoon peak as in the all-station average diurnal cycle (Figure
464 3). On the other hand, the east coast features a flatter diurnal cycle with a minimum in the morning
465 around 10-11 am and slightly more rain from the mid-afternoon until the end of the night.

466 Two hypotheses can be put forward to explain the flatter diurnal cycle in the East. First, the
467 east coast is on the windward side most of the time so it presumably undergoes precipitation that
468 is mostly related to the large-scale wind dynamics (cloud formation due to orographic lifting,
469 cloud advection from the open sea). This kind of precipitation is therefore independent from
470 the local diurnal variability. Second, the local diurnal variability of winds and solar radiation
471 is itself very weak on the east coast. This aspect has already been thoroughly investigated with
472 numerical modeling by Lefèvre et al. (2010). Because of the higher mean cloud cover on the east
473 coast, less solar radiation reaches the surface. The sea breeze then tends to be far weaker than
474 that on the west coast due to this difference in insolation, but also to a difference in sea surface
475 temperatures. Indeed, the sea surface temperature is also warmer off the east coast than off the west
476 coast because New Caledonia is located at the edge of the western Pacific warm pool. This creates
477 a smaller land/sea surface temperature contrast and a weaker sea breeze on the east coast. As a
478 result, rainfall on the east coast shows less diurnal variations, while the west coast experiences a
479 pronounced diurnal cycle of rainfall owing to its strong sea breeze, even if its average precipitation
480 is lower than in the other two parts of the island. As for the mountain range, the diurnal cycle of
481 thermal convection and the interaction with the sea breeze are likely to explain most of its strong
482 afternoon peak.

483 3) GEOGRAPHICAL INFLUENCE OF THE WIND REGIMES ON THE DIURNAL CYCLE

484 Figure 12 shows the influence of the wind regimes for each geographical cluster of stations. The
485 influence on rainfall in clusters Range and West (Figure 12a,c) is very similar to the influence that
486 is observed in Figure 9 for the diurnal cycle averaged over all 28 stations. In other words, the
487 rainiest regime is the northerly regime, followed by the southerly and easterly regimes, and finally
488 by the driest trade-wind regime. The diurnal amplitude is also similarly related to the average
489 rainfall: the rainier the regime, the larger the diurnal amplitude. However, the influence of the
490 wind regimes on the east coast (Figure 12b) shows an altogether different behavior. While the
491 easterly and trade wind regimes are associated with a relatively flat diurnal cycle with a minimum
492 in late morning, the northerly and southerly regimes differ significantly from the average east
493 coast diurnal cycle (Figure 11). The southerly regime, that is quite dry on the east coast, exhibits a
494 diurnal variability with a marked afternoon peak. The northerly regime is also characterized by a
495 similar afternoon peak and by another secondary peak at the end of the night that has already been
496 identified in Figure 9.

497 We can propose a few tentative explanations for the specific behavior of the diurnal cycle on
498 the east coast in the southerly and northerly regimes, although the mechanisms that explain this
499 sensitivity would deserve a thorough investigation that is beyond the scope of this article. In
500 Section 3d-2), two hypotheses have been put forward to explain the flatter average diurnal cycle
501 on the east coast: the continuous rainfall due to large-scale dynamics, and the weaker insolation
502 and sea breeze diurnal variability. These hypotheses are strongly linked to the fact the east coast is
503 the average windward coast. In the southerly regime, however, the east coast becomes the leeward
504 coast. Sheltered by the mountain range, a sea breeze circulation can develop and the absence of
505 clouds favors a diurnal cycle of surface heating and afternoon convection. As a result, the diurnal

506 cycle of rainfall on the east coast in the southerly regime exhibits an afternoon peak similar to the
507 diurnal cycle on the west coast in the easterly regime. During the northerly regime, very weak
508 winds and high humidity generally enhance the diurnal cycle of convection all over the island and
509 the east coast is also affected, hence the afternoon peak it also exhibits in this case. The secondary
510 nocturnal peak, on the other hand, can be attributed to the advection of precipitating clouds from
511 oceanic regions further north.

512 **4. MJO impact on the diurnal cycle via wind regimes**

513 The findings in Section 3 illustrate separately the impact of the MJO and of wind regimes on
514 the diurnal cycle. These two points can be linked by considering the influence of the MJO on the
515 wind regimes, as well whether the MJO influence on the diurnal cycle of rainfall is mediated by
516 the wind regimes.

517 *a. Frequency variability of wind regimes with the MJO*

518 We first investigate whether the MJO influences the frequency of occurrence of the wind
519 regimes, in line with Model 1 introduced in Section 2f. Following the methodology described
520 in Section 2e, we perform a statistical analysis of these frequencies of occurrence in the 8 MJO
521 phases. Table 2 shows the p-values of the chi-square test applied separately for each regime. The
522 p-value is always less than 5%, which enables to reject the null hypothesis that the regime frequen-
523 cies do not depend on the MJO phase. Table 3 indicates the percentage of the regimes per MJO
524 phase. Percentages corresponding to a significantly more frequent regime within the MJO phase
525 (according the values of Pearson's residuals) are in bold, those corresponding to a significantly
526 less frequent regime are in italics.

527 A striking fact from Table 3 is that the easterly, northerly and southerly regimes seem to succeed
528 each other in the MJO cycle in terms of over-representation. Indeed, the easterly regime occur
529 significantly more frequently in phases 2, 3, and 4, when the MJO convective envelope is still in
530 the Indian Ocean or over the Maritime Continent. On the contrary, it is significantly less frequent in
531 phases 6, 7, and 8 when the convective envelope is over the Central Pacific or weak and further east.
532 The northerly regime occurs significantly less frequently in the phases 1, 2, and 3 when convection
533 is suppressed over New Caledonia, and it occurs significantly more frequently in the wettest phases
534 5 and 6. As for the southerly regime, it is also significantly less frequent in the dry phases 2 and
535 3 and significantly more frequent in phase 6. Trade winds are frequent in all phases, except in
536 the phases 5 and 6 of intensified convection over New Caledonia, when they are significantly less
537 frequent. These findings are in agreement with the wind anomalies associated to the MJO phases
538 as represented in Figure 5. In phases 2 and 3, New Caledonia experiences easterly MJO low-level
539 wind anomalies. These MJO anomalies rotate counter-clockwise around New Caledonia with the
540 succession of phases: they have a northeasterly orientation in phase 4, a northerly orientation in
541 phase 5, a westerly orientation in phase 6 and a southerly orientation in phase 7. In phases 8
542 and 1, which are phases for which the MJO is less active over New Caledonia, the anomalies
543 are southeasterly, with the same orientation as the climatological trade winds. Considering these
544 observations and the transition probabilities in Table 1, it can be deduced that there is a sequence
545 of wind regimes (easterly \rightarrow northerly \rightarrow southerly) that is due to the propagation of the MJO
546 wind anomalies. This sequence will not necessarily be observed exactly for every MJO event,
547 because fast intraseasonal and synoptic variability allow all regimes to occur in all phases, but it
548 corresponds to a canonical evolution that the atmosphere tends to follow during such events. It is
549 typical of the MJO dynamical signature (Rui and Wang 1990; Zhang 2005), with easterly winds
550 east of the convective signal and two off-equatorial cyclonic gyres propagating along with the

551 equatorial convective center. The southern gyre is responsible for the wind anomalies around New
552 Caledonia, with a northerly component when New Caledonia is the poleward branch of the gyre
553 and a southerly component when it is in the equatorward branch.

554 *b. How does the interaction between MJO and wind regimes impact the diurnal cycle?*

555 As seen in Figures 4 and 6, the MJO modifies the diurnal cycle of precipitation over New Cale-
556 donia during its most active and suppressed phases. As for wind regimes, Figures 8 and 11 also
557 demonstrate their impact on the diurnal cycle. How do these two large-scale influences interact?
558 And how does this interaction help understand the impact of the MJO on the diurnal cycle? The
559 decomposition of the anomalous diurnal cycles proposed in Section 2f with two simple models, for
560 the particular case where the number of wind regimes is $N_w = 4$, is used to answer these questions.

561 The contributions of the 9 terms in the squared distance to the long-term mean diurnal cycle,
562 detailed in Equation (16), are represented in Figure 13. Consistent with Figure 6, the deviations
563 from the long-term mean diurnal cycle are weak for phases 3, 7 and 8. Consequently, Figure 13
564 only represents the decomposition for the five other MJO phases (1, 2, 4, 5 and 6). The contribu-
565 tions are shown as fractions of $\|\bar{\mathbf{r}}\|^2$ in the same way as in Figure 6. The first four bars correspond
566 to the $f_{i\phi} \langle \mathbf{r}'_{\phi} | \mathbf{r}'_i \rangle$ terms for each regime, associated with Model 1 and which we will call frequency
567 change terms, and their sum is indicated by the first background grey bar. The next four bars cor-
568 respond to the $f_i \langle \mathbf{r}'_{\phi} | \mathbf{r}_{i\phi} - \mathbf{r}_i \rangle$ terms associated with Model 2 and which we will call regime change
569 terms, and their sum is also represented in the background. The grey bar on the right indicates
570 the value of the residual term s . Note that all these terms correspond to the decomposition of
571 the overall distances represented in Figure 6, without separating between the daily mean and the
572 diurnal anomalies relative to the daily mean. The same decomposition has been carried out for
573 these two components separately (not shown). According to Figure 6, the change in daily mean

574 accounts for most of the changes in the diurnal cycle. As a result, when the decomposition in
575 Equation (16) is carried out on the daily mean only, the results are similar as those in Figure 13,
576 while the contributions related to the diurnal anomalies are less prominent. The results in Figure
577 13 are therefore mostly interpreted in terms of modification of the daily mean.

578 The contributions of frequency changes $f_{i\phi} \langle \mathbf{r}'_{\phi} | \mathbf{r}'_i \rangle$, associated with Model 1, need to be consid-
579 ered with caution. They tend to attribute prominent contributions to the northerly and trade wind
580 regimes because the average diurnal cycles of these regimes are the most different to the long-term
581 mean diurnal cycle, as shown in Figure 9b. When one of these two regimes is less represented than
582 usual, its contribution $f_{i\phi} \langle \mathbf{r}'_{\phi} | \mathbf{r}'_i \rangle$ will be negative: the decrease in frequency contributes to decreas-
583 ing the deviation $\|\mathbf{r}'_{\phi}\|^2$ from the long-term mean diurnal cycle in phase ϕ . On the contrary, when
584 one of these two regimes is more frequent than usual, the same contribution will be positive and
585 increase the deviation to the long-term mean diurnal cycle. Moreover, owing to the propagation
586 of the MJO, the frequency of these two regimes tend to vary in opposite ways. For instance, in
587 phases 1 and 2, the northerly regime is less frequent and the trade wind regime is more frequent,
588 while the contrary can be observed in phases 4, 5, and 6. As a result, the contributions of the
589 frequencies of the trade and northerly regimes tend to compensate each other partially (phases 1
590 and 2) or completely (phase 4 and phases 3, 7 and 8 not shown). In the case of a partial com-
591 pensation, an additional compensation by the residual term can also be noted. Therefore, except
592 for phases 5 and 6, during which the change in frequency of the northerly regime appears to play
593 an important role due its significant over-representation (see Table 3), the frequency change terms
594 include systematic strong compensating effects and are not as physically meaningful as the regime
595 change terms.

596 Phases 1 and 2 (Figures 13a and 13b) exhibit a similar behavior: the dominant term in
597 the modification of the diurnal cycle is the change in diurnal cycle for the northerly regime

598 $f_{north}\langle\mathbf{r}'_{\phi}|\mathbf{r}_{north,\phi} - \mathbf{r}_{north}\rangle$, associated with Model 2. According to Figure 5, these phases corre-
 599 spond to large-scale conditions that are not favorable for convection. Then, the northerly regime,
 600 which is supposed to be the wettest regime cannot be as wet as usual, hence the influence of the
 601 modification of its diurnal cycle in the overall changes. This contribution is positive: the change
 602 in the diurnal cycle of the northerly regime increases the difference between the diurnal cycles of
 603 phases 1 and 2 and the long-term mean diurnal cycle. Similar contributions can be observed, to
 604 a lesser extent, for the southerly and easterly regimes. Therefore, the diurnal cycle modification
 605 for MJO phases 1 and 2 is mostly a matter of unfavorable large-scale conditions for convection
 606 that impact almost all regimes but have the most effect on the regime with the strongest diurnal
 607 cycle. MJO phase 4 (Figure 13d) is also characterized by a positive contribution from the change
 608 in the northerly-regime diurnal cycle associated with Model 2. However, unlike in MJO phases
 609 1 and 2, in this phase convection intensifies over New Caledonia and as a result the diurnal cy-
 610 cle in the northerly regime is enhanced. A secondary contribution from the diurnal cycle of the
 611 trade-wind regime $f_{trades}\langle\mathbf{r}'_{\phi}|\mathbf{r}_{trades,\phi} - \mathbf{r}_{trades}\rangle$ is also significant, while the effects of the easterly
 612 and southerly regimes compensate. The diurnal cycle is enhanced in the northerly regime in MJO
 613 phase 4 compared to the all-phase northerly-regime composite, and this can be explained by three
 614 factors: the favorable large-scale conditions for convection mentioned above, the moister air that
 615 is brought by the northerly regime, but also the weaker wind speed in this regime. Indeed, results
 616 from previous work tend to demonstrate that all other conditions being identical, the diurnal cycle
 617 will be stronger when low-level wind is weak (Wang and Sobel 2017). Finally, phases 5 and 6, as
 618 mentioned previously, are dominated by a significant effect of the change in the northerly regime
 619 frequency $f_{north,\phi}\langle\mathbf{r}'_{\phi}|\mathbf{r}'_{north}\rangle$ that is not entirely compensated by the change in the trade regime
 620 frequency or by the residual term. This is in agreement with the findings by Moron et al. (2016,
 621 Figure 12), for which the wettest rainfall regime, associated with a southwestward shifted SPCZ

622 and prevalent northerly winds, also has its frequency strongly modulated by subseasonal vari-
623 ability. Here, the increase in northerly regime frequency in phases 5 and 6 can be held partially
624 responsible for the intensification of the diurnal cycle, along with changes in the diurnal cycle
625 for the easterly regime $f_{east} \langle \mathbf{r}'_{\phi} | \mathbf{r}_{east, \phi} - \mathbf{r}_{east} \rangle$. The easterly regime exhibits an enhanced diurnal
626 cycle in phases 5 and 6 owing to its orientation that is shifted northeasterly, its weaker speed and,
627 again, the favorable large-scale conditions for convection. These different interactions between
628 the MJO and the wind regimes have been considered for the diurnal cycle averaged on all stations.
629 Qualitatively similar results can be found separately for the three geographical groups of stations
630 (Range, East and West) identified in Section 3d (not shown).

631 **5. Summary and discussion**

632 This study demonstrates that the Madden-Julian oscillation is associated with rainfall anomalies
633 in New Caledonia that can be noted mostly in the daily average but also, to a lesser extent, in the
634 diurnal variability. These two components are in fact closely entangled together when it comes to
635 modulation by the MJO because the variations in the diurnal amplitude result in variations in the
636 daily mean. MJO phases 1 and 2 are responsible for a weaker diurnal cycle while it is enhanced
637 in phases 4, 5 and 6. The link between the large-scale intraseasonal variability and the local-scale
638 diurnal cycle of rainfall is established through the use of wind regimes as an intermediate tool. Four
639 regimes were identified to classify the surface wind circulation in a small domain encompassing
640 New Caledonia. They are also associated with differences in the rainfall average and its diurnal
641 cycle, depending on where the air masses come from and how they interact with the island's
642 topography. Owing to its complex topography, the island can also be objectively separated into
643 three distinct geographical zones that exhibit differences in rainfall amounts and diurnal cycles:
644 the mountain range, the east coast and the west coast. The diurnal cycle in these zones might be

645 subject to quantitative but also qualitative changes depending on the regime, the most notable ones
646 being for the east coast during the northerly and southerly regimes.

647 From a statistical point of view, the MJO appears to modulate the probability of occurrence
648 of the wind regimes. Its propagation brings about a counterclockwise rotation of surface wind
649 anomalies around New Caledonia that is suggestive of an easterly-northerly-southerly sequence.
650 This sequence is also discernible in the frequencies of occurrence of the wind regimes within the
651 MJO phases, some regimes being significantly more frequent in some phases while the others
652 are significantly less frequent. However, this undeniable relationship does not necessarily mean
653 that the influence of the MJO on the diurnal cycle of precipitation is entirely mediated by the
654 change in frequency of wind regimes. Indeed, Moron et al. (2016, see Figure 12) also highlight
655 the limitations of the frequentist interpretation for the influence of subseasonal variability when it
656 comes to rainfall itself, except for the wettest days.

657 This is why this study proposes a framework to assess the different contributions to the sensi-
658 tivity of the diurnal cycle to the MJO. This framework consists in a decomposition into (1) terms
659 associated with the modification of the frequency of occurrence of the wind regimes by the MJO,
660 and (2) terms due to changes of the characteristics of the wind regimes within the phases of the
661 MJO. It shows that the modification of the regimes' diurnal cycle of precipitation due to the MJO
662 (Model 2) eventually proves to account for the largest part of the MJO diurnal cycle anomalies, and
663 that the modification of regime frequencies (Model 1) plays a lesser role. This raises the question
664 of how the MJO influences changes in the wind regimes' diurnal cycles. We can provide several
665 hypotheses which would require further examination. First, the MJO-induced large-scale con-
666 vective conditions (enhanced, neutral or suppressed) might have different effects on the different
667 regimes but are not directly related to the wind patterns. Second, the regime circulation anoma-

668 lies in a given MJO phase are presumably involved through modifications of the wind orientation
669 and/or speed.

670 The application of this framework for New Caledonia therefore highlights complex interactions
671 that go far beyond the simple model assuming that the MJO mostly modulates the frequencies of
672 wind regimes, contrary to what was previously expected considering past work on other regions
673 (Ichikawa and Yasunari 2008; Hopuare et al. 2018). The complexity of these interactions even
674 suggests that other tools besides wind regimes should be considered in order to fully decompose
675 and understand the MJO signal that impacts New Caledonia at a local scale.

LIST OF FIGURES

834		
835	Fig. 1.	Long-term mean 10-meter wind velocity (vectors) and intensity (shadings) around New Caledonia. 45
836		
837	Fig. 2.	Average precipitation at the 28 stations in wet season (NDJFMA). Grey lines indicate elevation levels every 200 m from 200 m to 1000 m, retrieved from Shuttle Radar Topography Mission (SRTM) data. 46
838		
839		
840	Fig. 3.	Mean diurnal cycle of rainfall (mm/h) averaged over the 28 stations in the wet season (blue) and the dry season (orange). 47
841		
842	Fig. 4.	a) Daily mean rainfall (mm/day) averaged on the 28 stations for each MJO phase b) Amplitude (mm/h) of the spatially averaged composite diurnal cycle for each MJO phase. Error bars indicate the 95% confidence interval determined from a bootstrap procedure. 48
843		
844		
845	Fig. 5.	NOAA OLR anomalies (OLRa as defined in Wheeler and Hendon (2004)) (shadings, in W/m^2) and 10-m wind anomalies (vectors, m/s) in ERA-Interim for each MJO phase. The black rectangle indicates New Caledonia's region shown in Figure 1. 49
846		
847		
848	Fig. 6.	Squared distance between the composite diurnal cycle for each MJO phase \mathbf{r}_ϕ (weak MJO days not included) and the mean diurnal cycle $\bar{\mathbf{r}}$ expressed as a percentage of $\ \bar{\mathbf{r}}\ ^2$ ($100 \times \frac{\ \mathbf{r}_\phi - \bar{\mathbf{r}}\ ^2}{\ \bar{\mathbf{r}}\ ^2}$). The asterisks indicate distances that are significant at the 95% confidence level (see Section 2c). Dark shadings: contribution from the change in daily mean. Light shadings: contribution from the change in the hourly anomalies relative to the daily mean. 50
849		
850		
851		
852		
853	Fig. 7.	Classifiability index for each number of clusters, determined from the two first PCs of ERA-Interim 10-m winds in the New Caledonia domain (161°E-170°E, 25°S-17°S). 51
854		
855	Fig. 8.	Composite maps of ERA-Interim 10-m winds (arrows) and wind speed (shadings) for the four wet season regimes. 52
856		
857	Fig. 9.	a) Spatially-averaged diurnal cycle of rainfall for each wind regime (mm/h). b) Squared distance between the composite diurnal cycle for each wind regime \mathbf{r}_i and the mean diurnal cycle $\bar{\mathbf{r}}$ expressed as a percentage of $\ \bar{\mathbf{r}}\ ^2$ ($100 \times \frac{\ \mathbf{r}_i - \bar{\mathbf{r}}\ ^2}{\ \bar{\mathbf{r}}\ ^2}$). The asterisks indicate distances that are significant at the 95% confidence level (see Section 2c) 53
858		
859		
860		
861	Fig. 10.	a) Dendrogram of the hierarchical clustering of the 28 rain gauge stations b) Location of the 3 clusters retained with elevation levels indicated by grey lines. 54
862		
863	Fig. 11.	Diurnal cycles of rainfall (mm/h) for each geographical zone. 55
864	Fig. 12.	Spatially-averaged diurnal cycle of rainfall for each wind regime (mm/h) a) Mountain range b) East coast c) West coast 56
865		
866	Fig. 13.	Decomposition of the squared distances between the MJO composite cycles \mathbf{r}_ϕ and the long-term mean diurnal cycle $\bar{\mathbf{r}}$ as a percentage of $\ \bar{\mathbf{r}}\ ^2$, according to Equation (16). The first four terms represent the contribution of regime frequency changes, the next four terms the contribution of regime change at constant frequency. N: Northerly regime. S: Southerly regime. E: Easterly regime. T: Trade winds regime. 57
867

870		

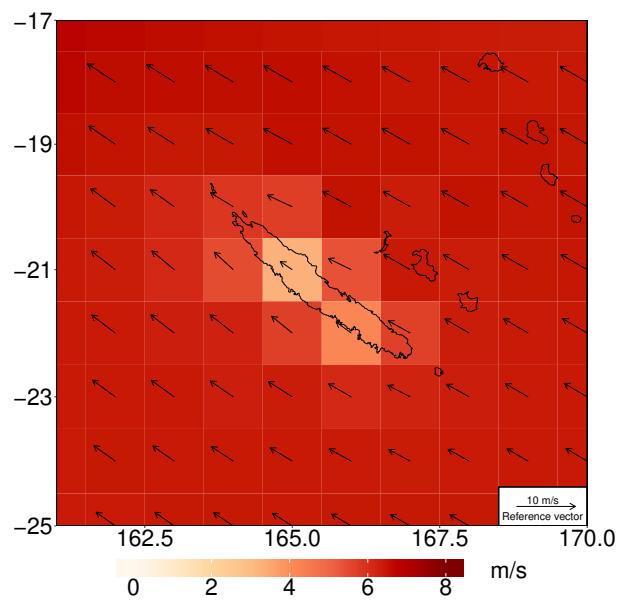

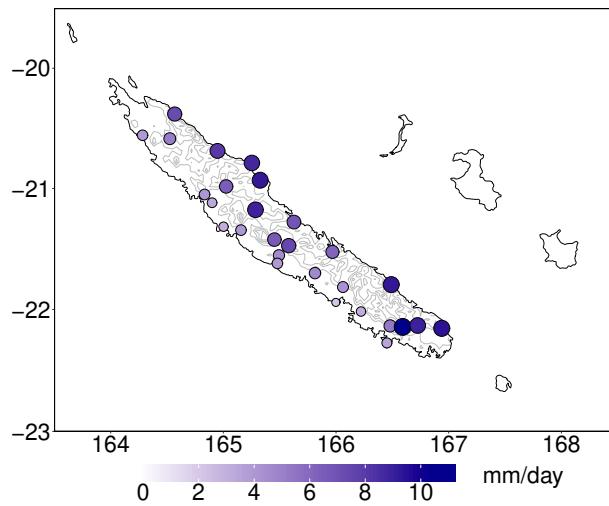

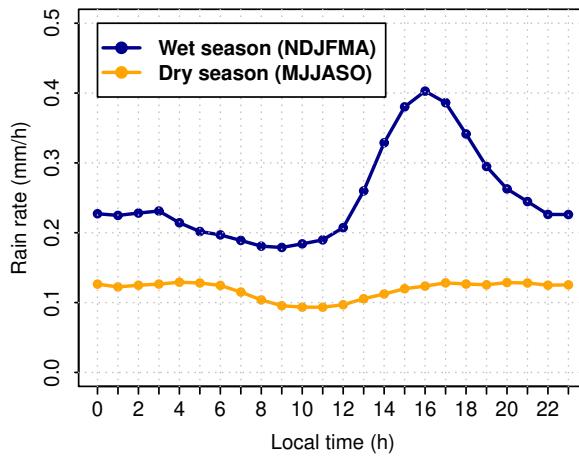

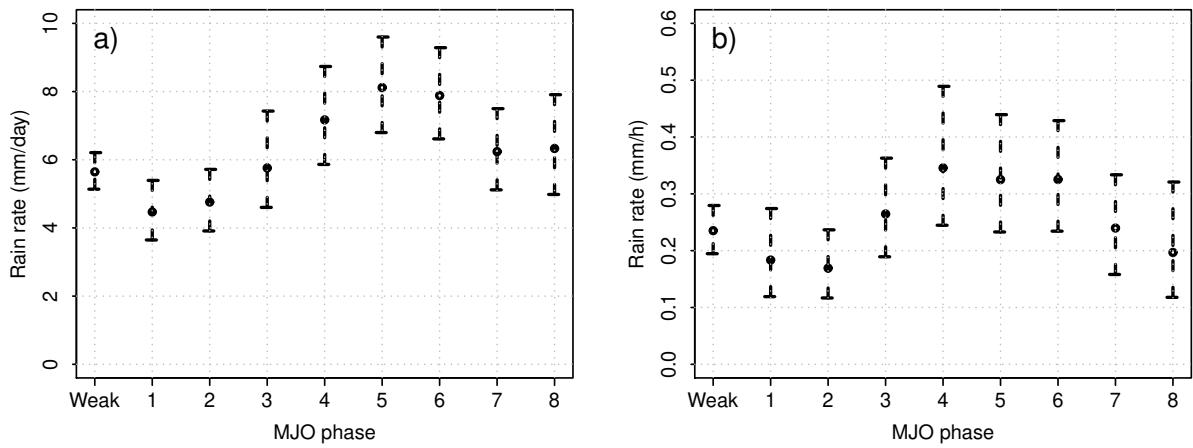

FIG. 1. Long-term mean 10-meter wind velocity (vectors) and intensity (shadings) around New Caledonia.

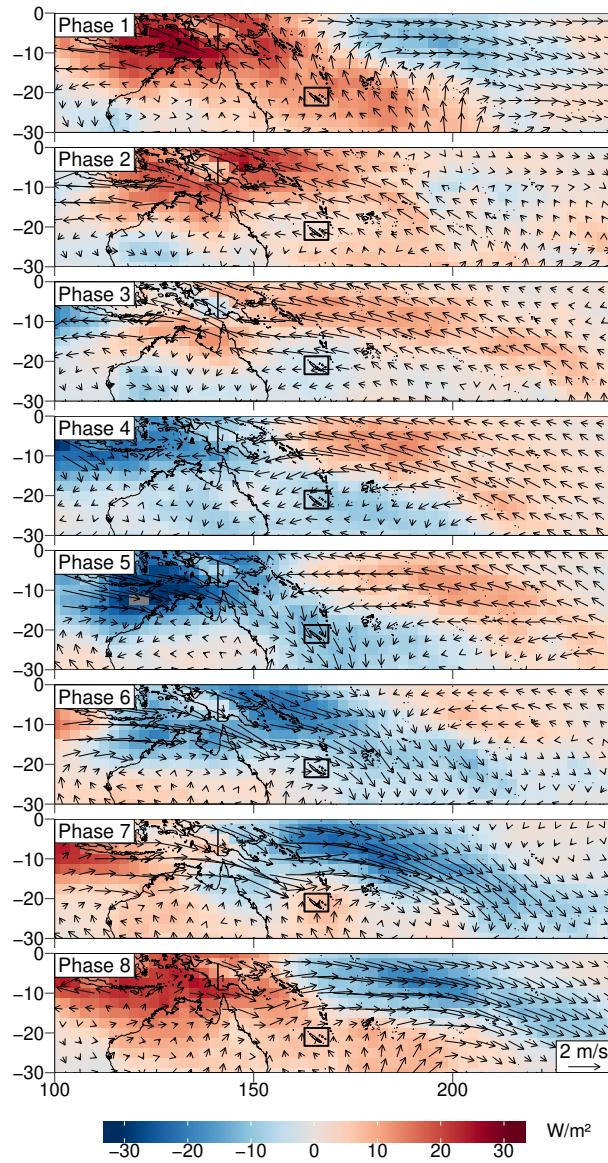

871 FIG. 2. Average precipitation at the 28 stations in wet season (NDJFMA). Grey lines indicate elevation levels
872 every 200 m from 200 m to 1000 m, retrieved from Shuttle Radar Topography Mission (SRTM) data.

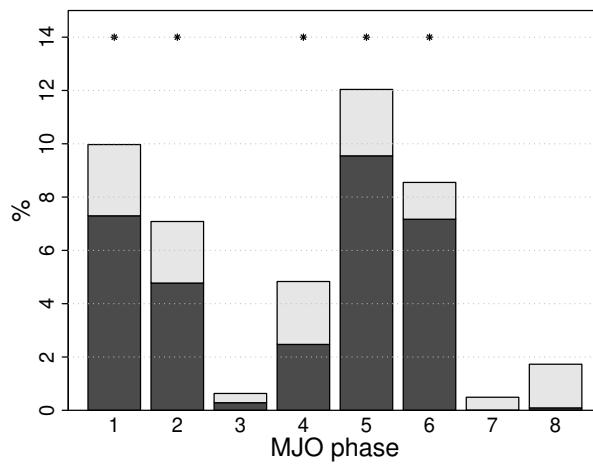

873 FIG. 3. Mean diurnal cycle of rainfall (mm/h) averaged over the 28 stations in the wet season (blue) and the
 874 dry season (orange).

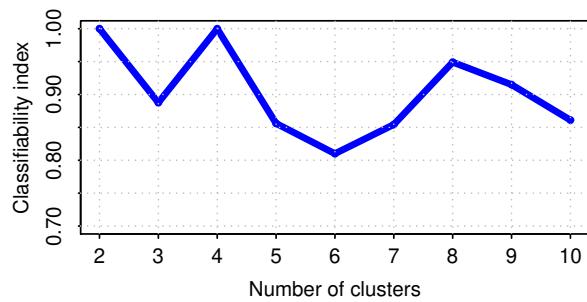

875 FIG. 4. a) Daily mean rainfall (mm/day) averaged on the 28 stations for each MJO phase b) Amplitude (mm/h)
 876 of the spatially averaged composite diurnal cycle for each MJO phase. Error bars indicate the 95% confidence
 877 interval determined from a bootstrap procedure.

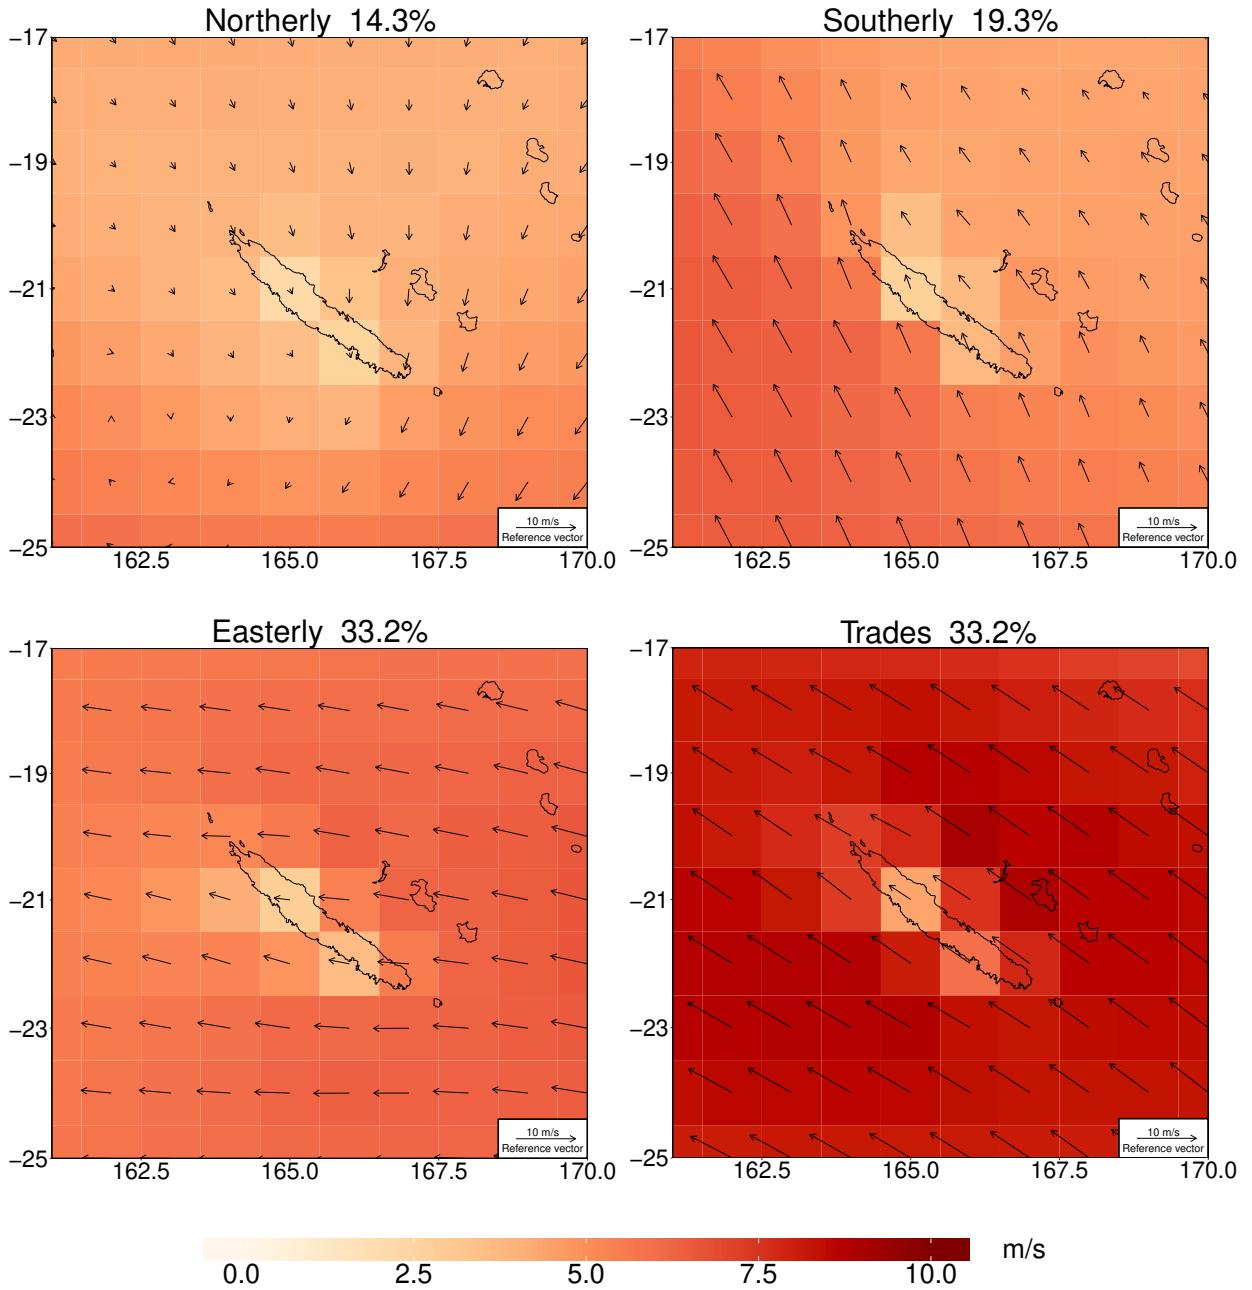

878 FIG. 5. NOAA OLR anomalies (OLRa as defined in Wheeler and Hendon (2004)) (shadings, in W/m^2) and
 879 10-m wind anomalies (vectors, m/s) in ERA-Interim for each MJO phase. The black rectangle indicates New
 880 Caledonia's region shown in Figure 1.

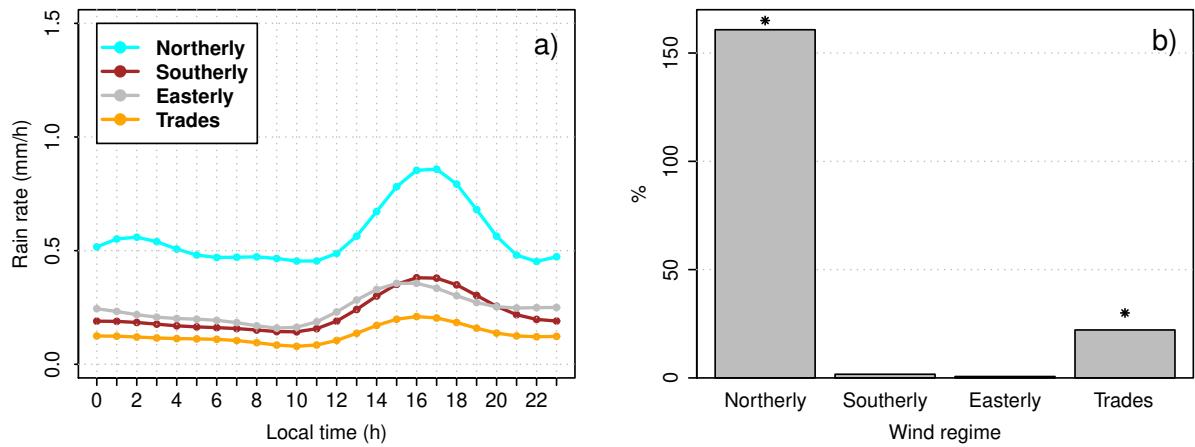

881 FIG. 6. Squared distance between the composite diurnal cycle for each MJO phase \mathbf{r}_ϕ (weak MJO days not
 882 included) and the mean diurnal cycle $\bar{\mathbf{r}}$ expressed as a percentage of $\|\bar{\mathbf{r}}\|^2$ ($100 \times \frac{\|\mathbf{r}_\phi - \bar{\mathbf{r}}\|^2}{\|\bar{\mathbf{r}}\|^2}$). The asterisks indicate
 883 distances that are significant at the 95% confidence level (see Section 2c). Dark shadings: contribution from the
 884 change in daily mean. Light shadings: contribution from the change in the hourly anomalies relative to the daily
 885 mean.

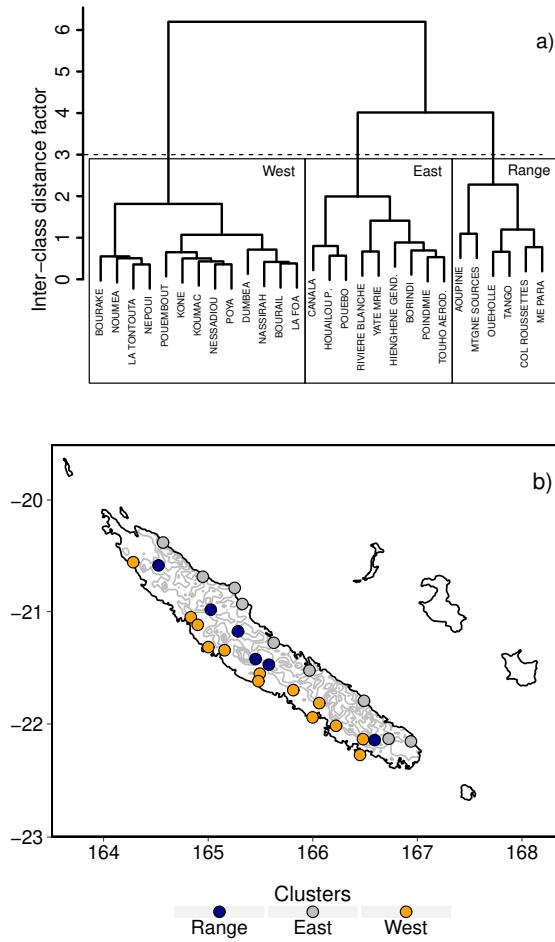

886 FIG. 7. Classifiability index for each number of clusters, determined from the two first PCs of ERA-Interim
887 10-m winds in the New Caledonia domain (161°E-170°E, 25°S-17°S).

888 FIG. 8. Composite maps of ERA-Interim 10-m winds (arrows) and wind speed (shadings) for the four wet
 889 season regimes.

890 FIG. 9. a) Spatially-averaged diurnal cycle of rainfall for each wind regime (mm/h). b) Squared distance
 891 between the composite diurnal cycle for each wind regime \mathbf{r}_i and the mean diurnal cycle $\bar{\mathbf{r}}$ expressed as a
 892 percentage of $\|\bar{\mathbf{r}}\|^2$ ($100 \times \frac{\|\mathbf{r}_i - \bar{\mathbf{r}}\|^2}{\|\bar{\mathbf{r}}\|^2}$). The asterisks indicate distances that are significant at the 95% confidence
 893 level (see Section 2c)

894 FIG. 10. a) Dendrogram of the hierarchical clustering of the 28 rain gauge stations b) Location of the 3 clusters
 895 retained with elevation levels indicated by grey lines.

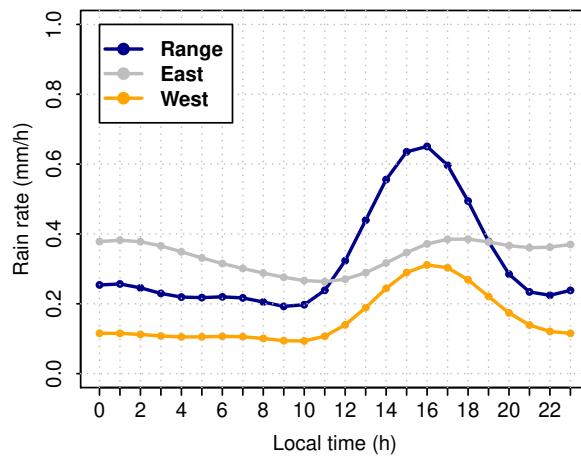

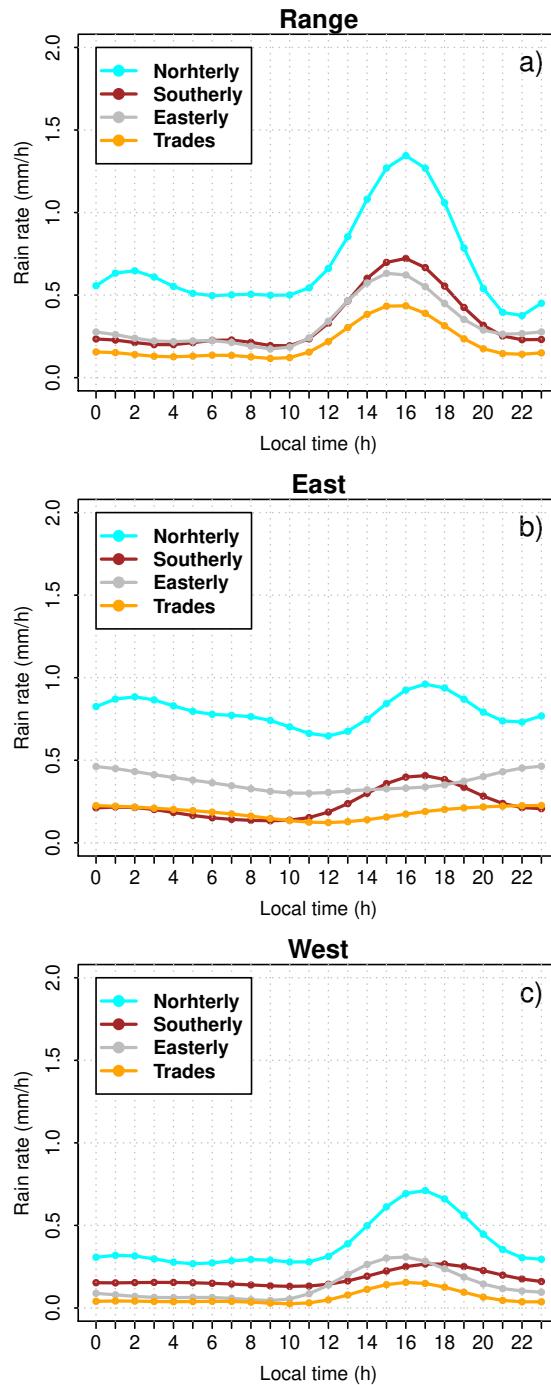

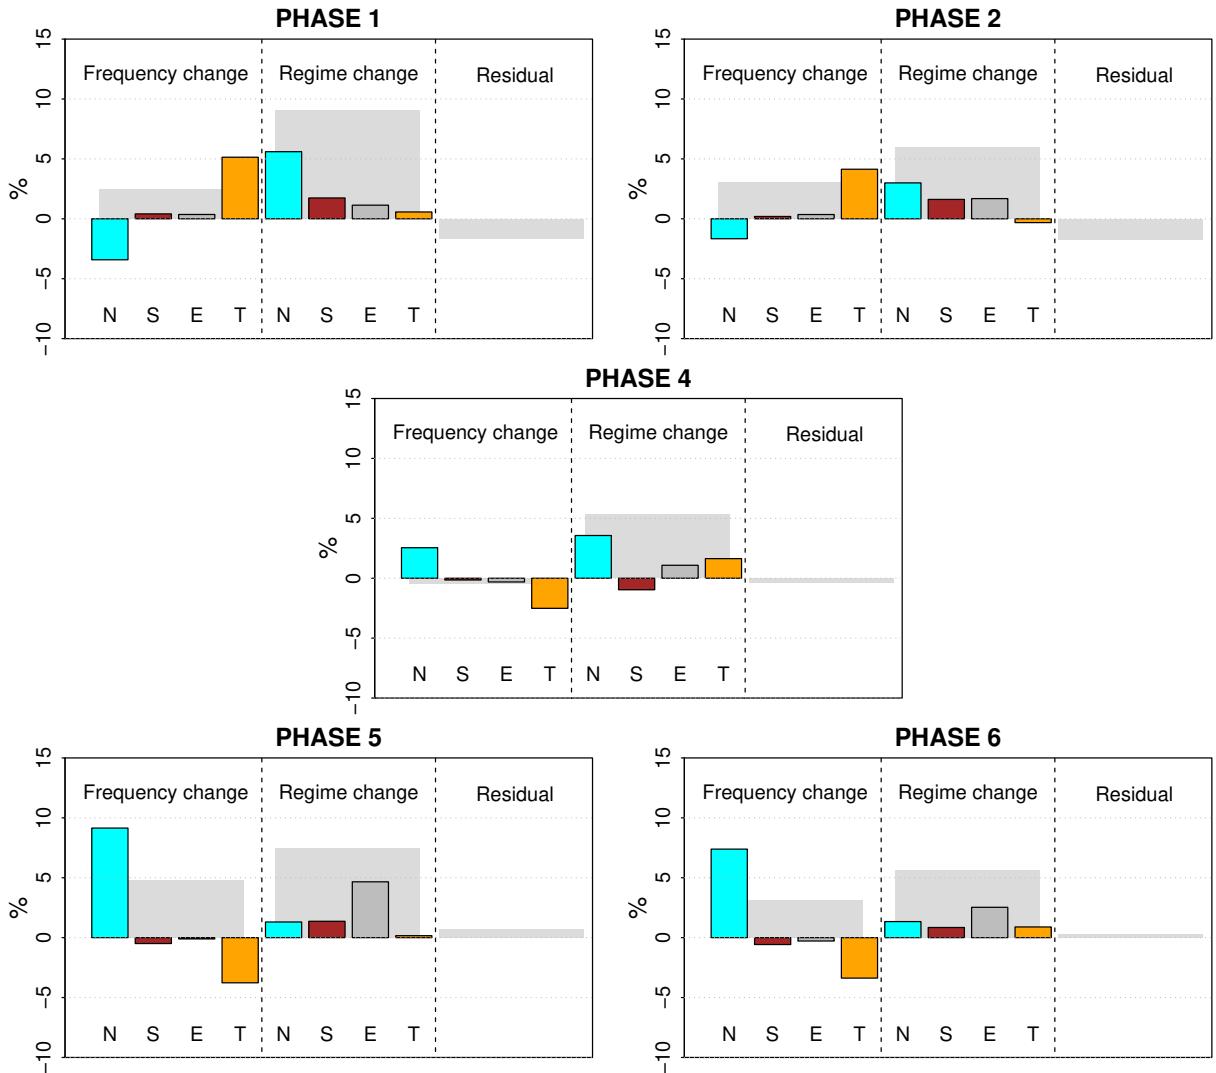

FIG. 11. Diurnal cycles of rainfall (mm/h) for each geographical zone.

896 FIG. 12. Spatially-averaged diurnal cycle of rainfall for each wind regime (mm/h) a) Mountain range b) East
 897 coast c) West coast

898 FIG. 13. Decomposition of the squared distances between the MJO composite cycles \mathbf{r}_ϕ and the long-term
 899 mean diurnal cycle $\bar{\mathbf{r}}$ as a percentage of $\|\bar{\mathbf{r}}\|^2$, according to Equation (16). The first four terms represent the
 900 contribution of regime frequency changes, the next four terms the contribution of regime change at constant
 901 frequency. N: Northerly regime. S: Southerly regime. E: Easterly regime. T: Trade winds regime.
