7 **Abstract**

8 This paper makes a regional evaluation of trend in yearly maxima of daily rainfall in
9 southern France, both at point and spatial scales on a regular grid of $8 \times 8\text{km}^2$. In order
10 to filter out the high variability of rainfall maxima, the current analysis is based on a non-
11 stationary GEV modeling in which the location parameter is allowed to vary with time.
12 Three non-stationary models are considered for each series of maxima by constraining the
13 location parameter to vary either linearly, linearly after a given date or linearly up to a final
14 date. Statistical criteria are used to compare these models and select the best starting or final
15 point of putative trends. The analysis shows that, at regional scale, the best distribution of
16 maxima involves a linear trend starting in year 1985 and that this trend is significant in half
17 the region, including most of the mountain ranges and part of the Rhône valley. Increases
18 in yearly maxima are considerable since they reach up more than 60 mm/day in 20 years,
19 which is more than 40% of the average maximum in this area.

20 **1 Introduction**

21 An exceptional number of heavy rainfall and flooding events occurred in 2014. A storm struck
22 the Brittany region of western France at the end of December 2013 and the subsequent flood
23 lasted until mid January 2014. In February, the Ulla storm passed over Brittany and flooded
24 again along its way to Great Britain. Southeastern Europe (Serbia, Croatia, Romania) faced
25 flood events in May, the Basque county (southwestern France) in July, northeastern France in
26 August, the eastern shore of Spain and southern France in Fall and then Italy in November and

*juliette.blanchet@ujf-grenoble.fr

27 December. Is this sudden large number of floods due to natural climate variability, or is it a
28 consequence of anthropogenic climate change?

29 Already at the end of the 70's, [Charney et al., 1979] envisioned the possible impact of human
30 activity on climate at a global scale. Then the successive Assessment Reports (AR) of IPCC
31 strengthened the evidence of a global change whose main manifestation is an increase in global
32 temperature. [IPCC, 2013] states that global surface temperature has increased by about 0.9°C
33 between 1880 and 2012, with a particularly marked warming since the 1970s. Analyzing climate
34 change impact on precipitation is more arduous, first because precipitation is highly variable
35 and second because its change in recent past shows multiple facets ([Alpert et al., 2002]). Mean
36 precipitation increased under the 40°N area in Europe, Russia, United States, South America
37 and the center of Australia between 1951 and 2010, whereas it decreased over the same period in
38 Eastern Asia, Southern Europe and most of Africa ([IPCC, 2013]). Then what about extreme
39 precipitation? Some studies support a causal relationship. [Planton et al., 2008], working in
40 the context of CMIP3 simulations, shows the impact of global warming on the French climate
41 and specifically on precipitation extremes at the end of the century. However, according to
42 [Gallant et al., 2013], this conclusion is not supported by the recent climate records at European
43 scale. Indeed, despite a clear warming signal in continental indices of temperature, no significant
44 trend is detected in continental indices of precipitation. Is there any trend hidden by the
45 spatial integration of [Gallant et al., 2013]? Focusing on point rainfall measurements, several
46 studies illustrate the spatial variability of extreme precipitation trends over these last decades.
47 [Haylock and Goodess, 2004] reports an increase in the occurrence of heavy rainfall days (defined
48 as the number of days with daily amounts above the 90th percentile) in northern Europe during
49 winter, while it decreases in southern Europe. [Zolina, 2014] considers the length of heavy
50 rainfall period as an extreme rainfall characteristics and shows that trends in these lengths are
51 highly variable across Germany. [Schmidli and Frei, 2005] uses 12 extreme precipitation indices
52 to characterize swiss rainfall records and finds again highly variable trends. In particular, the
53 number of heavy rainfall days in winter decreases in northeastern Switzerland while it increases
54 in the Southeast. [Toreti et al., 2010] shows that trend in the probability of observing an extreme
55 event varies along the mediterranean coast, with a significant negative trends found in 6 of the 20
56 studied costal sites. Still in the mediterranean region, [Alpert et al., 2002] shows that extreme
57 daily rainfall from Spain to Israel increased between 1951 and 1990 in spite of the fact that total
58 rainfall generally decreased.

59 Regarding recent trends in extreme precipitation in southern France, [Narrant and Douguédroit, 2004]
60 finds an increase in the 95th percentile of daily and monthly rainfall, however the inter-annual
61 variability of the 95th percentile suggests that this is only due to the occurrence of few high

62 values at the beginning of the study period. Analysing regional trends in monthly and annual
63 maximum series of precipitation in seven homogeneous climatological zones in southern France,
64 [Pujol et al., 2007b] finds a significant increase in both annual and monthly maxima in October
65 in the southern part of the Massif Central and a decrease in March and an increase in April
66 in the Languedoc-Roussillon. [Pujol et al., 2007a] studies the regional evolution of daily peaks-
67 over-threshold records in the same climatological zones and finds an increase of the occurrence
68 and intensity of extreme daily rainfall in the southern part of the Massif Central, as well as
69 an increase in the intensity of extreme rainfall in the Languedoc-Roussillon. Focusing on the
70 southern region including the Cévennes-Vivarais mountain range prone to flash flood events,
71 [Tramblay et al., 2013] shows in a peaks-over-threshold approach that a slight increase in the
72 number of the most extreme rainfall events are observed since 1980, however no significant
73 trend is detected with a Mann-Kendall test, neither in the event magnitudes nor in the number
74 of occurrences per year. Still in the same region, [Tramblay et al., 2011] shows that time is a
75 valid covariate for modelling peaks-over-threshold intensity, indicating an increasing trend in the
76 magnitude of heavy rainfall events between 1958 and 2008. [Soubeyroux et al., 2015] finds local
77 upward trends in annual maxima of daily precipitation in the french Mediteranean area with
78 a Mann-Kendall test, however this increase is usually not significant. Finally studying seasonal
79 maxima of daily precipitation in the Cévennes-Vivarais range, [Vautard et al., 2015] finds local
80 upward trends with a median increase of about 5% per decade but few of the local trends are
81 significant.

82 Clearly the variety of methodologies is a source of difficulty for summarizing the results
83 on this topic. Two main approaches are usually undertaken. The first one is based on cli-
84 mate indices ([Karl et al., 1996]). The usual methodology is to define a bench of indices that
85 are relevant for the studied region and to estimate changes in each of them by fitting re-
86 gression models (e.g. [Frich et al., 2002], [Klein Tank and Können, 2003], [Zolina et al., 2008],
87 [Alexander et al., 2006],[Karl et al., 1996],[Zhang et al., 2011]), or by comparing empirical prob-
88 ability density functions for various periods (e.g. [Alexander et al., 2006]). ETCCDI (Expert
89 Team on Climate Change Detection, Monitoring and Indices) recommends the use of 27 in-
90 dices, among which 11 are related to precipitation and usually describe ‘moderate extremes’
91 typically occurring several times a year ([Zhang et al., 2011]). This wide spectrum of indices
92 intends to cope implicitly with the great variety of rainfall regimes that can result from precipi-
93 tation interacting with air dynamics ([Schertzer and Lovejoy, 1987, Gupta and Waymire, 1979,
94 Fabry, 1996, Fraedrich and Larnder, 1993]). There are as many random variables characterizing
95 the rain intensity as there are spatial and temporal resolutions, i.e. an infinity. The approach
96 by indices chooses to summarize these many random variables by few statistics, but then part

97 of the information on the random variables is lost.

98 The second set of approaches focuses on the heaviest rainfalls but fully characterized them
99 by modeling their probability density function. These approaches are linked to the statistical
100 theory of extreme values. The current study focuses on annual maxima (so-called "block-maxima
101 approach") and models them with the so-called Generalized Extreme Value (GEV) distribution
102 ([Coles, 2001]). This approach shows the advantage of being scale-independent: whatever the
103 temporal and spatial scales of precipitations at hand, extreme value theory insures that the
104 right distribution to be used is the GEV distribution (whose parameters, of course, are ex-
105 pected to vary from one scale to another, see [Blanchet et al., 2015]). Thus the same theoretical
106 framework can be used for analyzing precipitations at different scales. This is particularly in-
107 teresting for rainfall since rainfall severity depends on the duration and spatial extension of
108 the events ([Ramos et al., 2005, Molinié et al., 2012, Ceresetti et al., 2010]). This is also par-
109 ticularly convenient for trend analysis because trends in extremes at different scales can be
110 analyzed in an easy and universal way through the use of non-stationary GEV distributions
111 ([Marty and Blanchet, 2012, Katz et al., 2002, Westra and Sisson, 2011]).

112 The goal of this article is to provide a regional evaluation of trend in yearly maxima of daily
113 rainfall in southern France in the recent past (several decades), both at point and spatial scales
114 on a regular grid of $8 \times 8 \text{ km}^2$. For this, we place ourself in a statistical extreme value frame-
115 work, which is convenient and theoretically-founded as soon as yearly maxima are concerned. A
116 novelty of this study compared to the litterature in the region ([Norrant and Douguédroit, 2004,
117 Pujol et al., 2007a, Pujol et al., 2007b, Trambly et al., 2011, Trambly et al., 2013, Soubeyroux et al., 2015,
118 Vautard et al., 2015]) is that not only local but also areal rainfalls are considered. A difference
119 with [Trambly et al., 2012] is that here the surface of aggregation is about 10 times smaller
120 than the smallest considered area therein, which enables to study trends at finer space-scales. A
121 second difference is that, unlike in [Pujol et al., 2007a, Pujol et al., 2007b] for example, trends
122 are first assessed locally, which makes possible to reveal the spatial variability of trends and to
123 highlight that the great majority of the significant trends are actually found in quite specific
124 spots. Regional testing is performed in a second step quite similarly to [Pujol et al., 2007b] but
125 focusing on the sub-region where trends are the most significant rather than mixing inhomoge-
126 neous trends encountered over the region.

127 The article is organized as follows. Section 2 presents the data and region of study. Section
128 3 describes the methodology based on non-stationary GEV distributions. The methodology is
129 neither region- nor scale-specific and could be applied at any space and time scales. Currently
130 it is applied to daily point and areal rainfall on a grid of $8 \times 8 \text{ km}^2$ in southern France. Section
131 4 discusses the results and a conclusion finishes the article.

2 Studied region and data

The studied region broadly covers the lower basin of the Rhône River (Figure 1). It includes the southeastern edge of the Massif Central towards the West and the first foothills of the Alps towards the East. It is surrounded by the Mediterranean Sea towards the South. The region features a rather flat alluvial plain containing the Rhône delta with on its edges two mountain ridges with elevations reaching between 1500 and 2000m a.s.l. in less than 30 to 50 km. The highest peaks located along the eastern branch of the V-shaped Massif Central mountain (Mounts Aigoual, Lozère, Gerbier de Jonc and Mézenc) are aligned with an orientation of N-30°-E. On the other side of the Rhône Valley, the main peak line is oriented N-160°-E. This funnel-shaped domain is known to experience severe storms generating flash-floods from various foothill rivers. Both sides of the valley can be affected as shown by quite recent severe events causing numerous human losses and considerable damages that occurred in 1992 on the Ouvèze River ([Sénési et al., 1996]) and in 2002 on the Gard River ([Delrieu et al., 2005]). Nevertheless a strong dissymmetry exists in terms of occurrence of such events in this area. The Massif Central edge, called Cévennes-Vivarais region, experiences most of the extreme storms and resulting flash-floods (Figure 2 of [Nuissier et al., 2008]).

This study makes use of both point and areal daily rainfall. Point rainfall stems from a rain-gage network maintained by Météo-France and covering the French administrative departments of Ardèche, Drôme, Gard, Haute-Loire, Herault, Lozère and Vaucluse, with a surface of about 38,000 km² (see Fig. 1). The network covers at most the 1958-2014 period. The SAFRAN database ([Quintana-Seguí et al., 2008]) provides the areal rainfall on a regular grid of 8 × 8 km². It covers the region in 1078 cells (excluding the Mediterranean Sea), see Fig. 1. Daily SAFRAN data are available for the 1958-2013 period, with no missing value. Since flash floods occur in Autumn in this region, we restrict all series to the three months of September, October and November. In order to filter out the point series with too many missing values, the following steps are applied sequentially:

1. For a given station, an autumnal maximum is considered as missing if its rank is smaller than $pmiss \times N$ where $pmiss$ is the proportion of missing values for that autumn, and N is the number of observed autumns.

2. The whole station is excluded from the analysis if less than 20 autumns are missing.

Step 1. in the above procedure is inspired from [Papalexiou and Koutsoyiannis, 2013] but differs in that here the probability to select a maxima is more continuously related to the proportion of missing values. The idea is essentially to consider that an incomplete year with a large proportion of missing values (large $pmiss$) may still have observed the maximum value if that

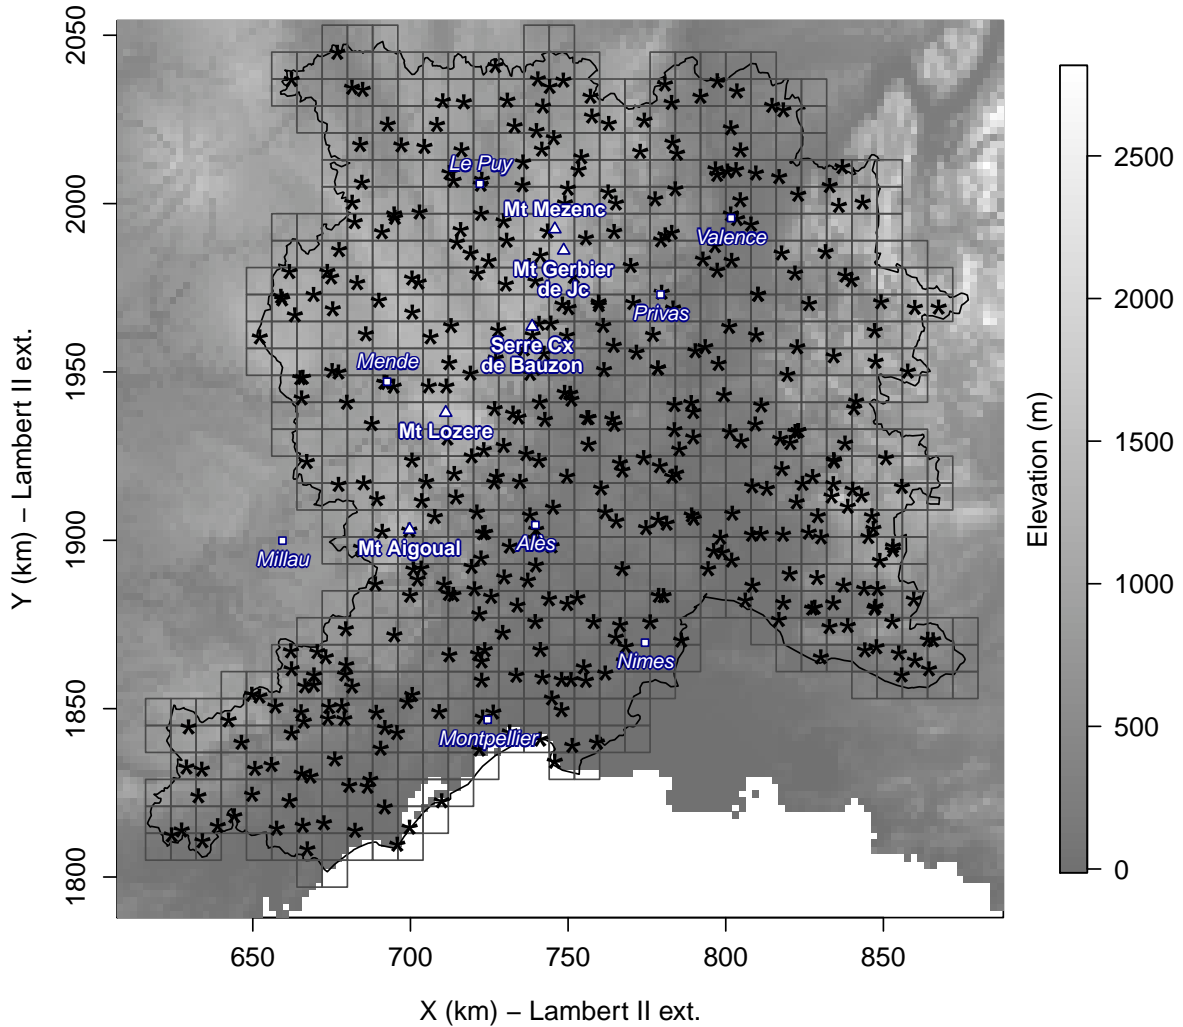

Figure 1: Main features of the region of analysis: elevation above sea level, main mountain peaks (white triangles) and main cities (white squares). Point rainfalls are provided by daily raingages (stars) and areal rainfalls by SAFRAN grids of size $8 \times 8 \text{ km}^2$ (squares). The black border delineates the instrumented area (French administrative departments of Ardèche, Drôme, Gard, Haute-Loire, Hérault, Lozère and Vaucluse).

166 value is large compared to the other maxima (i.e. its rank is large). Applying this selection
 167 procedure, we finally end up with a set of 428 daily point series.

168 3 Method

169 3.1 Modeling of maxima

170 Let R be the random variable of annual maximum rainfall intensity (in mm/h) at a given
 171 spatio-temporal scale, and at a given location. We model the statistical distribution of R us-
 172 ing the so-called Generalized Extreme Value (GEV) distribution. The reason for this latter
 173 choice relies in Extreme Value Theory ([Coles, 2001], chapter 3), which insures that this is
 174 the only possible distribution of independent and identically distributed (i.i.d.) maxima. In
 175 the stationary case, the cumulative distribution function of R , $\Pr(R \leq r)$, is then given by
 176 ([Coles, 2001, Katz et al., 2002]):

$$F(r; \mu, \sigma, \xi) = \begin{cases} \exp \left\{ - \left(1 + \xi \frac{r - \mu}{\sigma} \right)^{-1/\xi} \right\} & \text{if } \xi \neq 0, \text{ provided } 1 + \xi \frac{r - \mu}{\sigma} > 0, \\ \exp \left\{ - \exp \left(- \frac{r - \mu}{\sigma} \right) \right\} & \text{if } \xi = 0. \end{cases} \quad (1)$$

177 Here $\mu, \sigma > 0$, and ξ are the location (mm/h), scale (mm/h), and shape (dimensionless) param-
 178 eters, respectively. Three sub-families of distributions (EV-I, EV-II and EV-III, also known as
 179 Gumbel, Fréchet and Reverse Weibull distributions) can be derived from the GEV depending on
 180 the sign of its shape parameter, which governs the tail of the distribution. If the shape parameter
 181 $\xi > 0$, then the GEV distribution is said to be heavy tailed. This is often the case for rainfall
 182 data, in particular in our study area ([Ceresetti et al., 2010]). The case $\xi = 0$ corresponds to the
 183 Gumbel case whose distribution is light-tailed. This is also often used in hydrological studies
 184 ([Borga et al., 2005]) although there is some evidence that the more general GEV distribution
 185 should be preferred ([Papalexioiu and Koutsoyiannis, 2013]). The case when $\xi < 0$ is the Re-
 186 verse Weibull case, corresponding to upper-bounded random variables with upper-end point at
 187 $\mu + \sigma/|\xi|$. The case $\xi \leq -0.5$ corresponds to distributions with a very short bounded upper tail,
 188 which is unlikely to occur in practice ([Coles, 2001]).

189 In the non-stationary case, the GEV parameters vary with time (years). In this article, the
 190 location parameter is assumed to be a function $\mu(t)$, whilst the scale and shape parameters are
 191 constant. Three non-stationary models for $\mu(t)$ are considered:

- 192 • A linear trend:

$$\mu(t) = \mu_0 + \mu_1 t, \quad (2)$$

193 • A linear trend starting in year t_0 :

$$\mu(t) = \begin{cases} \mu_0, & t \leq t_0, \\ \mu_0 + \mu_1(t - t_0), & t \geq t_0. \end{cases} \quad (3)$$

194 • A linear trend before year t_0 :

$$\mu(t) = \begin{cases} \mu_0 + \mu_1(t - t_0), & t \leq t_0, \\ \mu_0, & t \geq t_0. \end{cases} \quad (4)$$

195 The linear case in $\mu(t)$ (Eq. 2) is used in many studies to model non-stationarities in precipitation
196 extremes (e.g. [Katz et al., 2002]). Here we extend this idea by allowing the change to start in
197 some year t_0 (Eq. 3) or to finish in some year t_0 (Eq. 4). [Panthou et al., 2013] uses in West
198 Africa a different model with a jump in t_0 , i.e. $\mu(t)$ takes value μ_0 before the change point t_0 and
199 μ_1 after t_0 . This induces a discontinuity in the distribution of maxima which seems unrealistic
200 in the region and will not be considered hereafter.

201 The three above equations involve two unknown parameters for $\mu(t)$, instead of one parameter
202 in the stationary case. This latter case is actually a particular case of Eqs. 2 to 4 under
203 $\mu_1 = 0$. This property will be used in the next section to make trend hypothesis test. The
204 corresponding GEV distribution is obtained by replacing in (1) μ by $\mu(t)$. Since the mean of the
205 GEV distribution is a linear function of μ while its standard deviation is independent of μ , the
206 mean of annual maxima is expected to experience a linear trend under Eq. 2, or a linear trend
207 with change point under Eqs. 3 and 4, while the standard deviation of the maxima is expected
208 to be constant within the observed period for all models.

209 Together with the stationary case, four GEV models are thus considered, with respectively
210 three (stationary case) and four (non-stationary case, Eqs. 2 to 4) unknown parameters. These
211 parameters have to be estimated for each series of maxima. In order to insure that enough data
212 are available, we consider:

- 213 • the linear case of Eq. 2 for all series having at least 20 years of observations (which is met
214 by all series);
- 215 • the linear case with change point in t_0 of Eqs. 3 and 4 for all series having at least 20
216 years of observations both before and after t_0 .

217 Since the series span over the 1958-2014 period, possible years of change t_0 will be considered
218 between 1977 and 1995. Models of Eqs. 3 and 4 may or may not be considered for a given series,
219 depending on its observation range and on t_0 .

220 All the models are fitted by maximum likelihood ([Coles, 2001], chapter 3.3), independently
221 for each raingauge and SAFRAN series. Let consider a given series of n annual maximum intensi-
222 ties, denoted $\mathbf{r} = (r_1, \dots, r_n)$, and (t_1, \dots, t_n) the corresponding years. Assuming independence

223 of annual maxima, the log-likelihood in the non-stationary case is given by

$$\log L(\mu_0, \mu_1, \sigma, \xi) = -n \log(\sigma) - (1 + 1/\xi) \sum_{i=1}^n \tilde{r}_i - \sum_{i=1}^n \tilde{r}_i^{-1/\xi} \quad (5)$$

224 where

$$\tilde{r}_i = 1 + \xi \left(\frac{r_i - \mu(t_i)}{\sigma} \right), \quad (6)$$

and $\mu(t)$ is a function of μ_0 and μ_1 as in Eqs. 2, 3 or 4, depending on the considered model. The log-likelihood in the stationary-case is function of (μ_0, σ, ξ) and is also given by Eq. 5, replacing $\mu(t_i)$ by μ_0 in Eq. 6. Denoting θ the three or four GEV parameters, the most likely parameters are those such that $\hat{\theta} = \arg \max_{\theta} L(\theta)$. Since there is no explicit solution, $\hat{\theta}$ is obtained numerically. Standard errors of the trend μ_1 in the non-stationary models of Eqs. 2 to 4 are obtained from the approximate normality of the maximum likelihood estimator (see [Coles, 2001], chapter 2.6.4) as

$$\text{std}(\hat{\mu}_1) = \sqrt{(I^{-1})_{22}}$$

where $(I^{-1})_{22}$ is the element (2, 2) of the inverse of the observed information matrix I defined by

$$I = \begin{pmatrix} -\frac{\partial^2 \log L(\hat{\theta})}{\partial \mu_0^2} & -\frac{\partial^2 \log L(\hat{\theta})}{\partial \mu_0 \partial \mu_1} & -\frac{\partial^2 \log L(\hat{\theta})}{\partial \mu_0 \partial \sigma} & -\frac{\partial^2 \log L(\hat{\theta})}{\partial \mu_0 \partial \xi} \\ -\frac{\partial^2 \log L(\hat{\theta})}{\partial \mu_0 \partial \mu_1} & -\frac{\partial^2 \log L(\hat{\theta})}{\partial \mu_1^2} & -\frac{\partial^2 \log L(\hat{\theta})}{\partial \mu_1 \partial \sigma} & -\frac{\partial^2 \log L(\hat{\theta})}{\partial \mu_1 \partial \xi} \\ -\frac{\partial^2 \log L(\hat{\theta})}{\partial \mu_0 \partial \sigma} & -\frac{\partial^2 \log L(\hat{\theta})}{\partial \mu_1 \partial \sigma} & -\frac{\partial^2 \log L(\hat{\theta})}{\partial \sigma^2} & -\frac{\partial^2 \log L(\hat{\theta})}{\partial \sigma \partial \xi} \\ -\frac{\partial^2 \log L(\hat{\theta})}{\partial \mu_0 \partial \xi} & -\frac{\partial^2 \log L(\hat{\theta})}{\partial \mu_1 \partial \xi} & -\frac{\partial^2 \log L(\hat{\theta})}{\partial \sigma \partial \xi} & -\frac{\partial^2 \log L(\hat{\theta})}{\partial \xi^2} \end{pmatrix}.$$

225

226 3.2 Model selection

227 Given the estimated models of the previous section, we now wish to decide for each series
 228 whether any of the non-stationary model is preferred to the stationary assumption, and if so
 229 which one and for which year of change. Here we use GEV likelihood criteria, even for the
 230 selection of the best year of change. It has two main advantages over the usual statistical tests
 231 relying not on GEV assumptions (see [Beaulieu et al., 2012] for a recent review). First, several
 232 studies showed the better performance of the GEV framework when dealing with extreme data
 233 ([Katz, 2013, Mallakpour and Villarini, 2015]). Second it allows us to use a common method-
 234 ological framework throughout all the process of selection of the best non-stationary model,
 235 selection of the best year of change, estimation of the trend and testing of trend significance.

236 In a first step we compare the non-stationary models to one another and select at regional
 237 scale which of them give(s) the best model-data fit. Since all considered non-stationary models
 238 have four degrees-of-freedom, namely $(\mu_0, \mu_1, \sigma, \xi)$, we can simply compare their likelihoods
 239 and select the subset of them giving the highest mean log-likelihood in the region. However,

240 strictly speaking, this cannot be considered has a regional test for two reasons: first, likelihood
 241 comparisons are, strictly speaking, not statistical tests. Second there is spatial dependence
 242 among the data and therefore among the likelihoods. This first step can therefore only give
 243 evidence about a possible non-stationary model, but not a final decision.

244 Now let \mathcal{M} be a putative non-stationary model selected at the previous step. In a second step
 245 we focus on each series independently. We wish to assess for each of them whether \mathcal{M} should
 246 indeed be preferred to the stationary model \mathcal{M}_0 . First evidence is obtained by comparing
 247 the penalized likelihoods under \mathcal{M} and \mathcal{M}_0 , with a penalization accounting for the difference
 248 in degrees-of-freedom between the two models. We use the well-known Akaike and Bayesian
 249 Information criteria (respectively AIC, [Akaike, 1974] and BIC, [Schwarz, 1978]), which only
 250 differ in the penalizing term. Let $L_{\mathcal{M}}$ and $L_{\mathcal{M}_0}$ be the likelihoods under \mathcal{M} and \mathcal{M}_0 (Eq. 5)
 251 and $\hat{\theta}$ and $\hat{\theta}_0$ the corresponding most likely parameters. Difference in AIC and BIC between
 252 both models is given by:

$$\Delta\text{AIC} = 2\{\log L_{\mathcal{M}}(\hat{\theta}) - \log L_{\mathcal{M}_0}(\hat{\theta}_0)\} - 2 \quad (7)$$

$$\Delta\text{BIC} = 2\{\log L_{\mathcal{M}}(\hat{\theta}) - \log L_{\mathcal{M}_0}(\hat{\theta}_0)\} - \log(n) \quad (8)$$

253 Positive values of ΔAIC (resp. ΔBIC) gives evidence of preference for the non-stationary model
 254 \mathcal{M} rather than \mathcal{M}_0 . Since our series have length greater than 20 (thus $\log(n) > 2$), BIC penalizes
 255 free parameters more strongly than AIC, which tends to favor models with more parameters,
 256 especially for small samples ([Wit et al., 2012]). A way to statistically test model \mathcal{M} versus
 257 \mathcal{M}_0 is to perform a likelihood ratio test (LRT, [Coles, 2001], chapter 2.6). The test applies
 258 here because \mathcal{M}_0 is a particular case of all considered non-stationary models (corresponding to
 259 $\mu_1 = 0$ in Eqs. 2 to 4). Define

$$D = 2\{\log L_{\mathcal{M}}(\hat{\theta}) - \log L_{\mathcal{M}_0}(\hat{\theta}_0)\} \quad (9)$$

260 to be the deviance statistic. Then, for large n , under the null hypothesis that the series comes
 261 from the stationary model \mathcal{M}_0 (i.e. $H_0 : \mu_1 = 0$), D should follow a χ_1^2 distribution. Hence, a
 262 test of the validity of \mathcal{M}_0 relatively to \mathcal{M} at the level of significance α is to reject the stationary
 263 model \mathcal{M}_0 in favor of \mathcal{M} if D is greater than the $(1 - \alpha)$ quantile of the χ_1^2 distribution.

264 4 Results and Discussion

265 4.1 Exploratory analysis: spatial features of maxima

266 This section contextualizes the daily rainfall maxima in the region. More detailed analyzes
 267 can be found in [Ceresetti et al., 2012] and [Molinié et al., 2012] for example. Figure 2 maps

268 the average of maximum intensity (left) and the 95% quantile of maxima (right), both for the
269 point (raingages) and areal (SAFRAN) rainfall data. On average the largest maxima of both
270 point and areal rainfall are found along the Cévennes-Vivarais slope facing South-East. It is
271 interesting to notice that the highest averages of areal rainfall maxima are located over the
272 northern part of the Cévennes-Vivarais slope, around the Serre de la Croix de Bauzon. All
273 along the Cévennes-Vivarais slope, river regularly spaced of about 15km have dug deep valleys.
274 Around the Serre, these secondary valleys are oriented West-East (while Northwest-southeast
275 elsewhere) i.e. perpendicular to the southern mediterranean flux. At this spot, the averages
276 of point and areal rainfall maxima are of the same order of magnitude, i.e. around 6 mm/h
277 accumulated over one day, which is about 140 mm/day. Going more southwest, around Mont
278 Aigoual, the average maximum of areal and point rainfall depart more. Mont Aigoual is well
279 known for experiencing heavy rainfall. The average maximum of point rainfall is similar that of
280 the Serre de la Croix de Bauzon. However, the area around Mont Aigoual is far less prone to
281 heavy rainfall and therefore the maximum of areal rainfall is one third of that of point rainfall.
282 Elsewhere in the study region, areal and point rainfalls are in a good agreement indicating that
283 the homogeneity scale of the average maximum is at least of 8 km.

284 It is important to keep in mind that the average filters out the variety of events impacting
285 the region. The right panel of Figure 2 intends to illustrate this variety by displaying the 95%-
286 quantile of point and areal rainfall maxima. Again rainfall is quite homogeneous around the
287 Serre de la Croix de Bauzon where the largest point and areal rainfall maxima are similar. The
288 largest point rainfalls are found in the foothills around the town of Alès, which departs from
289 the location of the largest average maxima. In this area, the 95%-quantile of point rainfall
290 maxima is more than twice that of areal rainfall maxima, which illustrates the spatial variability
291 of the largest maxima. The two spots experiencing the largest maxima, namely the foothills
292 around the town of Alès and around the Serre de la Croix de Bauzon, are prone to stationary
293 rainfall. Some processes favoring the stationarity of deep convection over the foothills such as
294 the cold pool have been revealed in [Ducrocq et al., 2008], while [Miniscloux et al., 2001] and
295 [Anquetin et al., 2003] show that the mountain shoulders perpendicular to the atmospheric flow
296 can sustain shallow convection.

297 4.2 Trend analysis

298 Now we address the question of whether daily rainfall maxima have exhibited a significant trend
299 in the study region since 1958. A simple way of detecting trends in time series is to fit regression
300 models. However fitting a linear trend on rainfall maxima reveals some weaknesses in terms of
301 robustness due to the high variability of rainfall maxima. Therefore we prefer the use of GEV-

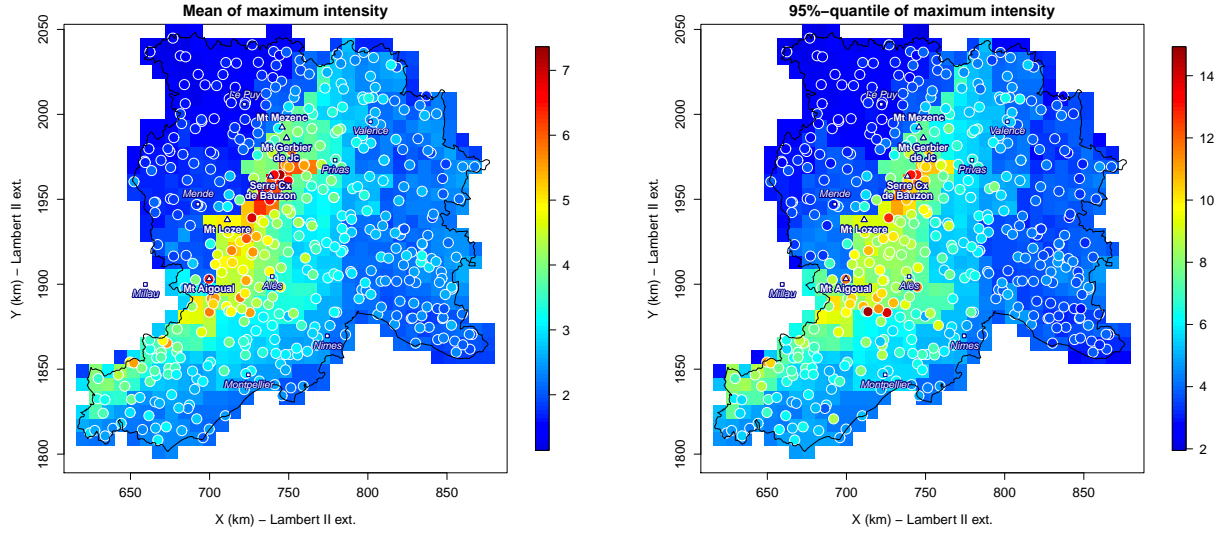

Figure 2: Maps of the daily data. Left: Mean maximum intensity (mm/h). Right: 95%-quantile of maximum intensity (mm/h).

302 based models (Section 3.1) in order to filter out the seldom occurrence of exceptionally high
 303 maxima in the series. An illustration is given by the following robustness analysis. First, we fit
 304 to each point series of yearly maxima i) the GEV model of Eq. 1 with linearly varying location
 305 parameter (Eq. 2) and ii) a linear regression. Second, we remove the overall maximum of each
 306 point series and fit to these new series the two previous models. Figure 3 shows the histograms
 307 of the differences in trend estimates, for the two cases. Among the 428 point series, 300 (70%)
 308 have an absolute difference smaller than 0.1 mm/day/year in the GEV modeling versus only 184
 309 (43%) when using a regression model, which clearly illustrates a lower sensitivity of the GEV
 310 modeling to sampling.

311 Having selected the GEV-based framework for trend analysis, we now estimate a GEV model
 312 to each point and areal series with $\mu(t)$ constrained to vary either linearly (Eq. 2), linearly after
 313 a given date t_0 (Eq. 3) or linearly up to a final date t_0 (Eq. 4). We first select which of these
 314 non-stationary models fits better the data at regional scale. As explained in Section 3.2, first
 315 evidence can be obtained by comparing the mean likelihoods of the different models within the
 316 region. Since models of Eqs. 3 and 4 have a change point t_0 , which is fixed but unknown, we
 317 make estimation of these models by varying t_0 between years 1977 and 1994, in order to insure
 318 that 20 years of data are available before the first change point (1977) and after the last one
 319 (1994). Figure 4 plots the regional mean of the likelihoods of the non-stationary models, for
 320 both point (left) and areal (right) rainfall, as a function of the change point (since the linear
 321 model has no change point, it is depicted with horizontal line). In the top of Figure 4 the
 322 mean is computed over the stations whose series of maxima has no missing year between 1958
 323 and 2013, which is the observation period of SAFRAN data. Thus each point of Figure 4 is a

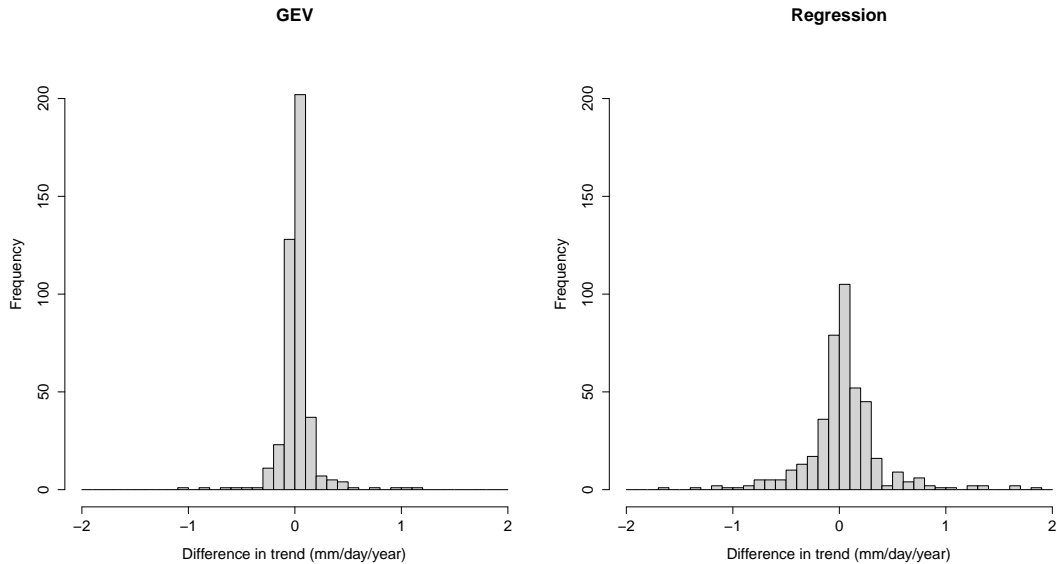

Figure 3: Histogram of difference in trend magnitude (mm/day/year) estimated with and without the overall maximum of each series of yearly point maxima, under either (left) the non-stationary GEV distribution of Eq.2, or (right) a linear regression model.

324 mean of 88 likelihoods for the point data, and a mean of 682 likelihoods for the areal ones. The
 325 same conclusions are drawn from mean log-likelihood comparison in the two cases: whatever the
 326 year of change, the model with a recent trend (green line) is more likely than the model with a
 327 trend since 1958 (black line), which is itself more likely than a model with a trend in the first
 328 subperiod (red line). The best model has a change point in 1985 with a linear trend afterwards.
 329 One may be concerned by the fact that the best change point occurs in 1985, which is exactly
 330 the center of the observation period. In order to check that there is no bias here, we repeat the
 331 same process but we make the GEV estimations on a reduced database starting in 1963 (thus
 332 skipping the 5 first years). The bottom of Figure 4 shows that the same conclusion is drawn:
 333 at regional scale, the selected model is the non-stationary model of Eq. 3 with a change point
 334 in 1985 – which is not anymore the center of the period.

335 Let stress however that, since rainfall maxima are likely to be spatially correlated over
 336 the region ([Bernard et al., 2013]), their joint probability density function is not a product of
 337 marginal probabilities, and thus the log-likelihood sum in Figure 4 is not a proper likelihood.
 338 Therefore, although Figure 4 gives first insight about some potential starting date of the trend
 339 at regional scale, one should keep in mind that this selection criterium relies somehow on an
 340 assumption of independence that is unlikely to hold. This assumption is actually made in the
 341 large majority of the studies of trends in extremes, including that of [Vautard et al., 2015] for
 342 extreme rainfall in the same region, due to the theoretical difficulty in modeling dependence in
 343 extremes ([Davison et al., 2012], [Cooley et al., 2012]). A complementary view not relying on

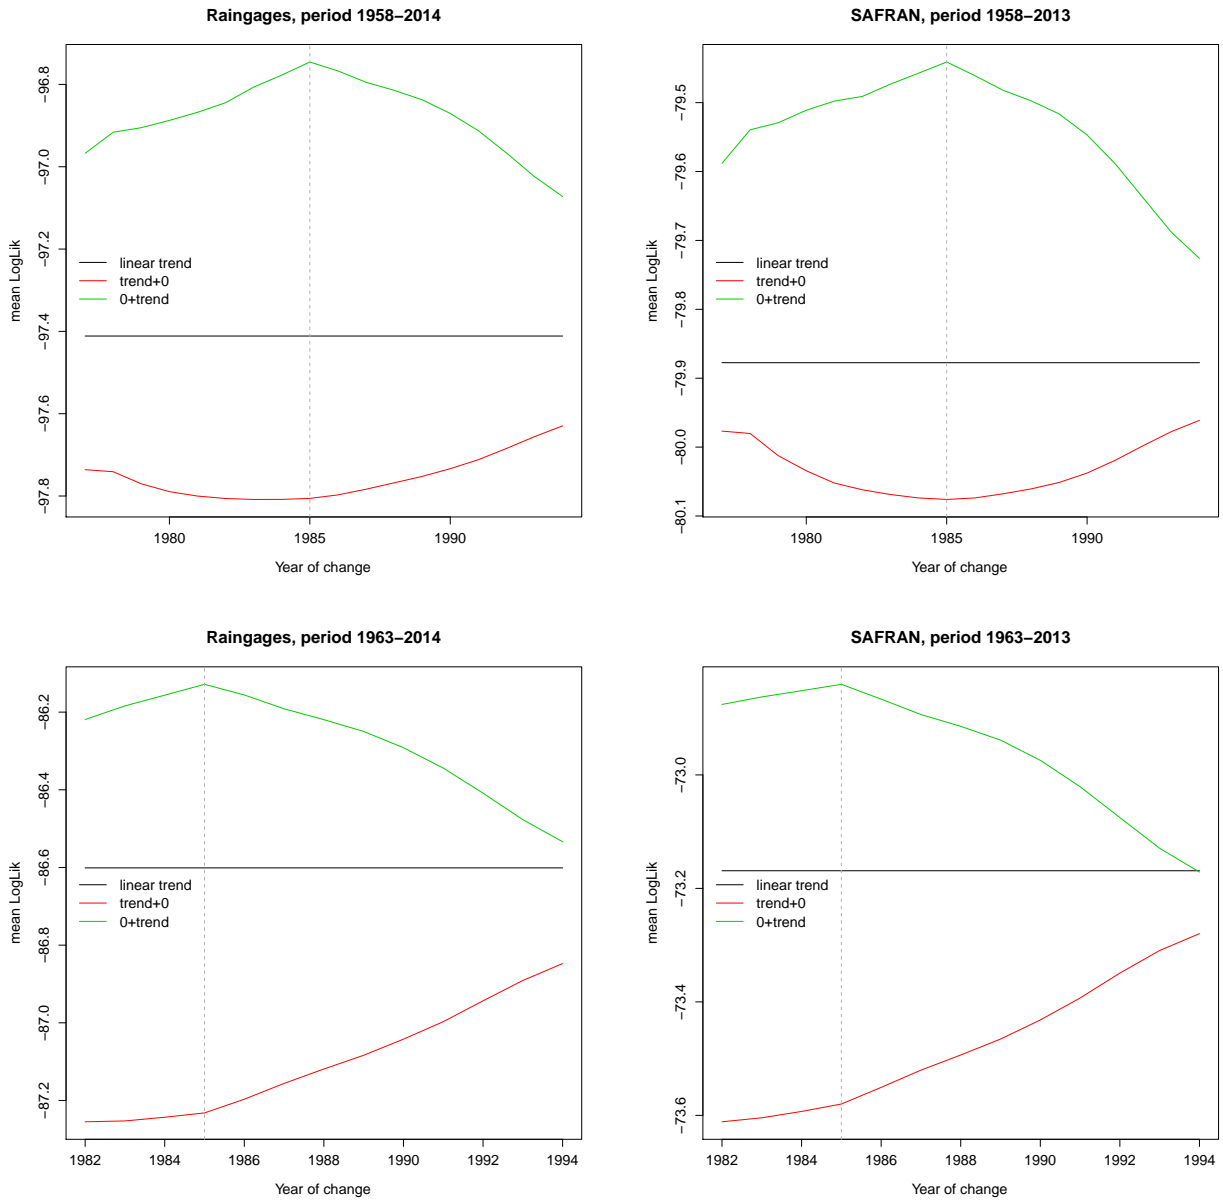

Figure 4: Mean log-likelihood for the three non-stationary models with respect to the year of change for both point (left) and areal (right) rainfall (since the linear model has no change point, it is depicted with horizontal line). Top: for the series with no missing years since 1958. Bottom: for the series with no missing years since 1963.

344 any regional modeling is obtained by checking for each series independently whether the non-
345 stationary model performs statistically better than the stationary one. Due to its clear better
346 performance compared to the two other considered non-stationary models (see Figure 4), we
347 here focus only on model of Eq. 3 with a trend starting at some date. Figure 5 shows, for each
348 year of change, the percentage of series for which model of Eq. 3 is statistically better than the
349 stationary model. Here we use the selection criteria presented section 3.2, namely AIC and BIC,
350 which are, strictly speaking, not statistical tests but penalized likelihood criteria, and the LRT
351 at levels 5% and 10%, giving in total four criteria per series. Figure 5 reveals a good concordance
352 between the results obtained with AIC and the LRT at level 10% on the one hand (plain lines),
353 and between BIC and the LRT at level 5% on the other hand (dotted lines). Therefore, although
354 they are strictly speaking not statistical tests, AIC and BIC are actually roughly equivalent to
355 likelihood ratio testing. Figure 5 also shows that less trends are detected as significant with BIC
356 than with AIC, which was expected since the former uses a stronger penalization (compare Eq. 7
357 to 8). The same applies obviously to the two likelihood ratio tests. One finding is that, whatever
358 the criteria, a larger proportion of trends are detected as significant for the point maxima than
359 for the areal ones (compare the blue lines to the red lines). Another finding is that, when using
360 moderately strict tests (in AIC and the LRT at level 10%), all years of changes between the 80's
361 and the 90's seem to be almost as likely, but when the test becomes stricter (in BIC and the
362 LRT at level 5%), the year 1985 pops out as the most likely, which agrees with the results of
363 Figure 4.

364 Figure 6 maps the series with a significant trend starting in 1985 according to each cri-
365 terium of Figure 5. The most striking feature is that AIC and the likelihood ratio test at
366 level 10% on one hand, and BIC and the likelihood ratio test at level 5% on the other hand,
367 give the same spatial patterns of trends. So not only the percentage of trends (Figure 5) are
368 similar in each case, but also the same series are detected as non-stationary. Grossly speak-
369 ing, yearly maxima of daily rainfall over both the Alps and the Cévennes-Vivarais relief, the
370 foothills and the Rhône river valley are likely to vary linearly with time since 1985. This forms
371 a sub-region of exactly half the size the original region where 95% of the significant trends are
372 located (dotted delineation in Figure 6). Furthermore, comparison of point and areal cases in
373 the two maps shows that trends are variable at small-scale. This localized pattern of trends is
374 smoothed out in SAFRAN rainfalls because these are computed as weighted averages of rain-
375 gage series ([Quintana-Seguí et al., 2008, Vidal et al., 2010]) that may exhibit inhomogeneous
376 trends, explaining why less significant trends are found for the areal maxima. Figure 7 shows the
377 magnitude of the estimated trends (left) together with their standard errors (middle) computed
378 following the method of Section 3.1. Most of the study area has undergone an increase in daily

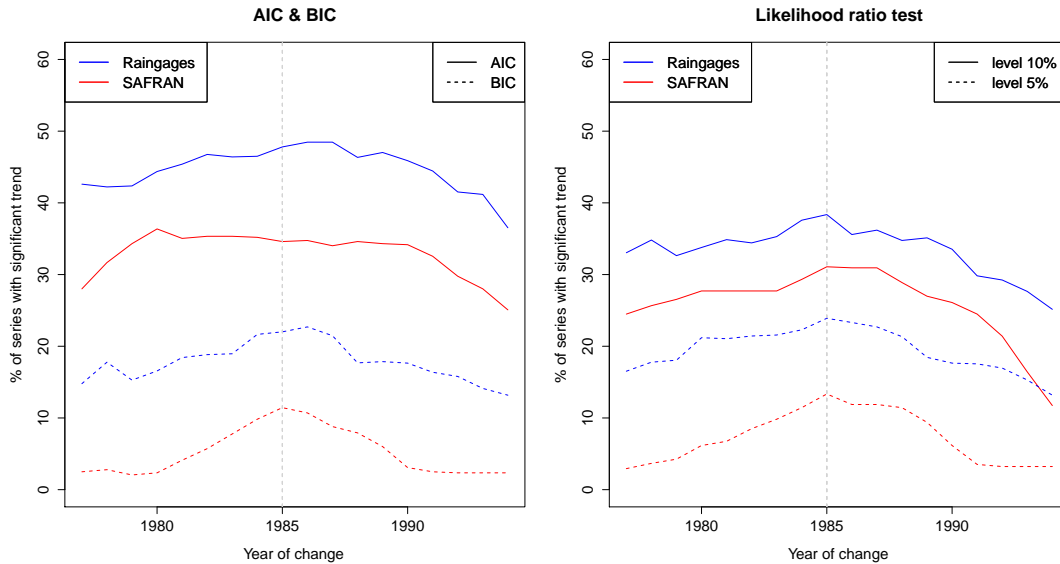

Figure 5: Percentage of series for which the non-stationary GEV distribution of Eq. 3 is preferred to the stationary GEV model of Eq. 1 when the year of change ranges between 1977 and 1994. Preference is assessed using AIC (plain-left), BIC (dotted-left) or the likelihood ratio test at levels 10% (plain-right) and 5% (dotted-right).

379 rainfall maxima since 1985 with larger values in the eastern sub-region where most significant
380 trends are found (see Figure 6). The largest increases of point rainfall maxima are found in two
381 spots: first, along the Cévennes-Vivarais mountain range where increases reach more than 60
382 mm/day in 20 years. This is however also where uncertainty in the highest, with standard errors
383 around 50% of this increase. Second, around the town of Alès with increases up to about 45
384 mm/day in 20 years, however again with standard errors of about 50% of this increase. Inter-
385 estingly, these two spots feature respectively the largest averages and the largest absolute values
386 of rainfall maxima (see Fig. 2). The largest trends in areal rainfall maxima are found in the
387 whole Cévennes-Vivarais slope with up to 1.5 mm/day/year increase. This area features also
388 the largest averages of yearly areal maxima (see Fig. 2). Thus, whatever point or areal rainfall,
389 the largest trends are found where rainfall maxima are the largest. This is however In order to
390 filter out this effect, we display in the right panel of Figure 7 the trend magnitudes relatively to
391 the averages of rainfall maxima. The same two spots, around Alès and the Cévennes-Vivarais
392 slope, still feature among the largest relative trends with increases in the last 20 years reaching
393 up to 40% of the average maxima in these areas. Few other spots stand out: the southwest of
394 the region, which is prone to heavy rainfall events when southeasterly low level flux is blocked by
395 the Pyrenees mountains at the South and by the Massif Central at the North, sustaining deep
396 convection ([Ducrocq et al., 2008, Duffourg and Ducrocq, 2011]); the coastal region of Montpel-
397 lier and the northern part of the Rhône river valley around the town of Valence. There, the

398 Vercors and Massif Central mountains are closed (about 20 km) drawing a strait where flows
399 the Rhône river. This topography may block southerly air mass flux. [Froidurot et al., 2015]
400 notices that 3-hourly rainfall is considerable in this area and features a marked diurnal cycle.
401 One possible mechanism is the influence of the sea breeze which can penetrate inland up to
402 Valence ([Bastin et al., 2005, Drobinski et al., 2006]) and which has been associated to rain in
403 other coastal areas ([Pielke, 1974, Hill et al., 2010]). On the other hand, the mountainous areas
404 south of the Massif Central or the area west of Montpellier have experienced very little increase,
405 if not decrease, in the last 20 years (see Fig. 7). This high variability of trends shows that
406 complex physical processes play a role in the occurrence of trends in the region.

407 The previous results show significance of local trends. Still remains the question: is the
408 number of trends detected in Figure 6 significant *at regional scale*? Answering this question
409 belongs to the domain of field significance. If the maxima were independent, then field sig-
410 nificance could be obtained either by comparing the distribution of the local test p -values
411 to the uniform distribution ([Vogel and Kroll, 1989]), or of the number of rejection of local
412 tests to the binomial distribution ([Livezey and Chen, 1983]), or by considering the regional
413 likelihood as a sum of local likelihoods and applying any test of non-stationarity, e.g. LRT,
414 possibly correcting for the effective degrees of freedom due to spatially dependent trends
415 ([Bretherton et al., 1999, Vautard et al., 2015]). However, applying these tests in our case would
416 be inconsistent owing to the spatial dependence of rainfall maxima ([Bernard et al., 2013]). It
417 would tend to an overestimation of the regional p -value and thus an underestimation of the
418 Type I error rate. Thus, properly testing field significance requires taking into account the
419 spatial correlation among maxima: is the number of trends detected in Figure 6 significant at
420 regional scale, given the spatial correlation of the rainfall maxima? We address this question by
421 a bootstrap procedure ([Douglas et al., 2000, Renard et al., 2008, Pujol et al., 2007b]), which is
422 an iterative simulation procedure allowing to empirically estimate the distribution of the number
423 of locally significant trends under the null hypothesis that the series of maxima are stationary
424 but spatially correlated. We use 1000 bootstrap runs. Each run consists of the following steps
425 ([Renard et al., 2008]): (i) Sample the years with replacement and create the new database
426 obtained by replacing the original series of maxima by the maxima corresponding to these boot-
427 strapped years; (ii) Apply the four tests of Figure 6 to each bootstrapped series; (iii) Maps the
428 series with significant trends as in Figure 6. In the end, 1000 maps such as those of Figure 6
429 are obtained. Comparing the number of significant trends in the original maps of Figure 6 to
430 the bootstrapped maps gives an approximate p -value of the test of field significance, estimated
431 as the proportion of the bootstrapped maps showing more significant trends than Figure 6. Ta-
432 ble 1 shows these p -values depending on the database, on the criterium for local testing and on

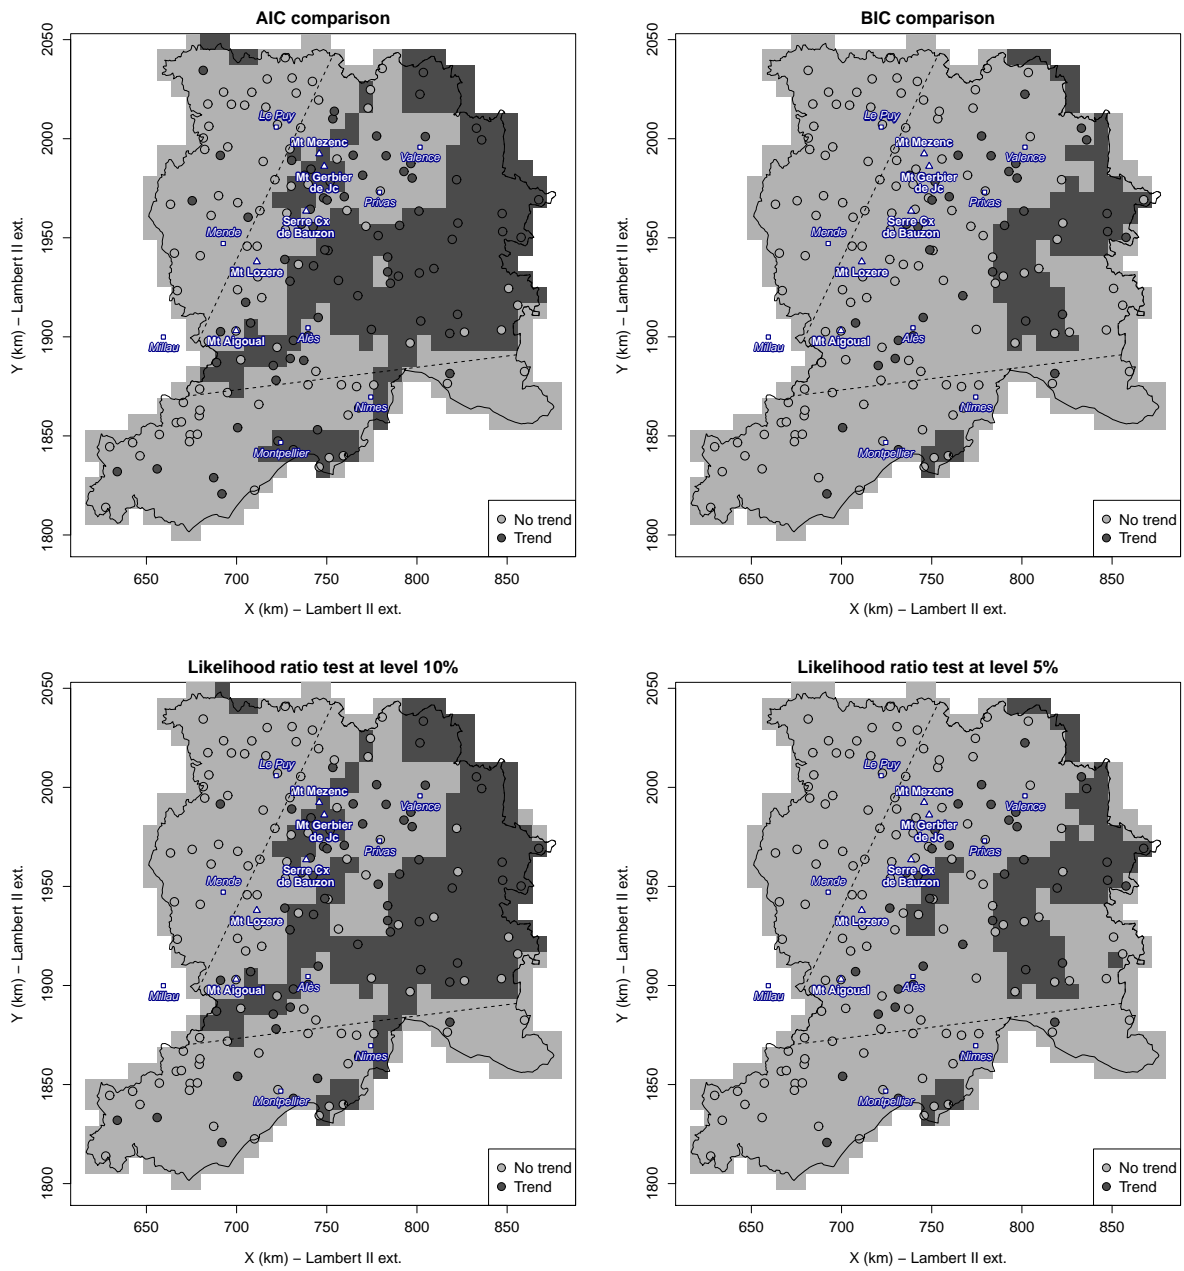

Figure 6: Test of trend at daily scale. The considered non-stationary model is that of Eq. 3 with a change in 1985. Preference is assessed using AIC (top-left), BIC (top-right) or the likelihood ratio test at levels 10% (bottom-left) and 5% (bottom-right). The dotted lines delineate the border of the eastern sub-region where the large majority of the significant trends are found.

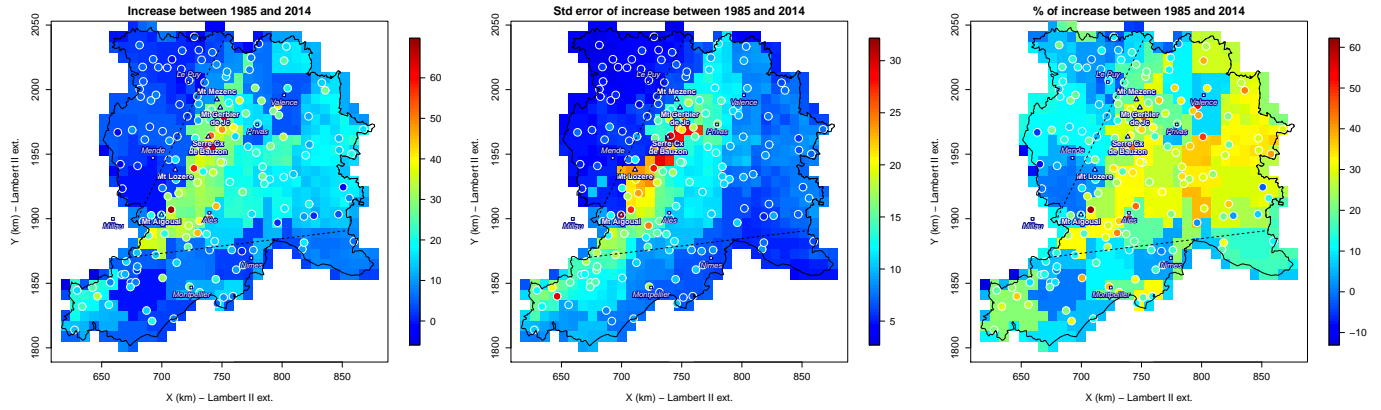

Figure 7: Trend in yearly maxima of daily rainfall accumulation between 1985 and 2014. Left: Magnitude of increase (mm/day). Middle: Standard error of increase (mm/day). Right: Percentage of increase with respect to the average maxima of the series. The dotted lines delineate the border of the eastern sub-region where the large majority of the significant trends are found.

		AIC	BIC	LRT 10%	LRT 5%
whole region	Raingages	3.5 **	4.3 **	2.8 **	4.2 **
eastern region	Raingages	2.3 **	3.2 **	2.2 **	3 **
whole region	SAFRAN	13.4	17	8.8 *	16
eastern region	SAFRAN	6.5 *	10 *	3.6 **	9.1 *

Table 1: Proportion (%) of the bootstrap runs detecting more significant trends than those detected on the original data, when considering either the whole region or the eastern part. The criteria to detect trends are AIC, BIC and LRT at levels 10% and 5%. Very significant trends at regional scale are shown with ** (p -value smaller than 5%), moderately significant trend with * (p -value between 5% and 10%).

433 the considered region. Point rainfall maxima show highly positive trends at the regional scale
 434 with all criteria (first row of Table 1), whereas areal rainfalls are moderately significant with a
 435 LRT at level 10% and non significant otherwise (third row). When restricting to the eastern
 436 sub-region where the large majority of the significant trends are (see Figure 6), trends in point
 437 rainfall maxima become even more significant (second row) and trends in areal maxima become
 438 all significant, and even very significant with a LRT at level 10% (fourth row).

439 5 Conclusion

440 This study addresses trends in yearly maxima of daily point and areal rainfall in southern
 441 France. The adopted methodology is to model the statistical distribution of rainfall maxima by
 442 different cases of non-stationary GEV models in which the location parameter changes linearly

443 with years either after or before a given date. Such non-stationary models assume a translation
444 of the distribution of maxima from year to year towards higher or lower values, before or after
445 a given date. The stationary model is a particular case when the linear trend is null. The
446 proposed methodology for trend analysis involves three steps. First, all the considered non-
447 stationary models are estimated for each point and areal rainfall series of maxima. Second,
448 the best model is selected at regional scale by likelihood comparisons, which also allows us to
449 select the best trend-starting/ending date. Third the corresponding non-stationary model is
450 objectively tested for each series of maxima to assess significance of the trends, both at local
451 and regional scales.

452 This statistical framework is applied to 52 years of both point and areal rainfall data on
453 $8 \times 8 \text{ km}^2$ grids in southern France. The results show a fairly good accordance of the detected
454 trends for the two spatial scales. At regional scale, the most likely starting date of the trend
455 lies between the 80's and the 90's, with 1985 as the most likely. The trend in point rainfall
456 is highly significantly positive in half the region including most of the mountain ranges and
457 part of the Rhône valley. Spatial rainfall also indicates positive trends in these area, however
458 usually of lower magnitude and thus of lower significance. In terms of trend magnitude, two
459 spots stand particularly out for the two spatial scales: the Cévennes-Vivarais ridge and around
460 Alès. These two spots feature both the largest rainfall maxima and the largest trends, which can
461 reach an increase in yearly maxima of more than 62 mm/day in 20 years. This is considerable
462 since it represents more than 40% of the average maximum in this area. Such a high relative
463 increase occurs also in areas where maxima are rather moderate, such as the Rhone river valley,
464 while the mountainous region south of the Massif Central and the area west of Montpellier have
465 experienced very little increase, if not decrease.

466 These results question the processes leading to trends. How are these results in agreement
467 with the well-known Clausius-Clapeyron relationship? If the atmosphere contains more precip-
468 itable water due to global warming, why does it imprint rainfall maxima in some regions and
469 not in others? Insights on the amount of precipitable water (e.g. [Duffourg and Ducrocq, 2011])
470 are necessary to understand the occurrence of trends. However the question of rainfall sampling
471 is of primary importance. Better understanding may be gained by analysing trends in sub-
472 daily rainfall maxima, which are less prone to stationary precipitation ([Ceresetti et al., 2010,
473 Molinié et al., 2012]). Unfortunately such chronological rainfall series are usually neither long
474 enough nor dense enough to provide reliable statistics at regional scale.
