Abstract

Electrical and piezoresistive properties of hybrid nanocomposite films and tubes made of a segmented aliphatic polyurethane modified with multilayer graphene sheets (MLGSs), multiwall carbon nanotubes (MWCNTs), and hybrid mixtures of both, were investigated. Hybrid nanocomposites were fabricated at a total weight concentration (Φ_T) of 5 wt.%, with relative weight concentration of MLGSs with respect to MWCNTs (Φ_R) of 25%, 50% and 75%. The electrical conductivity of these films is dominated by the MWCNT network, observing electrical MLGS-MWCNT collaborative effects only for $\Phi_R = 25\%$. Dielectric impedance spectroscopy indicates that the nanocomposites display capacitive effects at frequencies higher than tens of Hz, which is explained by interfacial polarization. The burst pressure and circumferential stiffness of internally pressurized tubes fabricated from these films is slightly higher for tubes containing only MWCNTs. The strain fields in the pressurized tubes, determined by digital image correlation, showed localized strain gradients, and the piezoresistive response of the electro-conductive tubes was nonlinear. The highest pressure-sensing factor (4.59 kPa^{-1}) was obtained for hybrid nanocomposite tubes with $\Phi_R = 25\%$.

1. Introduction

In recent decades, multifunctional and smart materials that undergo changes in their physical or physicochemical properties as a result of mechanical, thermal or electrical stimuli have attracted great interest from the scientific and industrial community. The exact definition of the term “smart material” may vary in the literature, but it can be generally defined as a material that is designed for a specific functional purpose and has one or more properties that change in a controllable fashion in response to externally applied stimuli, such as strain, stress, temperature, light, moisture, or pH, see e.g. [1–3]. The properties of these smart materials may be further engineered to develop sensors and actuators. At present, an important scientific and technological aim is to develop flexible materials that can be used as pressure and/or deformation (strain) sensors for multifunctional applications in biomedical devices, prostheses, piping, electronic skin, and robotics, to name a few [4–11]. Particularly, in the fields of robotics and biomedicine, there is a strong demand for flexible materials in tubular form working under pneumatic mechanisms, which are capable to self-measure their strain and internal pressure during service [4–6]. In this sense, the inclusion of carbon nanostructures into flexible polymers may render electroconductive (smart) nanocomposites which are able to self-sense strain and pressure through the piezoresistive phenomenon, while delivering additional functions [3,12]. Elastomeric composites modified with carbon nanostructures such as carbon nanotubes (CNTs) and, more recently, graphenic sheets (GSs), have been used to develop flexible materials with piezoresistive properties, although the great majority of them used planar film or membrane geometry [13–20]. The inclusion of CNTs or GSs into elastomeric polymers can result in materials with high piezoresistive sensitivity, reaching gage factors (slope of strain vs. fractional change of electrical resistance, in an approximately linear zone) even of the order of a few hundreds [13–16]. Recently, it has also

1
2
3 been hypothesized that a hybrid combination of CNTs and GSs could improve the
4 electromechanical properties of such polymer nanocomposites by a synergistic or
5 collaborative effect [21–27]. A synergistic effect would imply taking advantage of the
6 elongated (one-dimensional) geometry of the CNTs, and of the planar (two-dimensional)
7 geometry and high surface area of the GSs, to increase the hybrid network interaction and
8 hence the piezoresistive sensitivity. However, despite the recent progress in this field, there
9 are yet several unresolved issues regarding the hybrid formation and its effect on the network
10 formation and on the effective properties of the composite. For example, it is yet not clear
11 how CNTs and GSs interact at the nanoscale in order to form interconnected networks, which
12 are capable of yielding synergistic or at least collaborative effects. The mere concept of
13 “synergistic” has not been strictly defined in this field, and many studies have rushed to claim
14 synergistic effects when they do not even represent the weighted sum of both (CNT and GS)
15 contributions. Moreover, the large majority of the studies on carbon nanostructure-modified
16 elastomeric nanocomposites use film or membrane geometry [13–19], and very few of them
17 tackle the most challenging piezoresistive response of a tubular geometry [28,29]. Therefore,
18 the aim of this work is twofold. First, it is aimed to investigate the influence of multilayer
19 graphene sheets (MLGSs), multiwall carbon nanotubes (MWCNTs) and a hybrid
20 combination of both on the morphology of the hybrid network formation, and its effect on
21 the electrical properties of hybrid elastomeric nanocomposites; this is conducted using a more
22 strict rationale based on electrical conductivity models to define possible synergistic or
23 collaborative effects. The second aim is to extend the investigation by examining the strain
24 and pressure self-sensing (piezoresistive) responses of hollow cylinders (tubes) under
25 internal air pressure, manufactured with the electroconductive films obtained in the first part
26 of the research.

2. Materials and methods

2.1. Materials

The segmented aliphatic polyurethane (Tecoflex SG-80A, TF) was acquired from Lubrizol (Wickliffe, USA), while chloroform (J.T. Baker, purity $\geq 99.8\%$) was used as solvent. MWCNTs and MLGSs were both supplied by Cheap Tubes Inc. (Vermont, USA) and they were used as received without any further treatment. MWCNTs had a purity $> 95\%$, inner diameter $\sim 4\text{--}6$ nm, outer diameter $\sim 20\text{--}40$ nm (mean diameter of $d_{CNT} = 29.1$ nm), length $\sim 1\text{--}6$ μm (mean length of $L_{CNT} = 2.59$ μm), and interlayer separation of ~ 0.34 nm, as reported elsewhere [30]. Analysis of several transmission electron microscopy images indicate that MLGSs have lateral dimensions ranging $\sim 1\text{--}5$ μm (mean length of 3.19 μm) and number of graphene sheets ranging $\sim 3\text{--}32$. MWCNTs and MLGSs have, respectively, an atomic carbon/oxygen ratio (C/O) of 15.1 and 17.2 (obtained by X-ray photoelectron spectroscopy), D-to-G Raman spectroscopy ratio (532 nm green laser) of 0.71 and 0.25, and average specific (Brunauer-Emmett-Teller, BET) area of 110 m^2/g and 183 m^2/g . Further details about the physicochemical properties of both nanostructures are provided in section S1 of the supplementary information.

2.2. Specimen fabrication

For nanocomposite manufacturing, the carbon nanostructures (MWCNTs or MLGSs) were first dispersed in 15 ml of chloroform using an ultrasonic probe operating at 225 W and 20 kHz during 1 min, and subsequently with an ultrasonic bath at 110 W and 40 kHz for 2 h. Simultaneously, TF was dissolved in 15 ml of chloroform by stirring the pellets at 125 rpm for 2 h. The MWCNT/MLGS/Chloroform solution was then poured into the TF/Chloroform solution and stirred at 700 rpm for 2 h. Then, the solution was dispersed again by using an

1
2
3 ultrasonic bath at 110 W and 40 kHz for 5 min and stirred for 15 min at 700 rpm. The resulting
4
5 solution was cast into a rectangular glass mold, covered with a funnel to allow slow rate of
6
7 solvent evaporation, and dried at room temperature (~ 25 °C) for 24 h. After drying,
8
9 nanocomposites and neat TF solid films were obtained from the glass mold with dimensions
10
11 of 110×110 mm² and nominal thickness of ~ 0.12 mm. The obtained films were further dried
12
13 in a convection oven in a gradual (step-wise) fashion, to evaporate potential residual solvent.
14
15 This was achieved by drying from room temperature (~ 25 °C) to 60 °C in 4 h, holding at 60
16
17 °C for 20 h, heated again from 60 °C to 80 °C in 4 h, and kept at 80 °C for another 20 h.
18
19 Additional information on specimen fabrication can be found in section S2 of the
20
21 supplementary information.
22
23
24
25

26 Hollow cylinders (tubes) were manufactured by rolling chloroform-wet films onto a 6 mm
27
28 diameter polytetrafluoroethylene (Teflon) cylindrical mandrel, and then dried in a convection
29
30 oven following the procedure described above. The overhanging edges were cut to obtain
31
32 tubes with 6 mm internal diameter, ~ 7 mm external diameter (~ 1 mm wall thickness) and 80
33
34 mm length.
35
36

37 MLGS, MWCNT and hybrid nanocomposites were prepared by mixing MLGSs and/or
38
39 MWCNTs in a total weight concentration (Φ_T) of 5 wt.%, defined by,

$$\Phi_T = \left(\frac{m_{MWCNT} + m_{MLGS}}{m_T} \right) \quad (1)$$

42 where m_{MWCNT} and m_{MLGS} are the mass of the MWCNTs and the MLGSs, and m_T is the
43
44 total mass of the nanocomposite (MWCNTs + MLGSs + polymer, i.e. 2 g). For hybrid
45
46 composites at a fixed $\Phi_T = 5$ wt.%, a relative MLGS weight concentration (Φ_R) was defined
47
48 as,
49
50
51
52
53
54
55
56
57
58
59
60

$$\Phi_R = \left(\frac{m_{MLGS}}{m_{MWCNT} + m_{MLGS}} \right) \quad (2)$$

Table 1 summarizes the nomenclature used for the nanocomposites and their filler concentrations. For shortness, "GS" is used to refer to the hybrid nanocomposites (excepting GS100, which contains only MLGSs), and "NT" is used for nanocomposites with only MWCNTs. The number that follow the labels of the hybrid nanocomposites (GS#) indicates the relative concentration (in weight percentage) of MLGSs in the nanocomposite. In order to provide more information to assess the MLGS-MWCNT interactions in the hybrid composites, additional nanocomposites with only MWCNTs but less Φ_T were fabricated (NT75, NT50, and NT25). These nanocomposites have a total weight concentration of $\Phi_T = 1.25\%$ (NT25), 2.5% (NT50), and 3.75% (NT75) and served for direct comparison of the electrical conductivity with hybrid nanocomposites with $\Phi_R = 75\%$ (GS75), 50% (GS50), and 25% (GS25), respectively. Additionally, the weight concentration of MWCNTs in the composite (Φ_{CNT}) is a parameter that is of use for the electrical conductivity analysis, and is defined as,

$$\Phi_{CNT} = \left(\frac{m_{MWCNT}}{m_T} \right) \quad (3)$$

Notice in Table 1 that, for example, NT75 has the same total mass of MWCNTs ($\Phi_{CNT} = 3.75 \text{ wt.}\%$) than GS25, but NT75 does not contain MLGSs (only MWCNTs).

Table 1. Nanocomposites nomenclature, masses employed for $m_T = 2$ g, and concentrations of MLGSs and MWCNTs.

Composite	m_{MWCNT} (mg)	m_{MLGS} (mg)	Φ_{CNT} (wt.%)	Φ_T (wt.%)	Φ_R (wt.%)	Description
TF	0	0	0	0	-	Neat polyurethane (Tecoflex SG-80A).
GS100	0	100	0	5	100	Only MLGSs.
GS75	25	75	1.25	5	75	Hybrid concentration with 75% MLGSs and 25% MWCNTs.
GS50	50	50	2.5	5	50	Hybrid concentration with 50% MLGSs and 50% MWCNTs.
GS25	75	25	3.75	5	25	Hybrid concentration with 25% MLGSs and 75% MWCNTs.
NT100	100	0	5	5	0	Only MWCNTs.
NT75	75	0	3.75	3.75	0	Only MWCNTs in the same concentration than GS25.
NT50	50	0	2.5	2.5	0	Only MWCNTs in the same concentration than GS50.
NT25	25	0	1.25	1.25	0	Only MWCNTs in the same concentration than GS75.

2.3. Optical and scanning electron microscopy

Optical microscopy of the nanocomposite films was carried out with a Leica Microsystems DM LM optical microscope (Wetzlar, Germany) using transmitted light. The samples were obtained from a drop of the same suspension/solution used for preparing the nanocomposites, pressing the drop between two glass slides and allowing drying.

Scanning electron microscopy (SEM) was carried using a JEOL JSM-6360-LV microscope (Tokyo, Japan). The surface of the nanocomposites was analyzed using square samples with ~3 mm side-length cut from the nanocomposite films. The SEM images were obtained

1
2
3 without sample metallization, using an acceleration voltage of 20 kV and working distance
4
5 between 10 and 12 mm.
6

7 8 *2.4. Electrical characterization of nanocomposite films*

9
10 The electrical conductivity in direct current (DC) of the nanocomposites was measured by
11 using a high resistivity electrometer (Keithley 6517B, Cleveland, USA), using the 2-point
12 probe (2-wire) method. Rectangular film specimens of 20 mm length, 10 mm width and ~0.12
13 mm thickness were used. Electrodes were defined using “Bare Conductive” (London,
14 England) conductive paint, placed at the ends of the specimen, with a separation of 10 mm.
15

16
17 The electrical resistance of all specimens was in the M Ω range, and differences in electrical
18 resistance between the 2-point and 4-point probe methods were less than 2.4% (see section
19 S3.1 of the supplementary information). Thus, the use of the 4-point probe method was
20 deemed unnecessary.
21

22
23 A special guard (model 8009 from Keithley Instruments) was used to measure the electrical
24 resistivity of the most insulating materials, i.e. pure polymer (TF) and nanocomposites NT75,
25 GS75 and GS100. In this case, circular specimens were cut from the films with 90 mm
26 diameter and ~0.12 mm thickness, in order to fit the circular electrodes of the commercial
27 guard. Ten replicates per group were measured.
28

29
30 The Voigt and Reuss (series and parallel) electrical models [31] were originally developed
31 to describe properties of fiber-reinforced oriented composites in their longitudinal and
32 transverse directions. Although they are not directly applicable to nanoparticle-filled
33 composites, they can still provide a first approach to define upper and lower limits of the
34 expected properties. Taking into account this, two semi-empirical models are proposed here
35 as a calibrated frame of reference for the conductivity of the nanocomposites, adapting the
36
37
38
39
40
41
42
43
44

56
57
58
59
60

original Voigt and Reuss models to represent the weighted average of the constituent nanocomposites (instead of the weighted average of the matrix and filler), i.e.,

$$\sigma_e = \sigma_{e_{NT100}}(1 - \phi_{VR}) + \sigma_{e_{GS100}}\phi_{VR} \quad (4a)$$

$$\sigma_e = \left(\frac{(1 - \phi_{VR})}{\sigma_{e_{NT100}}} + \frac{\phi_{VR}}{\sigma_{e_{GS100}}} \right)^{-1} \quad (4b)$$

where $\sigma_{e_{NT100}}$ and $\sigma_{e_{GS100}}$ are the measured electrical conductivities of the nanocomposites NT100 and GS100, respectively. ϕ_{VR} is the relative volume concentration (vol.%) of MLGSs, which is expressed by,

$$\phi_{VR} = \frac{V_{MLGS}}{V_{MWCNT} + V_{MLGS}} \quad (5)$$

Volume fractions were obtained by means of the corresponding densities, i.e. $V_x = m_x/\rho_x$, where “x” can be MWCNT, MLGS or TF; ρ_{MWCNT} , ρ_{MLGS} and ρ_{TF} are the density of the MWCNTs (2.1×10^6 g/m³ [24]), MLGSs (2.2×10^6 g/m³ [24]) and TF (1.04×10^6 g/m³).

Notice that these modified series, Eq. (4a), and parallel, Eq. (4b), models are calibrated in such a way that they employ the measured data for nanocomposites with only one filler, i.e. 0% (NT100) and 100% of MLGSs (GS100), to predict the electrical conductivity of hybrid nanocomposites at an intermediate MLGS concentration.

Electrical properties in alternating current (AC) were obtained by analyzing the phase shift of the voltage and current signals of the specimens in a frequency range of 10^{-1} to 10^7 Hz at an applied voltage of 1 V_{rms}. For this, an Alpha-A broadband dielectric spectrometer from Novocontrol Technologies (Montabaur, Germany) was used. The nanocomposite films (~0.12 mm thickness) were cut into circular specimens of 35 mm diameter and sputtered with high purity gold (thickness ~ 50 nm) on both sides, defining 25 mm diameter electrodes. All samples reported herein were tested at room temperature (~25 °C). Further information of

1
2
3 the experimental setup used for electrical measurements (both, in DC and AC) is provided in
4
5 section S3.1 of the supplementary information.
6

7 8 *2.5. Mechanical and piezoresistive characterization of tubes*

9
10 Hollow cylinders (tubes) of 80 mm long, 6 mm inner diameter and ~1 mm wall thickness
11
12 (see Fig. 1a) were manufactured from the nanocomposite films NT100, GS25, GS50, GS75
13
14 and GS100, as well as from the neat polymer (TF). GS50, GS75 and GS100 nanocomposites
15
16 were only tested mechanically (burst strength), since their electrical conductivity in tube
17
18 geometry was not enough to characterize their piezoresistivity. The burst strength test
19
20 (internally pressurized cylinder) [32] using air pressure, was conducted with an equipment
21
22 specifically designed and manufactured for this type of test [33], as depicted in Fig. S7 of
23
24 section S3.2 of the supplementary information. This equipment pumps filtered air into the
25
26 tubular specimen and gradually increases the internal pressure (at 1 psi/s, ~6.9 kPa/s, for all
27
28 tests herein) while continuously measures its diameter using a laser curtain micrometer
29
30 (optoCONTROL 1200-30 from Micro-Epsilon, Ortenburg, Germany). Circumferential strain
31
32 (ε_{θ}) was calculated as the instantaneous change in diameter divided by the initial diameter,
33
34 and tube compliance was obtained from the slope of the pressure (P) vs. ε_{θ} curve at strains
35
36 $\varepsilon_{\theta} \leq 5\%$.
37
38
39
40

41
42 In order to conduct piezoresistive tests of NT100 and GS25 nanocomposite tubes, 40-gauge
43
44 copper wires were cemented (using “Bare Conductive” paint) on two opposite sides of the
45
46 circumference of the tubes (see Fig. 1a), forming 5 mm side-length square electrodes. The
47
48 electrical resistance was measured using the 6517B Keithley electrometer described earlier.
49
50 Since it was experimentally confirmed that the thin electrodes did not affect the mechanical
51
52 response, the mechanical and piezoresistive responses were obtained simultaneously (from
53
54 the same specimen/test). Five tubular specimens were tested for each type of nanocomposite.
55
56
57
58
59
60

To quantify the piezoresistive sensitivity of the tubes, a gage factor (GF^T) was defined by,

$$GF^T = \frac{\Delta R/R_0}{\varepsilon_\theta} \quad (6)$$

where R is the instantaneous electrical resistance, R_0 is the initial (unloaded) electrical resistance, and $\Delta R/R_0$ is the fractional change in electrical resistance. Given the nonlinear piezoresistive response of the specimens, gage factors were calculated in two regions of the $\Delta R/R_0$ vs. ε_θ curves (I and II). GF^T_I was obtained from $0 \leq \varepsilon_\theta \leq 5\%$ (region I), while GF^T_{II} (region II) was obtained from $15 \leq \varepsilon_\theta \leq 20\%$. Also, the pressure sensitivity factors (PF) of tubes were obtained as a function of the applied (internal) pressure (P) as,

$$PF = \frac{\Delta R/R_0}{P} \quad (7)$$

Similar to gage factors, the pressure sensitivity factors were measured at two regions of the $\Delta R/R_0$ vs. P curves, viz. $0 \leq PF_I \leq 35$ (kPa) and $150 \leq PF_{II} \leq 200$ (kPa).

An ARAMIS 5M digital image correlation (DIC) equipment from GOM (Brunswick, Germany) was used to measure the strain fields of the tubular specimen upon pressure. For this purpose, an speckle pattern was painted on the surface of the tube with an area of 50×6 mm² (see Fig. 1c). Images were captured using two 2448×2050 pixels (5 Mpx) cameras, with 35 mm Schneider lenses, using a 35×29 mm field of view, and a camera distance of 21.5 cm, as shown in Fig. 1b. The full experimental setup can be seen in Fig. S7 of section S3.2 of the supplementary information. Figure 1c shows the speckle pattern and mask (measurement zone) used to measure the DIC strain fields. The DIC mask is placed between the electrodes (see Fig. 1a) and has an approximate length of 50 mm and an arc-width of 6 mm. In this area, the strain fields along the x , y , z axes (ε_x , ε_y , ε_z) were measured, according to the axes depicted in Fig. 1c.

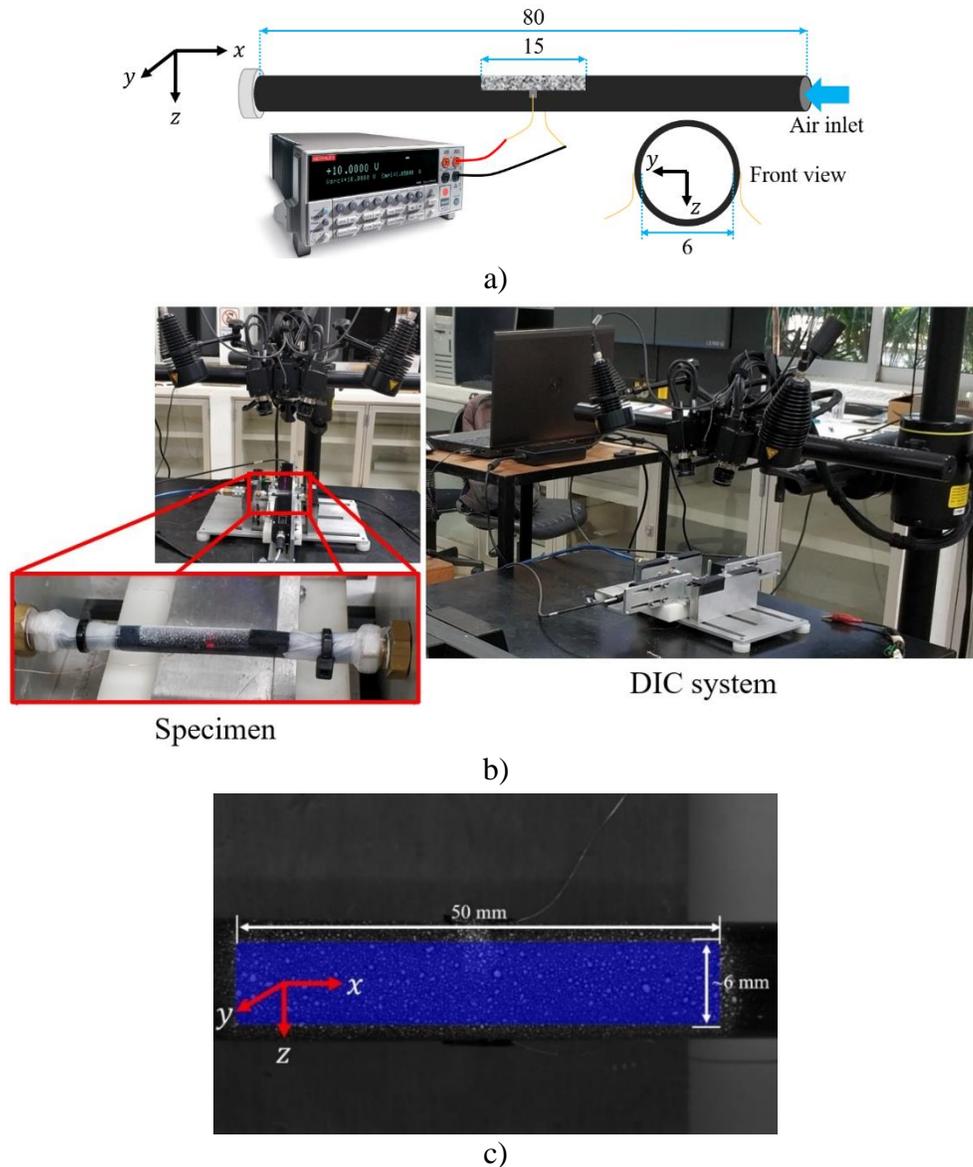

Fig. 1. Burst strength test of the nanocomposite tubes. a) Schematic of the tube and meter, b) photograph of the experimental setup, c) DIC measurement mask on a tube.

3. Results

3.1. Visualization of the interconnected networks

Figure 2 shows optical microscopy images of the nanocomposite films with a magnification of 10x. It is seen that carbon nanostructures form interconnected networks within the polymer matrix, comprising well-distributed groups of nanostructures but also some heterogeneous islands of grouped nanostructures, especially for the hybrid nanocomposites (GS25, GS50,

1
2
3 and GS75). The agglomerates found in the nanocomposites with a single type of
4 nanostructure (NT100 or GS100) are smaller than those found in the hybrid nanocomposites
5 (GS25, GS50 and GS75), achieving better dispersion and distribution for composites with
6 only MWCNTs (NT100). Agglomerates in CNT and graphenic nanocomposites are typically
7 attributed to van der Waals and Coulombic attractions [34]. The elongated geometry and high
8 aspect ratio of MWCNTs promote agglomeration, as has been previously pointed out [34].
9 On the other hand, given the geometry, two-dimensional topology and flexibility of MLGS,
10 they are prone to become folded or crimped when dispersed into a polymer matrix [35,36].
11 It is worth noticing that the network morphology of the hybrid nanocomposites is very
12 different from that of GS100 and NT100. This fact suggests that the morphology and
13 dimensionality of the nanostructure plays a paramount role in their physico-chemical
14 interactions and consequent network formation, especially for non-functionalized
15 nanostructures such as those used herein. Furthermore, the surface area of MWCNTs and
16 MLGSs (see section S1.1 of the supplementary information), as well as their compatibility
17 with the solvent (chloroform), are determining factors in their state of dispersion [37,38].
18 Compared to MWCNTs, MLGSs have a larger surface area, which implies a higher tendency
19 to agglomerate.

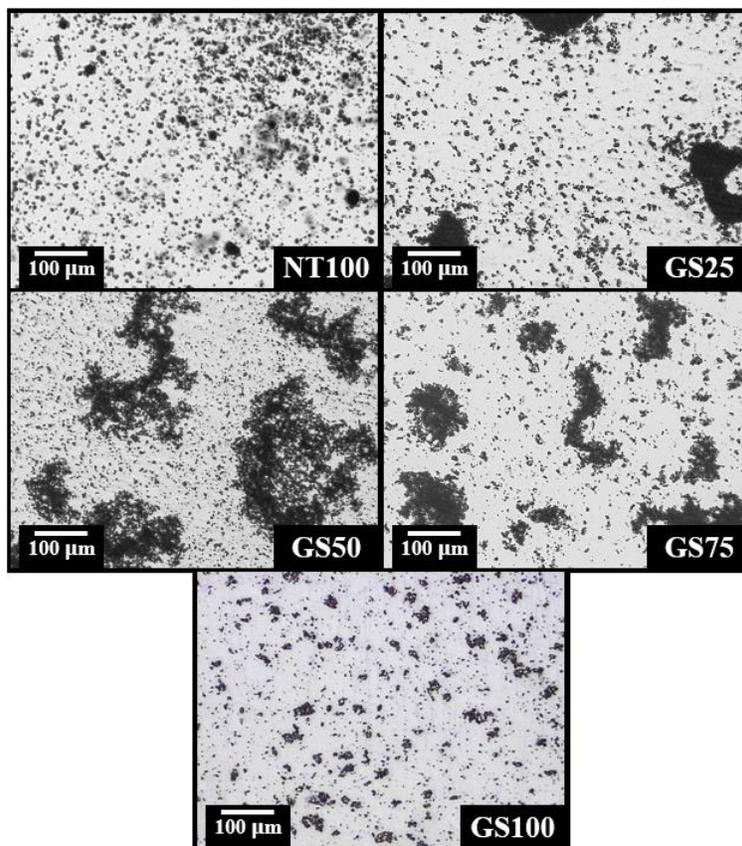

Fig. 2. Optical microscopy images of the hybrid nanocomposites showing the fillers (dark entities) dispersed within the polymer matrix.

Further confirmation of the dispersion state can be obtained from the SEM images of Fig. 3, although in a significantly smaller scale. In this scale, the MWCNTs still show signs of agglomeration, and better dispersion than the MLGSs. For the GS25 hybrid, MWCNTs and MLGSs are intercalated within the polymer matrix. Similar features are observed in the other two hybrid nanocomposites (GS50 and GS75), but the presence of stacked MLGSs is more evident. The greater tendency of the MLGSs to stack and agglomerate as compared to the MWCNTs, can be attributed to their higher specific surface area ($\sim 183 \text{ m}^2/\text{g}$, see Table S1). It is also observed that some MLGSs present an irregular geometry, with dimensions significantly smaller than the few microns expected. This can be attributed to the

manufacturing process of the nanocomposites, where the MLGSs are prone to fold and crumple during nanocomposite processing.

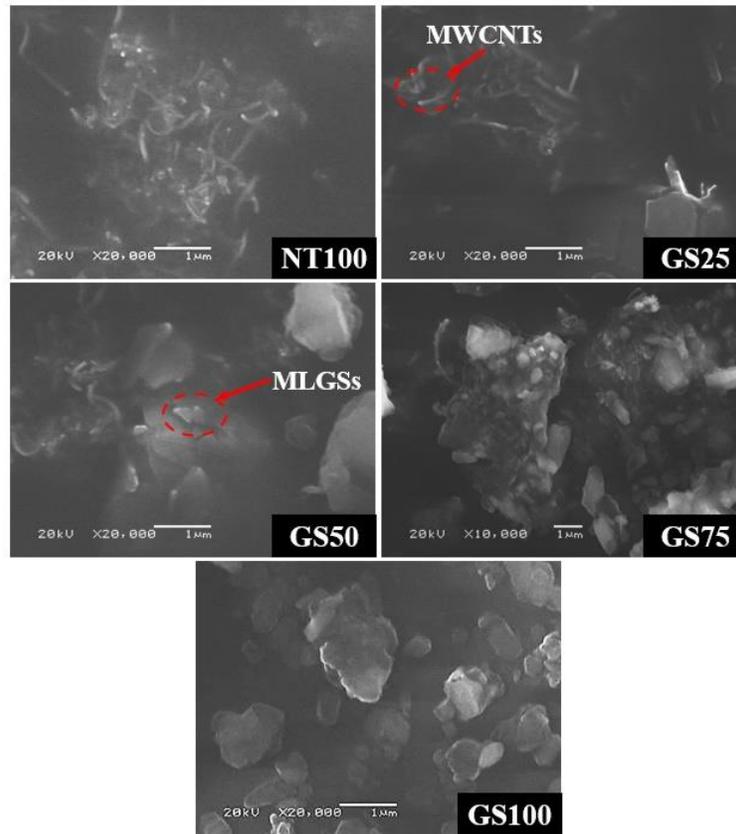

Fig. 3. SEM images of the nanocomposites showing MWCNTs and MLGSs dispersed in the polymer matrix.

3.2. Electrical conductivity in direct current

Figure 4 shows the electrical (DC) conductivity (σ_e) of the investigated films as a function of Φ_R (bottom horizontal axis) and Φ_{CNT} (top horizontal axis). The continuous plots produced by the semi-empirical models stated in Eqs. (4) are included in this graph. It is clear that the conductivity of TF ($\sigma_{eTF} = 3.16 \times 10^{-13}$ S/m) increases several orders of magnitude with the inclusion of carbon nanostructures (MWCNTs or MLGSs). The electrical conductivity varies according to the relative concentration of MLGSs with respect to that of MWCNTs (Φ_R), being higher for nanocomposites with only MWCNTs ($\sigma_{eNT100} = 1.33 \times 10^{-3}$ S/m), and

1
2
3 decreasing as the MWCNTs are replaced by MLGSs, until the lowest value is reached for
4
5 GS100 ($\sigma_{e_{GS100}} = 1.01 \times 10^{-9}$ S/m). This decrease in electrical conductivity as the relative
6
7 concentration of MLGSs increases is not linear, showing a sigmoidal behavior (for $\log[\sigma_e]$),
8
9 as pointed out in Fig. S8 of section S4 in the supplementary information. The higher electrical
10
11 conductivity of nanocomposites with MWCNTs with respect to that of nanocomposites with
12
13 MLGSs can be explained by the geometry, morphology (long tubes against disks), and
14
15 dimensions of both nanostructures, and is supported by the theory of excluded volume [39],
16
17 as further explained in section S5 of the supplementary information. In addition, the tunneling
18
19 effect between nanostructures plays an important role in the electrical conductivity and
20
21 piezoresistivity of this type of nanocomposites [40,41]. Electrons between conductive fillers
22
23 can quantumly tunnel through a thin layer of insulating polymer, which has been estimated
24
25 to be less than ~ 5 nm [40,41]. The effective electrical conductivity of the nanocomposites
26
27 strongly depends on the agglomerate size, and how these agglomerations are distributed
28
29 within the polymer [42,43]. The elongated geometry of the MWCNTs and better agglomerate
30
31 distribution observed in Fig. 2 and 3, may be a contributed factor for their better electronic
32
33 transport. The semi-empirical models of Eq. (4) enclose the measured data in Fig. 4, given
34
35 that they are calibrated with the measured conductivity of NT100 and GS100
36
37 nanocomposites. The model of Eq. (4a) (series model) for hybrids represents a simple
38
39 weighted summation of the contribution of each nanocomposite comprising a single
40
41 nanostructure (NT100 and GS100); as such, it is proposed here to represent a boundary that
42
43 can be used as a reference frame to distinguish the electrical interaction between the hybrid
44
45 nanostructures within the nanocomposite (either synergistic or collaborative), as depicted in
46
47 Fig. 4. This is, if the electrical conductivity of the nanocomposite is above the weighted sum
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 of the electrical conductivity of the nanocomposites with a single type of filler, Eq. (4a), then
4
5 a synergistic effect is identified. If the conductivity is not higher than that predicted by Eq.
6
7 (4a), but still higher than that of the single-filler MWCNT nanocomposites at identical Φ_{CNT}
8
9 (NT75, NT50, and NT25, for $\Phi_R = 25\%$, 50% and 75%, respectively), then a collaborative
10
11 effect is expected. As seen from Fig. 4, in the case of the nanocomposites examined herein,
12
13 for $\Phi_R = 25\%$ (GS25 nanocomposites in Table 1) there are collaborative electrical effects
14
15 between the MWCNTs and the MLGSs. However, for $\Phi_R = 50\%$ and 75%, the conductivity
16
17 is predominantly governed by that of the MWCNT network, and the MLGS have further no
18
19 significant effect on the conductivity of the hybrid nanocomposite. This is undoubtedly
20
21 related to the morphology of the network of carbon nanostructures formed within the
22
23 nanocomposite (Fig. 2 and 3), as well as to the dimensionality, size, agglomeration state, and
24
25 physicochemical properties of the nanostructures, as reported in section S1 of the
26
27 supplementary information. As seen in Table S1 of the supplementary information, the
28
29 nanostructures used herein contain low functionalities (less for MLGSs), less surface area
30
31 and higher aspect ratio for MWCNTs, yielding better dispersion for MWCNT composites.
32
33 However, it has been pointed out that well distributed, connected agglomerates of moderate
34
35 size may enhance the electrical conductivity of polymer nanocomposites [42].

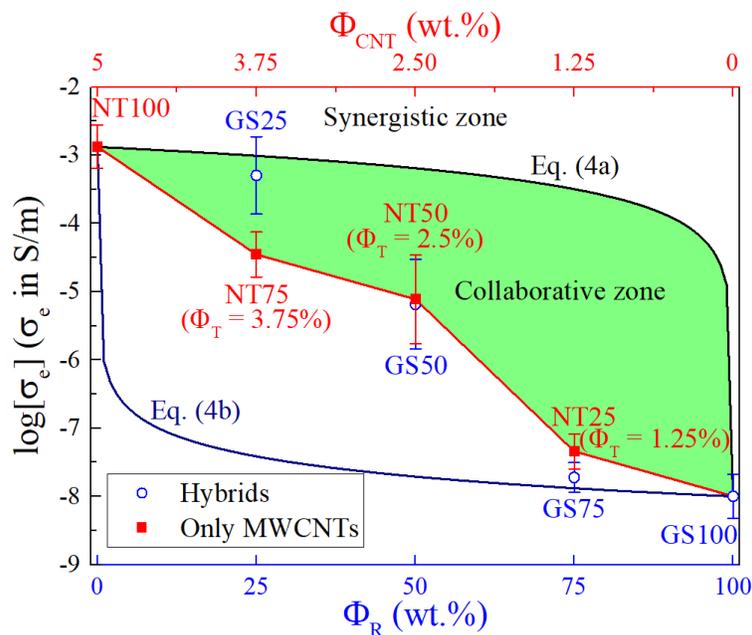

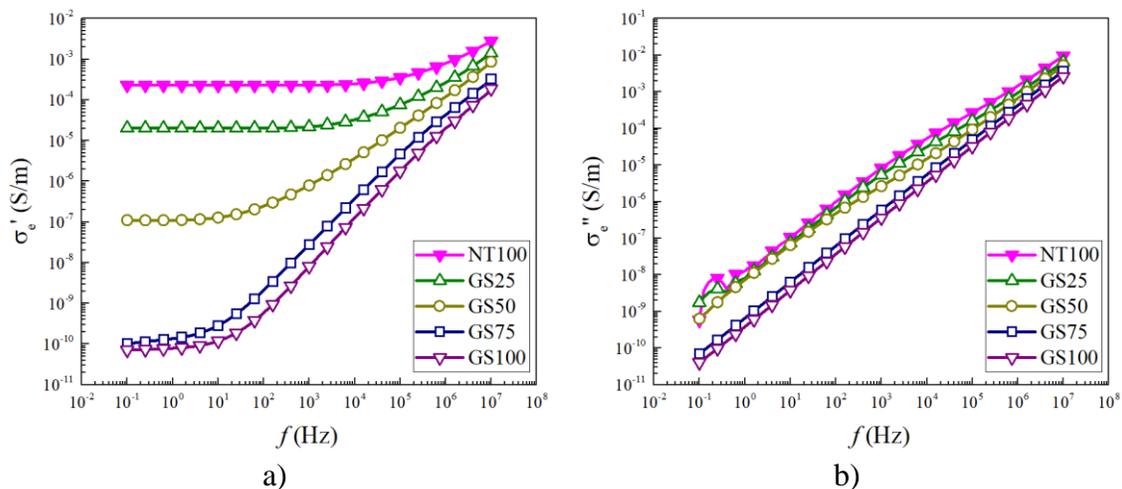

Fig. 4. Measured electrical conductivity of the films (data points) and models (Eq. (4), continuous lines), defining the synergistic and collaborative zones.

3.3. Electrical properties in alternating current

Figure 5 shows the real (σ_e' , Fig. 5a) and imaginary (σ_e'' , Fig. 5b) components of the AC electrical conductivity of the nanocomposites as a function of AC frequency (f). As seen from Fig. 5a, the hybrid nanocomposites have a higher conductivity (σ_e') as the relative concentration of MWCNTs with respect to that of MLGS increases, with the maximum conductivity for nanocomposites with only MWCNTs (NT100) and minimum for GS100. This is consistent with the results of the DC electrical conductivity shown in Fig. 4. For all nanocomposites, σ_e' remains constant (resistive-like behavior) at low frequencies and increases linearly at higher frequencies (capacitive-like behavior), leveling off as f approaches $\sim 10^7$ Hz. The critical frequency (f_c) at which the trend of σ_e' changes (from resistive to capacitive), varies depending on the MLGS/MWCNT ratio, Φ_R . For the imaginary component (σ_e'' , Fig. 5b), a linear increase of σ_e'' as a function of f is seen for all materials investigated. NT100, GS25 and GS50 have a σ_e'' of approximately one order of

1
 2
 3 magnitude higher than that of GS75 and GS100, with particularly important differences for
 4
 5 frequencies below 10^4 Hz. The increase of σ_e'' with increased f indicates an important
 6
 7 capacitive contribution in the impedance of the nanocomposite, see e.g. [43,44]. Since σ_e''
 8
 9 correlates with the difficulty for charge carriers to respond to rapid changes in the applied
 10
 11 electric field, this can be related to an interfacial polarization which occurs in the
 12
 13 nanocomposites when an AC electric field is applied [45,46]. Figure 5c shows the critical
 14
 15 frequency (f_c) as a function of Φ_R . Herein, f_c was calculated as the intersection of two straight
 16
 17 lines corresponding to the slopes of each linear zone, as depicted in the inset of Fig. 5c. From
 18
 19 Fig. 5c, it is observed that the highest critical frequency ($f_c = 166$ kHz) corresponds to
 20
 21 NT100, while the lowest ones (6.5–8.7 Hz) correspond to G100 and G75 nanocomposites.
 22
 23 GS50 presents an average $f_c = 789$ Hz with relatively large dispersion in the measured values
 24
 25 among replicates (standard deviation), marking a transition between the **dominance** of
 26
 27 MWCNTs and MLGSs. The higher data scattering for this nanocomposite is believed to be
 28
 29 due to the random filler dispersion in the nanocomposites, their 50:50 hybrid constitution,
 30
 31 and the increased structure-property (dispersion-conductivity sensitivity) relationship of this
 32
 33 50:50 hybrid network, since it is in the vicinity of electrical percolation.
 34
 35
 36
 37
 38
 39

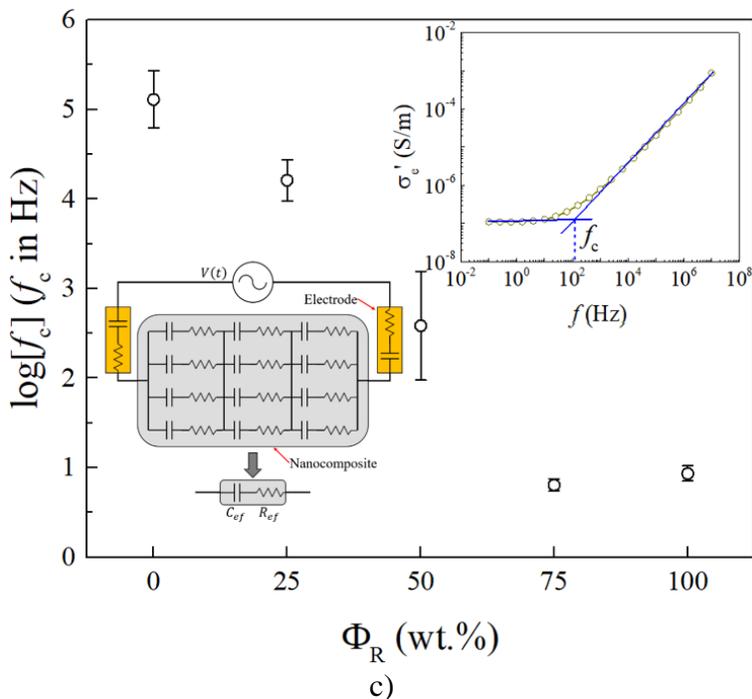

Fig. 5. AC electrical response of the investigated materials. a) Real part of the electrical conductivity (σ_e'), b) Imaginary part of the electrical conductivity (σ_e''), c) critical frequency (f_c).

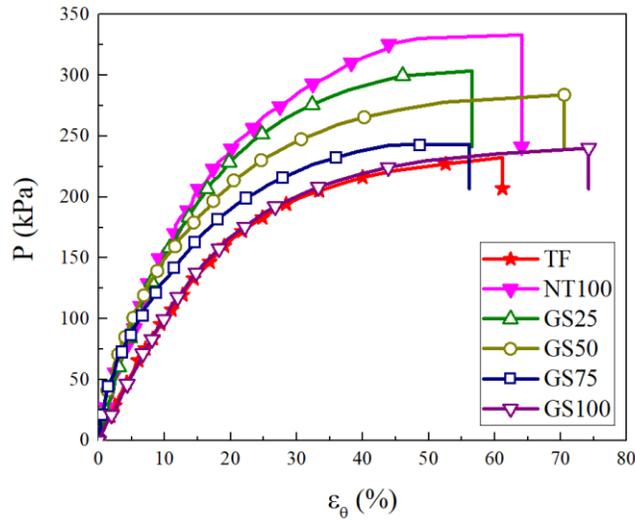

It is known that the electrical properties of nanocomposites with carbon nanostructures (MWCNTs or MLGSs) can be frequency-dependent [47,48]. The enormous difference in electrical conductivity between the carbon nanostructures and the polymer matrix can lead to a large charge accumulation at the filler/matrix interface above a certain frequency. This accumulated charge is proportional to the difference in conductivities, shifting the electrical response at a given frequency. This mechanism is described as a Maxwell-Wagner-Sillars (MWS) interfacial polarization, and accordingly, Xia et al. have proposed that the graphene/polymer interface can behave as a nanocapacitor [48]. The inset in Fig. 5c shows a schematic representation of the model proposed by Xia et al. [48], where the nanocomposite effective resistance (R_{ef}) and capacitance (C_{ef}) comes from a series-parallel combination of distributed resistance-capacitance elements. It is expected that the MWS effect becomes more important as f increases. Increased frequency provide more energy to the charge carriers

1
2
3 to hop through the nanostructure/polymer interface, rendering higher conductivity [48]. The
4
5 switch between the resistive-like behavior to the capacitive one will occur when the interface
6
7 of these nanocapacitors slows down (or blocks) the charge motion across it. The actual
8
9 frequency where this occurs (f_c), will depend on the type of nanostructure/polymer interfaces,
10
11 filler concentration, dispersion state, particle morphology and mismatch in conductivities. In
12
13 this case, there are one or two electro-conductive nanostructures within the insulating TF
14
15 polymer, each one with different state of dispersion and morphology (see Fig. 2). Therefore,
16
17 it is expected that different interfaces are formed between each of the nanocomposites
18
19 examined, which explains the different contribution of the interfacial polarization to σ_e' , and
20
21 the shift of f_c as a function of Φ_R observed in Fig. 5c. Given the higher surface area of MLGSs
22
23 compared to that of MWCNTs (see Table S1 of the supplementary information), MLGSs
24
25 further promote the conditions for the MWS effect to occur. This may explain the decrease
26
27 in f_c with increased MLGS content observed in Fig. 5c.
28
29
30
31
32

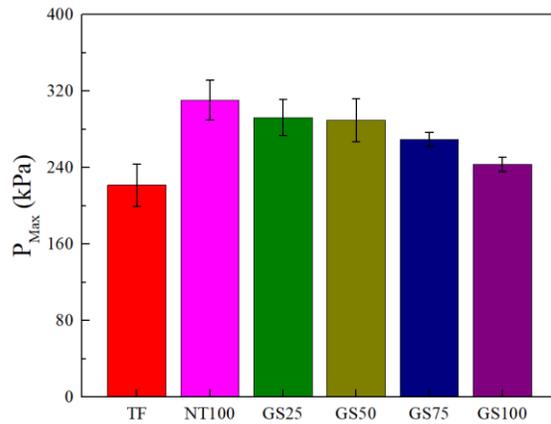

33 *3.4. Mechanical and piezoresistivity properties of the nanocomposite tubes*

34
35 Figure 6 summarizes the mechanical response of nanocomposite tubes under internal
36
37 pressure. The pressure (P) - circumferential strain (ε_θ) response in Fig. 6a is rather linear
38
39 below ~ 150 kPa. Above this pressure, the curve acquires a nonlinear response until tube
40
41 bursting at a pressure P_{Max} , which is summarized in Fig. 6b. The average burst pressure
42
43 (P_{Max}) increases with the inclusion of any of the nanostructures with respect to that of the
44
45 TF tubes ($P_{Max} = 222$ kPa), being higher (311 kPa) for composites with only MWCNTs
46
47 (NT100). For hybrid nanocomposites, the burst pressure decreases as the concentration of
48
49 MLGSs increases. As for the elastic response, it is seen in Fig. 6c that the average compliance
50
51 (C) of the TF (9.88×10^{-4} kPa $^{-1} \approx 1.32 \times 10^{-2}$ %/mmHg) decreases with the inclusion of any
52
53
54
55
56
57
58
59
60

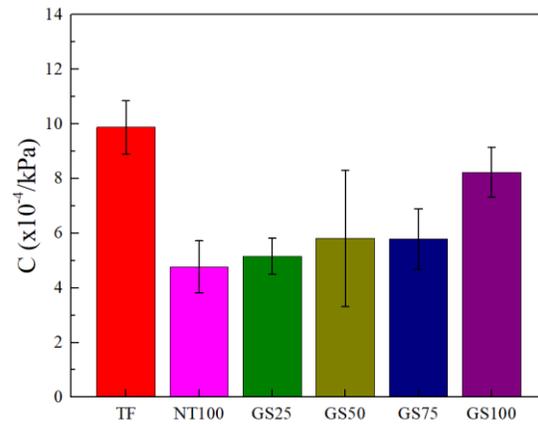

carbon nanostructure, also achieving the stiffest composite for NT100 ($C = 4.77 \times 10^{-4} \text{ kPa}^{-1}$
 $\approx 0.64 \times 10^{-2} \text{ \%/mmHg}$).

a)

b)

c)

Fig. 6. Mechanical properties of the nanocomposite tubes. a) Pressure-circumferential strain response, b) burst pressure (P_{Max}), c) compliance (C).

The DIC strain fields (ε_x , ε_y , ε_z) of a representative (GS75) tube under internal pressure, at pressures of 75 kPa and 150 kPa are shown in Fig. 7. Since distinctive features were not observed for other nanocomposite tubes, strain fields of other selected nanocomposite tubes and the neat polymer are shown in Fig. S9 of section S6 in the supplementary information. Also, a video showing the DIC strain fields and failure of a tube is included in the supplementary information. Theory of elasticity indicates that the longitudinal strain (ε_x) of

1
2
3 a linear-elastic hollow cylinder with restricted ends (as in this case) subjected to internal
4 pressure is uniform [49], which is consistent with what is observed in the DIC images for ε_x .
5
6 In addition, this was further confirmed with a finite element analysis (FEA) describe in
7 section S6 of the supplementary information. However, localized strain gradients up to 3%
8 are observed, which are attributed to stress/strain concentrations and the elastomeric nature
9 of the TF [50]. This becomes more evident as the pressure increases, since the elastomeric
10 tubes are prone to bend laterally at higher pressures (which is not considered in the theory of
11 elasticity). In the case of ε_y , theory of elasticity [49] and FEA (Fig. S10 of the supplementary
12 information) indicates that ε_y is maximum at the zenith ($y = 0, z = \pm r$, where r is the tube
13 radius, see Fig. 1), decreasing symmetrically as z approaches the azimuth or horizontal plane
14 ($y = r, z = 0$). For ε_z , theory of elasticity and FEA (Fig. S10) predicts the maximum at the
15 azimuth ($y = r, z = 0$), while for the zenith ($y = 0, z = \pm r$) the strain is minimum. The
16 combination of these three strain fields (transformed to hoop and radial) under internal tube
17 pressure cause the pressure-strain response observed in Fig. 6a. Overall, the strain fields
18 predicted by theory of elasticity and by FEA (see Fig. S10) are in reasonable agreement with
19 those measured by DIC in Fig. 7, but the measurements show localized strain gradients. This
20 is because TF is not a linear elastic material, but rather an hyperelastic one, with large
21 nonlinear deformation capabilities [13,50]. The gradients in the strain fields can also be
22 influenced by the state of dispersion and distribution of the nanostructures within the
23 nanocomposites (see Fig. 2 and 3). Imperfect adhesion between the tube layers may also be
24 a contributing factor.

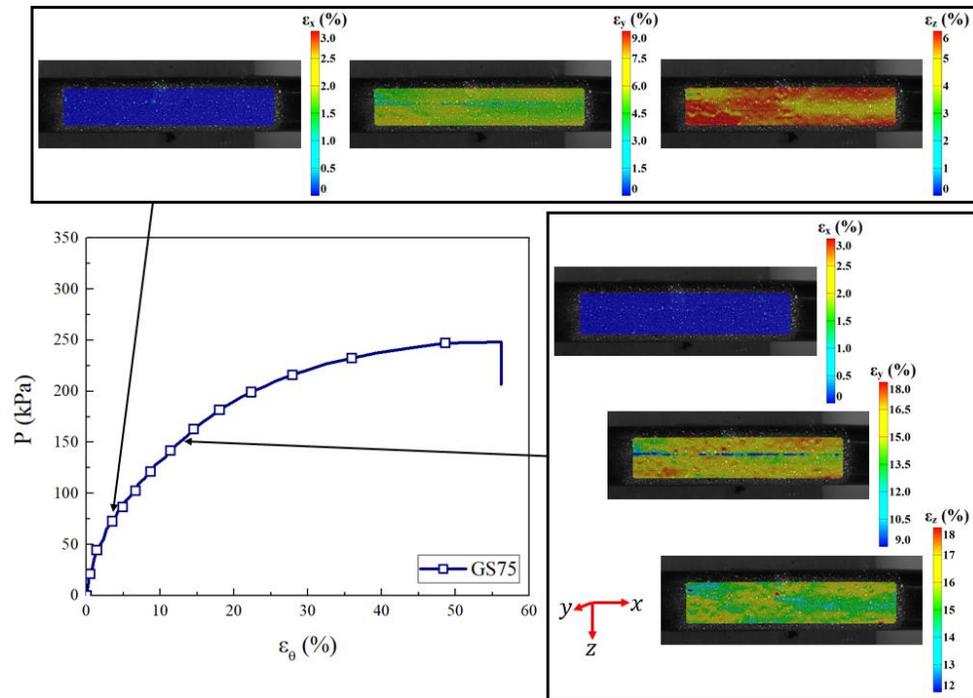

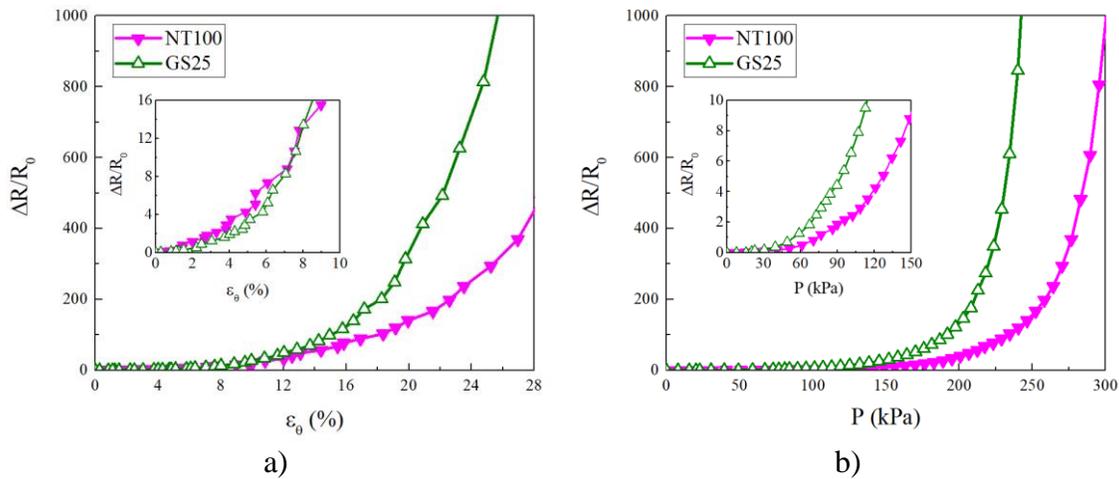

Fig. 7. DIC strain fields of a representative GS75 nanocomposite tube.

Figure 8 shows the piezoresistive response of the NT100 and GS25 tubes subjected to internal pressure. The rest of the tubes (GS50, GS75 and GS100) were not characterized because of their high resistivity. The curves of fractional change of electrical resistance ($\Delta R/R_0$) are presented as a function of the circumferential strain (ε_θ) in Fig. 8a, and as a function of the internal pressure (P) in Fig. 8b. From Fig. 8a it is observed that both nanocomposites have a nonlinear behavior with ε_θ , and that GS25 has higher change in electrical resistance upon deformation. This change in electrical resistance becomes up to 1000 times for circumferential strains of $\sim 25\%$, which renders a very high piezoresistive sensitivity (Fig. 8c and 7d). The sensitivity of both tubes to pressure is relatively low at pressures below 150 kPa, with values of $\Delta R/R_0 \sim 30$ (GS25) and ~ 10 (NT100) for $P = 150$ kPa. For $P > 200$ kPa, the values of $\Delta R/R_0$ for both composites are greatly increased, with a steep change of slope. Therefore, gage factors (Fig. 8c and 7d, GF^T) and pressure sensitivity factors (Fig. 8e and 8f, PF) were calculated in two regions (as described in section 2.5), and both factors were always

1
2
3 significantly higher in the zone of higher pressures (region II). In the zone of lower pressures
4
5 (< 35 kPa, Fig. 8c), NT100 has an average gage factor of $GF^T_I = 71.0$, while GS25 presents
6
7 $GF^T_I = 89.1$. For the second zone (from 150 kPa to 200 kPa, Fig. 8d), $GF^T_{II} = 2514$ and
8
9 $GF^T_{II} = 4573$ for NT100 and GS25, respectively. Similarly, for the pressure factors, $PF_I =$
10
11 $4.84 \times 10^{-3} \text{ kPa}^{-1}$ for NT100, while $PF_I = 11.6 \times 10^{-3} \text{ kPa}^{-1}$ for GS25. For higher pressures (150–
12
13 200 kPa), $PF_{II} = 0.84 \text{ kPa}^{-1}$ for NT 100 and $PF_{II} = 4.59 \text{ kPa}^{-1}$ for GS25. Given the cylindrical
14
15 geometry of the tubes and **the internal** pressure in the burst test, the tube strain in the principal
16
17 axes are a combination of radial, circumferential (hoop), and axial (longitudinal) strain,
18
19 forming a three-dimensional state of stress [49]. Notice that GS25 also showed collaborative
20
21 effects in Fig. 4. Thus, the hybrid network formation favors the electromechanical sensitivity
22
23 of the GS25 hybrid nanocomposite in a hyperelastic tube subjected to a complex three-
24
25 dimensional state of stress/strain, triggered by internal pressure.
26
27
28
29
30

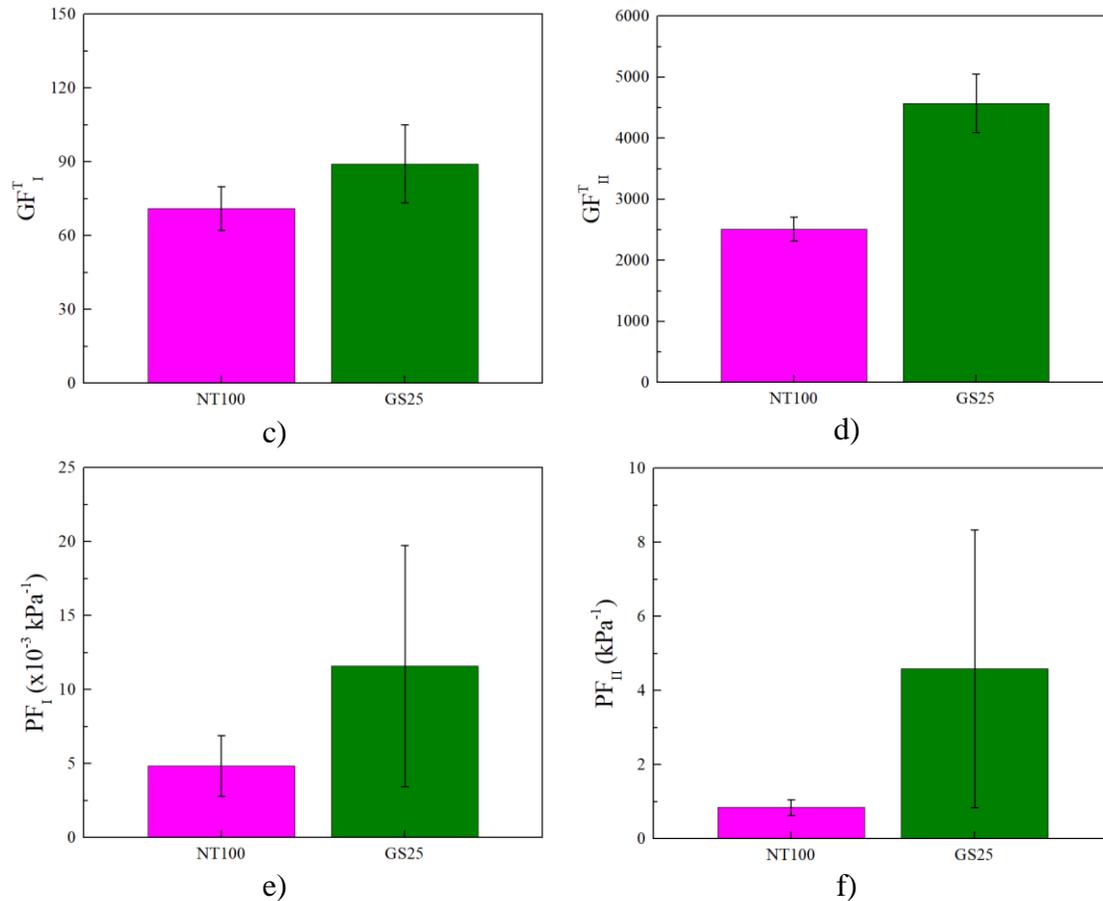

Fig. 8. Piezoresistive properties of the nanocomposite tubes NT100 and GS25.

- a) Piezoresistive response as a function of strain, b) Piezoresistive response as a function of pressure, c) gage factor in the interval $0 \leq \varepsilon_\theta \leq 5\%$ (GF_I^T), d) gage factor in the interval $15\% \leq \varepsilon_\theta \leq 20\%$ (GF_{II}^T), e) pressure factor in the interval $0 \leq P \leq 35 \text{ kPa}$ (PF_I), f) pressure factor in the interval $150 \text{ kPa} \leq P \leq 200 \text{ kPa}$ (PF_{II}).

As context for the prospective applications of these tubes, the commercial medical pressure sensor NPC-100 from NovaSensor (Fremont, USA) [51] has a pressure sensitivity (pressure factor) of $3.75 \times 10^{-5} \text{ kPa}^{-1}$ [7], which is less than that of the tubes made with the nanocomposite GS25 herein ($11.6 \times 10^{-3} \text{ kPa}^{-1}$). The cyclic response of such nanocomposite tubes would also be of great interest for developing commercial applications, since thermoplastic polyurethanes may present hysteresis in their mechanical and piezoresistive responses. The magnitude of such hysteresis depends on the rigid/flexible segment content, strain level, filler type, and concentration [52].

4. Conclusions

The electrical and piezoresistive behavior of a segmented aliphatic polyurethane (Tecoflex, TF) modified with multilayer graphene sheets (MLGSs), multiwall carbon nanotubes (MWCNTs), and a hybrid combination of both were investigated, using coupons in geometry of planar films and tubes. The logarithm of the DC electrical conductivity of the nanocomposite films presented a sigmoidal (Boltzmann) function with the relative concentration of MLGSs (Φ_R), with highest conductivity for the composites with only MWCNTs and the lowest one for those with only MLGSs. It was found that the measured DC conductivities of the hybrid films are contained within an area bounded by the predictions of the series and parallel semi-empirical models proposed herein, which are calibrated with measured data for composites with only MLGSs and MWCNTs. Hybrid nanocomposite films with 25 wt.% of MLGSs and 75 wt.% of MWCNTs ($\Phi_R = 25$ wt.%, GS25) showed collaborative interactions, with an electrical conductivity higher than that of composites with the same amount of MWCNTs or MLGSs. Correlations with microscopic observations suggest that the elongated one-dimensional morphology and lower excluded volume of the MWCNTs with respect to MLGSs yields a more dispersed network for MWCNT composites. However, in this material system, the inclusion of **small amounts** of MLGSs can create **interconnected agglomerates**, which favor electrical conductivity. Dielectric spectroscopy showed a dependence of the AC electrical conductivity with frequency, which evidences a capacitive response at high frequencies; the onset frequency where capacitive effects significantly influence the impedance of the hybrid composites depends on the relative concentration of MLGSs, and occurs at lower frequencies as the relative concentration of MLGSs increases. Thus, the presence of MLGSs favors capacitive effects, which was

1
2
3 explained by the Maxwell-Wagner-Sillars interfacial polarization mechanism and the larger
4 surface area of the MLGSs over that of the MWCNTs.
5

6
7 The mechanical response of nanocomposite tubes subjected to internal pressure showed that
8 the burst pressure and tube compliance also depend on the relative concentration of MLGSs.
9
10 Tubes made of any of the nanocomposite films were much stiffer than those made of neat
11 TF, by factors between 1.2 and 2.1 times. Composite tubes containing only MWCNTs
12 showed the highest reinforcement effect (burst pressure and stiffness), once again due to the
13 higher aspect ratio and one-dimensional character of the nanotubes. Full field strain fields of
14 the pressurized tubes measured by digital image correlation indicated that the strain fields
15 predicted by elasticity theory (and finite element analysis) are disturbed by localized strain
16 gradients in this kind of elastomeric materials. The piezoresistive response of the
17 nanocomposite tubes was nonlinear with a high piezoresistive sensitivity, especially for
18 pressures greater than 60 kPa. The hybrid nanocomposites with $\Phi_R = 25$ wt.% (GS25)
19 presented the highest sensitivity (pressure factor), being this 4.59 kPa^{-1} in the range of 150
20 to 200 kPa. The results indicate that elastomeric tubes fabricated with these nanocomposites
21 could be used as smart materials in vast applications such as medicine, flexible robotics, and
22 aerospace (astronaut) suits.
