Keywords: Antiferroelectric, Energy storage, Lead zirconate, Sol-gel deposition, Titanium seed layer.

Abstract - Enhancement of lead zirconate (PbZrO₃) polarization is achieved by using a titanium seed layer on alumina polycrystalline substrate. Thanks to the reduction of the lattice mismatch between the platinum electrode (3.92 Å) and the PbZrO₃ films (4.14 Å), lead zirconate thin films oriented along the (111) direction with an orientation factor of around 65 % has been obtained. The (111) PbZrO₃ presents an increase of 56% of the polarization compared to the (100) PbZrO₃. This enhancement is responsible of the higher recoverable energy storage density obtained in the (111) PbZrO₃ thin films (8 J/cm³ at 600 kV/cm with an efficiency of 72%). The (111) PbZrO₃ also has a higher figure of merit, which indicates that the (111) crystallographic plan is the most favorable direction for energy storage.

Introduction

The study of thin film capacitor for energy storage application is receiving more and more attention due to the growing demand for autonomous and wireless sensors[1],[2]. Advantages of thin film capacitors are a high energy density with a low footprint [3],[4] and the security of the device since it is entirely solid [5]. Among the dielectric materials, antiferroelectric PbZrO₃ thin films are the most widely used for energy storage applications due to their low remnant polarization, high dielectric breakdown and large saturation polarization.

Previous works on single crystal substrates show the influence of a thin titanium seed layer (< 5 nm) on the crystallographic orientation of PbZrO₃ thin films [6],[7]. This allows us controlling the dipole orientation and hence the material's dielectric properties. In this study, the lead zirconate crystallographic orientation is optimized while using an alumina polycrystalline substrate. This optimization should lead to a significant

reduction of the production cost since monocrystalline substrates represent an important part of the device price.

Experimental procedure

The PbZrO_3 thin films are prepared by a sol-gel process. Lead acetate trihydrate $[\text{Pb}(\text{CH}_3\text{CO}_2)_2 \cdot 3\text{H}_2\text{O}]$ with 10% molar excess is dissolved in deionized water and acetic acid. An excess of lead is used in order to compensate the loss during the annealing treatment due to the formation of the volatile PbO [8]. Zirconium isopropoxide $[\text{Zr}(\text{O}(\text{CH}_2)_2\text{CH}_3)_4]$ is then added to the solution. In addition, Ethylene glycol $[\text{HO}-\text{CH}_2-\text{CH}_2\text{OH}]$ is used to reduce the appearance of cracks [9] in the film and improves the solution stability [10]. The concentration of the final solution is 0.5 M. The precursor solution is then deposited on a polished alumina substrate precoated with a 40 nm titanium adhesion layer and a 300 nm platinum bottom layer done by magnetron sputtering. Twelve layers have been deposited at 4000 rpm during 25 s by a multi-step spin coating process and each layer is annealed during 10 min in a pre-heated open air furnace at 650°C . The overall films thickness is 800 nm. Square platinum electrodes of 0.5 mm broad are deposited by RF magnetron sputtering in order to realize a Metal-Insulator-Metal capacitor. To study the influence of a titanium seed layer on the crystallographic orientation of the PbZrO_3 layers, 1 nm, 2 nm and 3 nm of titanium are deposited by sputtering before the PbZrO_3 layers (Fig. 1). The thickness of titanium is calculated according to the deposition rate of the sputtering process.

The cross-sectional morphology of the films is examined with a *Jeol 7600* scanning electron microscope (SEM). The structure and phase purity of the films are analyzed using a *Bruker D8X*- ray diffractometer (XRD) with $\text{CuK}\alpha$ radiation. The polarization versus electric field ($P-E$) hysteresis loops are measured at 1 kHz using a classical Sawyer Tower circuit and the energy storage performance is calculated according to the ($P-E$) results. The current - electric field hysteresis loops are obtained thanks to a modified Sawyer Tower circuit by replacing the sense capacitor by a resistor of 100 Ω . The capacitance and the dielectric losses ($\tan \delta$) are measured with an *Agilent 4294A*, the relative permittivity of each sample is calculated from the measured capacitance.

Fig. 1. Schematic diagram of the MIM capacitors for the different structures

Results and discussion

A. Structural properties

The X-ray diffraction patterns of the PbZrO₃ thin films are shown in Fig. 2 with the indices of the pseudocubic perovskite structure. All samples are well crystallized and no parasitic pyrochlore phase is found.

The orientation factor (α_{hkl}) can be calculated for each peak thanks to the following equation [11],[12] :

$$\alpha_{hkl} = \frac{I_{hkl}}{I_{total}} \times 100, \quad (1)$$

where I_{hkl} corresponds to the peak intensity of the selected plane and I_{total} is the sum of all diffraction peaks.

Fig 2. X-ray diffraction patterns of the lead zirconate thin films with different thickness of titanium seed layer

The sample with no titanium seed layer (Ti: 0 nm) is oriented along the (100) crystallographic plane at around 99 % which is similar to what is obtained when single crystal substrate is used [6]. This orientation on smooth polycrystalline alumina substrate is due to a most thermodynamically favorable growth direction [13],[14] on a lowest surface energy [7]. Contrary to this sample, a (111) preferential orientation is obtained at 65 % when introducing 2 nm of Ti seed layer, which is in agreement with the work of Murali *et al.* [6]. During the crystallization, the titanium seed layer forms an intermetallic (Pt_3Ti) layer with the platinum bottom electrode [7],[15], reducing the lattice mismatch between the Pt electrode (3.92 Å) and the PbZrO_3 films (4.14 Å). This intermetallic layer facilitates the PbZrO_3 growth in the (111) crystallographic direction on the highly (111) oriented platinum bottom electrode. However, when using 1 nm and 3 nm of Ti seed layer, less oriented materials are obtained (at 37 % and 58.5 % respectively).

In order to compare the orientation degree of the lead zirconate films, the diffraction intensity ratios have been calculated using the main planes (111), (110) and (100) (Fig. 3). The I_{111}/I_{100} ratio shows that the maximum orientation along (111) is obtained with 2 nm of Ti which corresponds to what we observed in the XRD pattern. This ratio is closed to zero for the sample with no seed layer due to the highly (100) oriented PbZrO_3 . A similar evolution is observed for the I_{110}/I_{100} ratio, which shows that the use of the titanium seed layer also promotes a slightly growth of the (110) PbZrO_3 plane, but the texture in this orientation is less

pronounced compared to the (111) direction. Therefore, the evolution of the I_{111}/I_{110} ratio is quite stable, indicating a constant growth of the (111) texture in relation to the (110) plane.

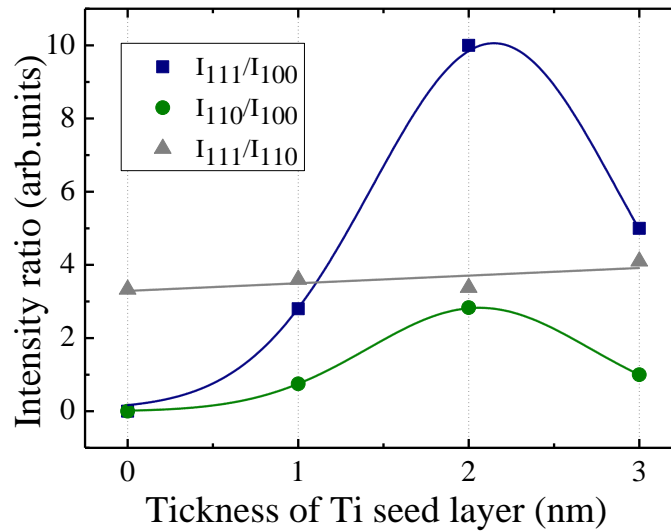

Fig. 3. Evolution of the diffraction intensity ratios as a function of the Ti seed layer thickness

Fig.4 shows cross-sectional SEM morphology of the (100) and (111) oriented lead zirconate. Both samples have a similar columnar like structure and all films are uniform and crack-free. Due to the multicoating deposition process of the PbZrO_3 , layer interfaces could clearly be observed. In the (111) PbZrO_3 , the Ti seed layer cannot be seen because of the formation of the thin intermetallic Pt_3Ti layer during the crystallization. The thickness of the film and of one layer is respectively 800 nm and 70 nm for all samples.

Fig. 4. Cross-sectional SEM morphology of (100) and (111) PbZrO₃

B. Dielectric properties

Polarization loops of the lead zirconate thin films at 600 kV/cm are shown in the Fig.5. All films have developed double hysteresis loops, indicating their antiferroelectric nature. The sample which is oriented along the (111) direction (Ti: 2 nm) has the higher maximum polarization ($36 \mu\text{C}/\text{cm}^2$) while the (100) PbZrO₃ (Ti: 0 nm) has the lowest polarization ($23 \mu\text{C}/\text{cm}^2$) at 600 kV/cm. For the less oriented materials, Ti: 1 nm and Ti: 3 nm, intermediate values are obtained of $31 \mu\text{C}/\text{cm}^2$ and $32 \mu\text{C}/\text{cm}^2$ respectively. These results can be explained by the modification of the polar axis orientation. For PbZrO₃ thin films with a (111) orientation, the angle between the applied electric field and the [111] polar axis (\vec{P}_{FE}) of the ferroelectric rhombohedral phase is lower compared to the (100) PbZrO₃ [7],[16] (Fig. 6). Thus, for the (111) PbZrO₃ films the energy necessary to align the dipoles in the direction of the electric field is smaller compared to the (100) PbZrO₃. Therefore, more the orientation factor along the (111) direction is high, more the polarization is important. The polar direction (\vec{P}_{AFE}) of the antiferroelectric tetragonal cell which is along the [110] axis has less effect on the dielectric properties of the material because in this state the elementary dipoles are anti-parallel [17].

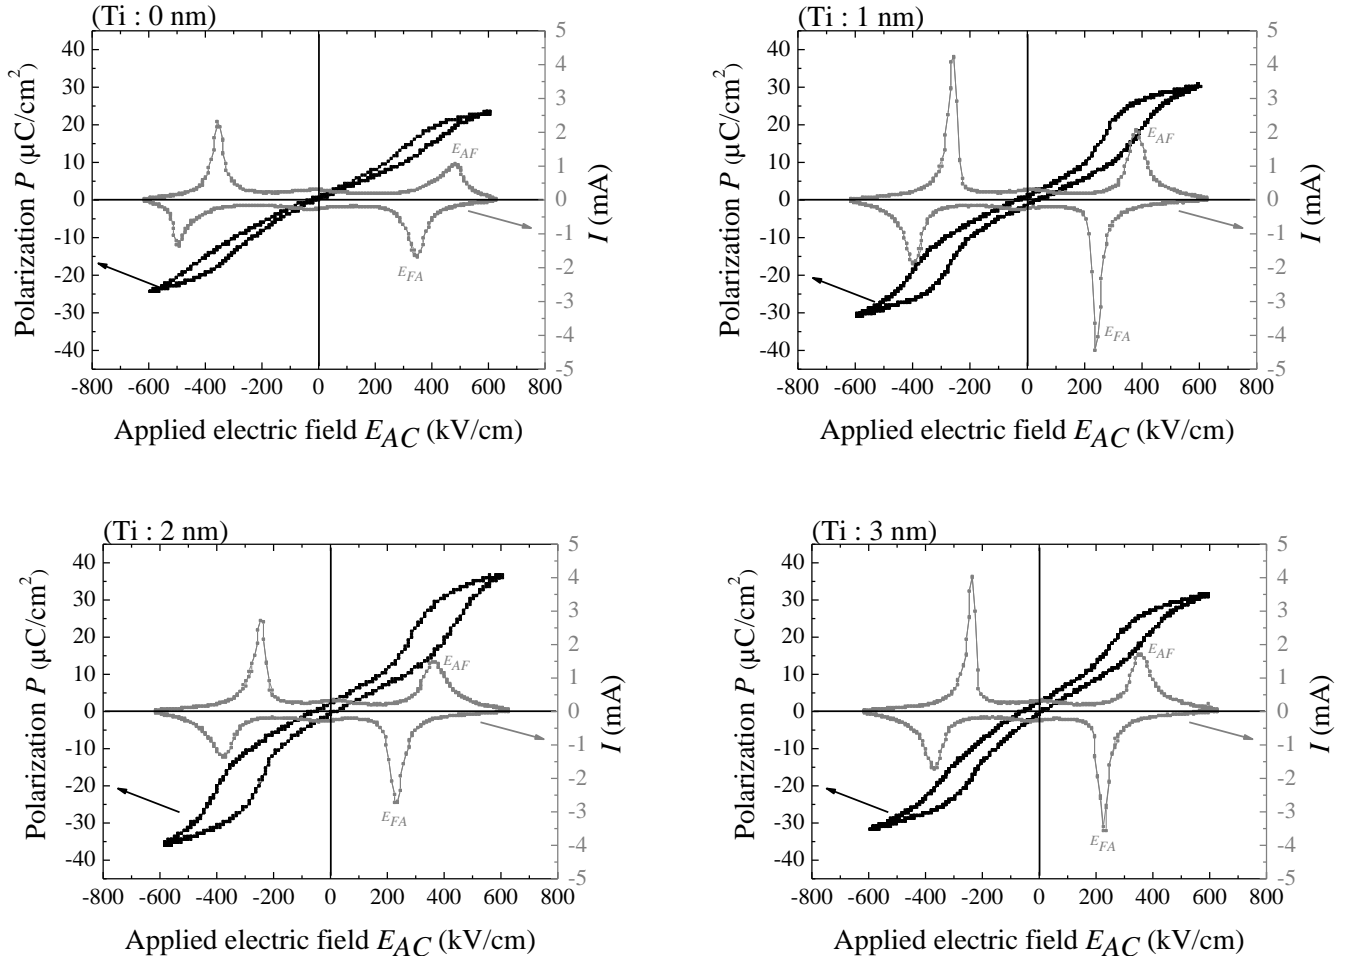

Fig. 5. Polarization and current – electric hysteresis loops of the lead zirconate thin films as function of Ti seed layer thickness at 1kHz. E_{AF} and E_{FA} are the transitions fields.

The current – electric field (Fig.5) loops obtained show the same evolution than polarization loops. The (111) PbZrO_3 (Ti: 2 nm) has the lowest antiferroelectric-ferroelectric field transition ($E_{AF} = 350$ kV/cm) and the (100) PbZrO_3 has the highest one ($E_{AF} = 490$ kV/cm). The ferroelectric-antiferroelectric fields transitions (E_{FA}) are also influenced by the crystallographic orientation of the material, it is induced by the reduction of the angle between the applied electric field and the ferroelectric polar axis (\vec{P}_{FE}). As a result, the (111) lead zirconate is easier to polarize compared to the (100) PbZrO_3 . For the same reason, the (111) PbZrO_3 has a lower ferroelectric-antiferroelectric transition field ($E_{FA} = 230$ kV/cm) than the (100) PbZrO_3 ($E_{FA} = 350$ kV/cm).

Fig. 6. Schematic diagram of the primitive cells for the (100) and (111) oriented PbZrO_3

Polarization is important for energy storage performances as the recoverable energy density (W) stored in the capacitor can be calculated from the discharge branch of the polarization loop (Fig.7) by [18]:

$$W = \int_0^{P_{sat}} E dP \quad (2)$$

The energy storage efficiency (η) can be obtained by considering the energy consumed (W_L) during the discharge [18]:

$$\eta = \frac{W}{W + W_L} \quad (3)$$

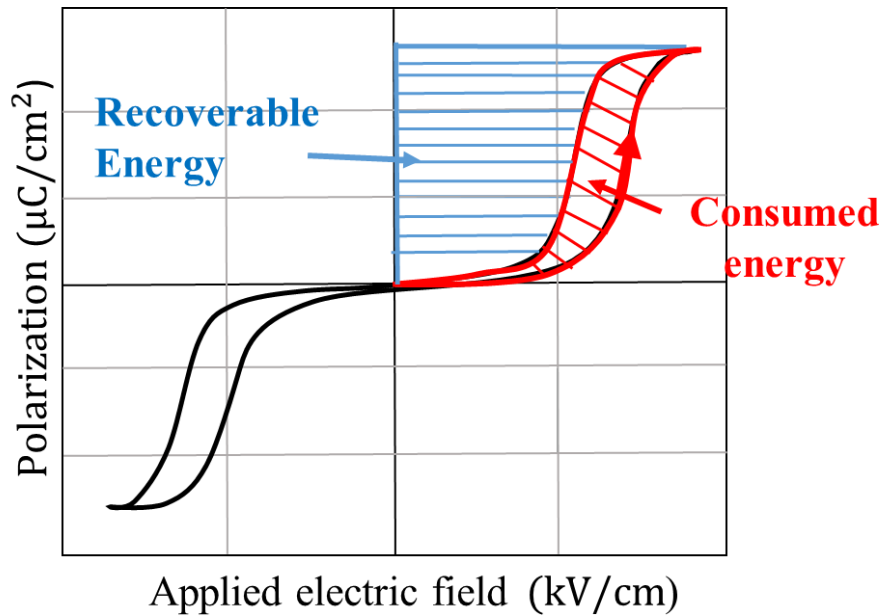

Fig.7. Schematic presentation of the stored energy in an antiferroelectric polarization cycle

The recoverable energy stored is higher for the (111) PbZrO_3 (Ti: 2 nm), which is in accord with the higher polarization of the (111) PbZrO_3 (Fig.8). Due to low polarization, the (100) PbZrO_3 (Ti: 0 nm) and less oriented materials have lower energy densities. A high polarization is necessary to obtain a large energy stored.

The (111) PbZrO_3 presents a recoverable energy density of ($8 \text{ J}/\text{cm}^3$) with an efficiency of 72 %, which is similar to what is reported in (111) PbZrO_3 [3] deposited on SrTiO_3 single crystal. This shows that the use of a single crystal substrate is not mandatory for the development of an energy storage device and can be replaced by a low cost alumina polycrystalline substrate without damaging its properties.

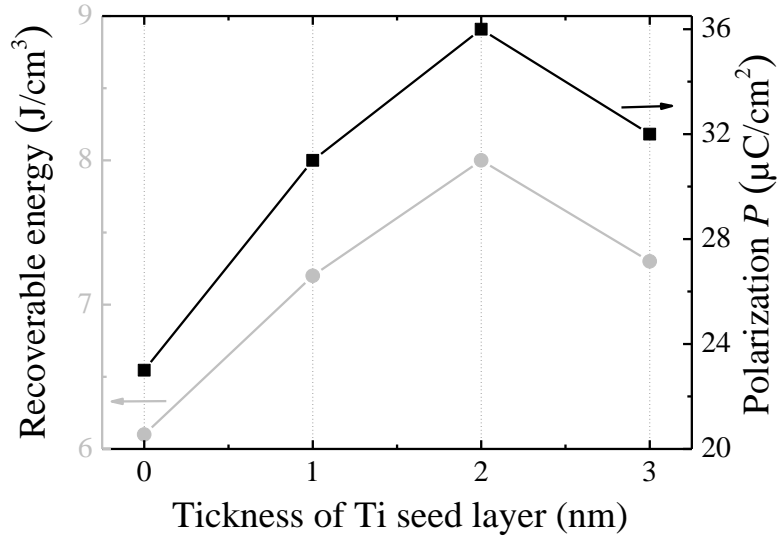

Fig.8. Recoverable energy stored and the polarization as function of the titanium seed layer thickness at 600 kV/cm.

On the other hand, the (100) PbZrO_3 ($\eta = 82\%$) has a higher efficiency compared to the (100) PbZrO_3 ($\eta = 72\%$). This higher efficiency is related to its slimmer polarization loop, which is characteristic of a material with low dielectric losses.

In order to determine which of the crystallographic orientations is the most favorable for energy storage, a figure of merit (F.O.M.) is calculated [4].

$$F.O.M = W \times \eta \quad (4)$$

A F.O.M. of 5.75 J/cm^3 is obtained for the (111) PbZrO_3 (Ti: 2 nm), while the (100) PbZrO_3 has a F.O.M. of 5 J/cm^3 . This shows that the (111) crystallographic plan is the most favorable direction for energy storage.

The real part of relative permittivity and dielectric losses of the PbZrO_3 films as a function of frequency are presented in Fig. 9. The (111) PbZrO_3 (Ti: 2 nm) has the higher relative permittivity ($\epsilon_r' \approx 155$ at 1 kHz) while the (100) PbZrO_3 (Ti: 0 nm) has the lowest value ($\epsilon_r' \approx 137$ at 1 kHz). The high permittivity observed in (111) PbZrO_3 can be explained by the easy rotation and incline of domain and polar vectors in this texture due to a highly c -axis material [19]. Zhao et al. [11] have reported a same evolution in lead zirconate antiferroelectric films.

All samples have low dielectric losses ($\tan \delta < 0.02$). Nevertheless, dielectric losses are slightly higher for samples using a Ti seed layer, which explains their lower efficiencies. This phenomenon is related to the oxidation of the Ti seed layer, which induces a raise of the dielectric losses. Indeed, titanium has a poor oxidation stability [20],[14] in the crystallization conditions of lead zirconate ($\approx 650^\circ\text{C}$) and induces the generation of oxygen vacancies in the lead zirconate structure. In previous research [3] the same behavior was noticeable in (111) PbZrO_3 deposited on (111) SrTiO_3 single crystal.

Fig. 9. Real part of relative permittivity and dielectric losses as a function of frequency of the lead zirconate thin films for different Ti seed layer thickness

Conclusion

Optimization of lead zirconate (PbZrO_3) polarization by using titanium seed layer has been investigated. Thanks to the reduction of the lattice mismatch between the platinum electrode (3.92 \AA) and the PbZrO_3 films (4.14 \AA), lead zirconate thin films oriented along the (111) direction on an alumina polycrystalline substrate has been grown. The sample with 2 nm of titanium seed layer presents an orientation factor of around 65 % along the (111) plane, which shows that the modification of lead zirconate crystallographic orientation is possible even when using a polycrystalline substrate. This optimization leads to the control of the PbZrO_3 crystallographic growth without having recourse of an expensive monocrystalline substrate which is an important achievement in order to optimize dielectric and energy storage properties in a low cost way.

The (111) PbZrO_3 has a higher maximum polarization ($36 \mu\text{C}/\text{cm}^2$) compared to the (100) PbZrO_3 saturation polarization ($23 \mu\text{C}/\text{cm}^2$) at $600 \text{ kV}/\text{cm}$. These results can be explained by the modification of the polar axis orientation when the crystallographic orientation is modified. When the PbZrO_3 has a (111) orientation, the angle between the applied electric field and the [111] polar axis of the ferroelectric rhombohedral phase is lower compared to the (100) PbZrO_3 . Enhancement of the polarization also contributes to the amelioration of the energy storage performances. The recoverable energy density ($8 \text{ J}/\text{cm}^3$) obtained for the (111) PbZrO_3 is higher than the (100) PbZrO_3 density ($6 \text{ J}/\text{cm}^3$), which indicates that (111) crystallographic orientation is more suitable for an energy storage application. The calculation of F.O.M confirms this result. Nevertheless, samples using a Ti seed layer present higher dielectric losses, which is due to the titanium weak oxidation stability in the crystallization conditions ($\approx 650^\circ\text{C}$).
