Summary (200 mots)

Secreted proteins are key players in fungal physiology and cell protection against external stressing agents and antifungals. OSIP1 is a fungal-specific protein with unknown function. By using *Podospora anserina* and *Phanerochaete chrysosporium* as models, we combined both *in vivo* functional approaches and biophysical characterization of OSIP1 recombinant protein. Our data showed an increased sensitivity of the *P. anserina OSIP1^A* mutant to both caspofungin and oak-extractives. This correlated with the weakened extracellular matrix produced by the mutant compared to the wild type, as highlighted by SEM imaging. This alteration quantitatively modified the global secretome of *P. anserina* grown in presence of wood, such as proteins associated to the cell-wall integrity signaling pathway. Since the recombinant OSIP1 form *P. chrysosporium* self-assembled as fibers and was capable of gelation, these results argue for a structural role of OSIP1 proteins in fungi at the cell wall or within the matrix confering cell protection against external toxic compounds. These data could be of great interest for increasing protein secretion in a context of lignocellulosic biomass degradation, such as improving the efficiency of antifungals that could be trapped within the extracellular matrix.

Introduction

During evolution, fungi had to adapt to environmental constraints. The secretome, *i.e.* the proteins secreted in the extracellular medium, is a good marker of fungal physiology and trophic modes. Indeed, the secretome is involved in the first steps of the symbiosis or infection establishment and plays essential roles in plant biomass degradation (Kämper *et al.*, 2006; Bouws *et al.*, 2008; Vincent *et al.*, 2012). Fungal secretomes are composed of degradative enzymes such as proteases, lipases, Carbohydrate-Active enZymes (CAZymes), and ligninolytic enzymes for some wood-decaying species (Zhu *et al.*, 2016; Pellegrin *et al.*, 2015). This degradative system has been intensively studied due to its important application in lignocellulose biomass valorization. In plant-associated fungi, other proteins can be secreted to modulate plant immunity and establish symbiosis or allow pathogenic infection (Plett *et al.*, 2011; Pazzagli *et al.*, 1999; Frias *et al.*, 2011; Baccelli *et al.*, 2014). Some of them, the hydrophobins, are involved in the attachment of fungal structures to different kinds of surfaces and the development of hyphae at the water/air interface (Wessels *et al.*, 1991; Wessels, 1996). In fungal pathogens, hydrophobins might act as virulence factors to enhance fungal infection (Ruocco *et al.*, 2015; Kubicek *et al.*, 2008), while in symbiotic associations, these proteins could be involved in mycorrhizae formation (Plett *et al.*, 2012). Most of the studied hydrophobins are directed to the extracellular medium through the secretory pathway. However, they often remain associated with the fungal cell wall and can be found inside fruiting bodies and on the surfaces of hyphae, spores and conidia (Dynesen *et al.*, 2003; Linder, 2009). Many other secreted proteins have been identified but remain of unknown function. This is the case for SSP (for Small Secreted Proteins with sequence less than 300 amino acids) (Alfaro *et al.*, 2014). The percentage of SSP-coding genes in the genomes of saprophytic fungi such as *Phanerochaete chrysoporium*, *Trametes versicolor* or *Aspergillus fumigatus* is similar to the one of the ectomycorrhizal fungus *Laccaria bicolor* (between 2 and

3

70 3 % of the predicted gene models) (Pellegrin *et al*., 2015; Valette *et al*., 2016). At the protein

71 level, SSPs represent between 4 and 12% of the proteins identified in the secretomes of

72 various *Aspergillus* species grown on sugar beet pulp or wheat bran (Valette *et al*., 2016).

73 However, only few have been functionally characterized. One SSP of the lignolytic fungus

74 *Pleurotus ostreatus* is involved in the regulation of the lignolytic system by modulating

75 expression and activity of aryl-alcohol oxidases, aryl-alcohol dehydrogenases and versatile

76 peroxidases (Feldman *et al*., 2017) and in the transition from primary to secondary

77 metabolism, development, aging, and fruiting body initiation (Feldman *et al*., 2019).

78 In a previous analysis, we have highlighted the up-regulation of various SSP-coding genes of

79 the lignolytic fungus *Phanerochaete chrysosporium* in presence of oak extractives (Thuillier

80 *et al*., 2014, Fernández-González *et al*., 2018). Oak extractives are mainly composed of

81 phenolic compounds and flavonoids (Zhang *et al*., 2015; Fernández-González *et al*., 2018).

82 These molecules are released from wood during the degradative process and can be toxic for

83 cells by various mechanisms such as metal and free radical scavenging activity, direct

84 interaction with enzymes, perturbation of ionic homeostasis and disruption of membrane and

85 cell wall integrity (Valette *et al*., 2017). One of these up-regulated genes retained our attention

86 because the corresponding protein was also detected at high amount in the secretome of

87 another white rot fungus *Trametes versicolor* grown on oak wood chips (Deroy et al.,

88 unpublished). This protein was thus named OSIP1 for Oak Stress Induced Protein. It shows

89 no sequence homology with characterized proteins in the databases. In this study we used two

90 fungal models to decipher the role of OSIP1: *Podospora anserina* for functional analysis

91 because genetic engineering is easy, contrary to *P. chrysosporium* or *T. versicolor;* and *P.*

92 *chrysoporium* for the biochemical analysis because only PcOSIP1 was successfully produced

93 as a recombinant protein.

94

Results

Comparative genomic analysis reveals that OSIP1 is widespread in fungi

OSIP1 sequences from the ascomycete *P. anserina* (*PaOSIP1*: ProtID JGI 208230, a.k.a. Pa_5_3780 according to the *P. anserina* genome project) and the basidiomycete *P. chrysosporium* (*PcOSIP1:* ProtID JGI 2981896) were used as templates to search for fungal sequences using the BlastP search tool onto the whole fungal JGI database (Mycocosm from Joint Genome Institute). The sequence of *P. anserina P209725* (ProtID JGI 209725) was also used as template since it displays 38% similarity with *PaOSIP1*). A total of 1057 protein sequences were retrieved and analyzed by clustering. These sequences grouped into nine clusters (Fig. 1A). *PaOSIP1* and *PcOSIP1* belonging to cluster 1, this latter was thus named OSIP1 cluster (species and accession numbers are available in Table S1). It gathers sequences from both ascomycetes (*Pezizomycotina*) and basidiomycetes (*Agaricomycotina* and *Pucciniomycotina*). Moreover, this analysis revealed that *OSIP1* is present in genomes of wood decay fungi, and also in mycorrhizal, pathogenic fungi and other saprotrophs (Fig. 1A). Although OSIP1 was found induced by oak extractives in lignolytic fungi (Thuillier *et al.*, 2014; Deroy, unpublished), this genomic analysis showing that OSIP1 is present in fungi with various trophic modes, argues against its direct involvement in the lignolytic process and suggests a more general role in fungal physiology.

OSIP1 sequences contain a DUF3129 domain, like some appressoria-specific proteins

OSIP1 sequences exhibit a signal peptide of secretion, a conserved DUF3129 domain and a variable C-terminal tail (Fig. 1B). In ascomycetes, 8 cysteinyl residues are conserved, while only four have been detected in the analyzed basidiomycete sequences (Fig. 1B and Fig S1). The DUF3129 domain is not restricted to OSIP1 sequences. It can be identified in both ascomycetes and basidiomycetes and was retrieved in 442 sequences from the Pfam 31.0

120 database. Although most of the proteins having the DUF3129 are annotated as
121 uncharacterized proteins, some of them are described as being related to CAS1
122 (*Colletotrichum gloeosporioides* appressoria-specific protein), MAS (*Magnaporthe*
123 appressoria-specific protein), gEgh16 from *Blumeria graminis* proteins, all being putatively
124 involved in fungal cell wall remodeling. A phylogenetic analysis was performed with the
125 sequences from the OSIP1 cluster and the 442 sequences containing the DUF3129 domain
126 (Fig. 1C). PaOSIP1 clusters with ascomycete sequences but independently of CAS1 from *C.*
127 *gloeosporioides*, MAS3 from *M. grisea* and gEgh16 from *B. graminis*. Among
128 basidiomycetes, sequences from *Agaricomycotina* with lignolytic, saprotrophic or
129 mycorrhizal lifestyles (Group A) cluster independently from sequences of pathogenic
130 basidiomycetes from *Pucciniomycotina* and *Agaricomycotina* (Group B) (details are given in
131 Table S1).

132

133 **PaOSIP1 maintains cell wall integrity under caspofungin stress**

134 To functionally characterize OSIP1, the OSIP1 knock-out mutant was generated in *P.*
135 *anserina* (*PaOSIP1^Δ*) (Fig S2). *PaOSIP1^Δ* was tested for its ability to grow on various carbon
136 sources (cellobiose, fructose, cellulose, pectin, glucose) and various biomasses (whatman
137 paper, hay, miscanthus, wood chips). No differences in growth, sporulation, nor appressoria-
138 like structure formation (as described in Brun *et al*., 2009) was highlighted between the wild
139 type and the *PaOSIP1^Δ* mutant strains in the tested conditions (data not shown). Because the
140 DUF3129 domain is present in cell wall remodeling proteins, cell wall destabilizing agents
141 were thus tested. No phenotype was observed for Congo red that prevents glucan microfibril
142 assembly mainly by binding β-1,3 glucans (Nodet *et al*., 1990) nor Calcofluor white, which
143 binds chitin. By contrast, a significant deleterious growth phenotype was observed for the
144 mutant compared to the wild type in presence of caspofungin (Fig. 2). Caspofungin is a cell

wall-targeting antifungal compound extensively used in clinical settings for the treatment of infections caused by diverse fungi. Caspofungin inhibits the synthesis of β-1,3-glucan, a crucial cell wall component for many fungi, by targeting the β-1,3-glucan synthase (encoded by *fks1*) in a non-competitive way (Van Den Bossche, 2002; Aguilar-Zapata *et al*., 2015). Functional complementation of *PaOSIP1[A]* by PaOSIP1 restored the growth defect confirming the role of PaOSIP1 in protecting cell wall under caspofungin treatment.

PaOSIP1[A] mutant is affected in extracellular matrix production

To check whether caspofungin sensitivity was due to a thinner cell wall in the mutant compared to the wild type, SEM imaging was performed after cryosection of the hyphae (Fig. 3). The whole reconstituted images are shown as supplementary data. The thickness of the cell wall was measured (n>50) based on the microscopic images. No difference was detected between the WT and the mutant, nor between the caspofungin and the control condition. The measured cell wall thickness of hyphae cross-sections was around 150 nm for all conditions analysed. Interestingly, the main difference highlighted by comparing SEM images of both mutant and WT strains was the extracellular matrix (ECM) density. Fungal extracellular matrix is mainly composed of carbohydrates and proteins in complex interactions. This matrix is strongly reduced in *PaOSIP1[A]* even in the absence of caspofungin (Fig. 3). Since this matrix was shown to prevent drugs from reaching their cellular targets (Mitchell *et al*., 2016), this could explain why *PaOSIP1[A]* showed an increased sensitivity to the antifungal caspofungin.

Recombinant OSIP1 self-assembles as fibers and forms a gel

The heterologous *Escherichia coli* system was tested for recombinant PaOSIP1 and PcOSIP1 productions. Only PcOSIP1 expressed in *E. coli* was successfully produced. After

170 purification, 3 mg of pure protein per liter of bacterial culture were obtained. To check

171 whether the protein was correctly folded, far-UV circular dichroism analysis was performed.

172 Spectrum of PcOSIP1 revealed secondary structures, mainly alpha helices as highlighted by a

173 positive band at 190 nm and two negative bands at 208 and 222 nm (Fig. 4A).

174 After purification, PcOSIP1 rapidly self-assembled as big oligomers in Tris-NaCl buffer (30

175 mM Tris-HCl pH 8.0, 200 mM NaCl), as shown by dynamic light scattering (DLS) analysis

176 (Fig. 4B). Huge hydrodynamic radii (Rh) of 789.3 ± 388 nm and 2 281 ± 880 nm were

177 respectively measured for 56.7% and 28.7% of the PcOSIP1. This aggregation was not

178 observed when the protein was dialyzed in 50 mM phosphate buffer pH 8.0 directly after

179 purification, suggesting that this process was driven by the physicochemical properties of the

180 buffer. To check whether this aggregation was due to protein instability and thus precipitation

181 or rather a specific organization, the macromolecular structures of PcOSIP1 was analyzed by

182 Atomic Force Microscopy (AFM). In Tris-NaCl buffer, PcOSIP1 was able to self-assemble

183 into fibers with a mean diameter of 1.5 ± 0.2 nm (Fig. 4C). In phosphate buffer, a crown

184 structure was evidenced. This crown organization could be the transient states of PcOSIP1

185 fibril formation, since such structure was already described in transient states of the human α-

186 synuclein fibril formation that contributes to Parkinson's disease (Lashuel *et al*., 2002 ; Apetri

187 *et al*., 2006).

188 All the experiments described above were performed directly or few days after protein

189 purification. Interestingly, storing PcOSIP1 in Tris-NaCl buffer in the freezer led to the

190 formation of a gel, that was quite compact and elastic (Fig. 4D). This specific feature was

191 already described for other proteins as α-synuclein that can form gels in buffer at pH 7.4 in

192 the presence of NaCl (Semerdzhiev *et al*., 2018). These atypical properties of self-assembly

193 and jelly structure formation support a putative structural role of OSIP1 protein within the

194 fungal cell wall or the extracellular matrix.

Oak-extractives affect *PaOSIP1^A* growth

During wood degradation, extractives act as important stressors for fungal cells (Thuillier *et al*., 2014 ; Valette *et al*., 2017 ; Fernández-González *et al*., 2018). Some of them can act directly on cell wall integrity. For example, similarly to caspofungin, cinnamaldehyde and poacic acid inhibit β-1,3-glucan synthesis within the fungal cell wall (Bang *et al*., 2000; Piotrowski *et al*., 2015). Because OSIP1 gene expression was induced by oak extractive-induced stress both in *P. chrysosporium* (Thuillier *et al*., 2014) and *P. anserina* (data not shown), this condition was used to test *PaOSIP1^A* growth phenotype. The results showed a growth delay of *PaOSIP1^A* compared to the wild type in presence of wood extractives, which was observable from 5 days (Fig. 5). This phenotype was partially restored by functional complementation with PaOSIP1. These results support the hypothesis that PaOSIP1 could participate in cell wall protection against extractives toxicity.

The deletion of OSIP1 strongly modifies the composition of the secretome and the cell-wall related proteins of *P. anserina* in presence of oak sawdust

To analyze how the deletion of PaOSIP1 affects the fungal physiology in a context of biomass degradation, a proteomic analysis was performed for the *PaOSIP1^A* mutant grown in presence of oak sawdust, in comparison with the wild type strain. The comparative analysis of the secreted proteins reveals strong modification of the global secretome of *PaOSIP1^A* mutant compared to the wild type strain (Fig. 6A). Indeed, over the 250 proteins detected, 150 were more abundant (Protein abundance index (PAI) fold>2) or specifically identified in the mutant compared to the wild type, while this number was only 41 in the case of the wild type. By looking at the various classes of enzymes that were more abundant in the mutant secretome compared to the WT, no clear specificity was observed except for proteases that

220 were less represented (Fig. 6B). Globally, more than half (around 60%) of the detected

221 proteins of a specific class were more abundant in the secretome of the mutant compared to

222 the wild type. It is likely that the deletion of OSIP1 globally affected the secretion process of

223 the enzymes.

224 Glycoside hydrolases (GH) were the most abundant proteins with a total of 66 GH detected in

225 both secretomes. By looking at the individual GH families, we showed again that the increase

226 in protein abundance is not restricted to specific families, but was observed for many of them

227 (Fig. 6C). However, it is interesting to note that 16 GH families (over the total of 29) were

228 specifically detected in the mutant strain, especially GH5, GH11 and GH43 with at least 3

229 isoforms.

230 A high number of cell wall-related proteins, in particular glucan-acting enzymes have also

231 been found more abundant in the secretome of the mutant strain (Fig. 6D). Moreover, many

232 Wall Stress responsive Component (WSC) proteins have been detected. These proteins serve

233 as sensors of external stress cues upstream of cell wall integrity (CWI) pathway in

234 *Saccharomyces cerevisiae* (Verna *et al*., 1997) and *Aspergilli* (Futagami *et al.*, 2011; Dichtl *et

235 al*., 2012). In line with this observation, respectively 3 and 6 DUF1996-containing proteins

236 were found more abundant and specifically detected in the mutant among the 10 detected in

237 total (Supplementary data). These proteins are of unknown function, however the DUF1996

238 domain has been associated to fungal stress sensing and response (Tong *et al*., 2016a and

239 2019).

240

241 **Discussion**

242 In this study, we characterized a new fungal protein, which participates in cell wall fitness

243 under stress. The comparative genomic analysis revealed that such proteins are widely present

244 in fungi, suggesting their involvement in a general process of stress rescue. All analyzed

245 OSIP1 possess a domain of unknown function DUF3129 that was previously identified by

246 few studies in proteins of both plant and insect pathogens (Shang *et al*., 2016). DUF3129 is an

247 expanded gene family highly expressed during infection in nematode-trapping fungi that form

248 adhesive branches and adhesive knobs (Andersson *et al*., 2014). The role of this domain was

249 attributed to the cell wall remodeling for fungal penetration to host cuticles with an unclear

250 mechanism (Justesen *et al*., 1996 ; Xue *et al*., 2002 ; Grell *et al*., 2003 ; Cao *et al*., 2012).

251 More recently, seven DUF3129 proteins of the insect pathogenic fungus *Metarhizium*

252 *robertsii* were found localized to cellular lipid droplets mediating their degradation and

253 subsequently controlling appressorial turgor required for infection (Huang *et al*., 2019).

254 However, nothing has been described concerning the role of these DUF3129-containing

255 proteins in saprophytic fungi. The jelly structure of the recombinant PcOSIP1 and the

256 reduction of the extracellular polysaccharide network observed for the PaOSIP1 mutant

257 strongly suggest the involvement of OSIP1 in the formation of such adhesive structures in

258 fungi. The weakened extracellular matrix of the mutant could thus be responsible for the

259 higher susceptibility of the fungus to both caspofungin and oak extractives.

260 This phenomenom has been already described in *A. fumigatus*, where the downregulation of a

261 hydrophobin gene by a polyphenolic compound resulted in a weakened extracellular matrix

262 and therefore increased the susceptibility of the fungi to antifungal drugs (Luo *et al*., 2018).

263 Hydrophobins are small (100–120 aa) secreted proteins characterized by the presence of eight

264 highly conserved cysteine residues and the ability to self-assemble as amyloid-like structure

265 and forms rodlets (Ball *et al*., 2020). Amyloids serve diverse purposes for structure, adhesion

266 and defence in microorganisms (Shanmugam *et al*., 2019) and can be evidenced *in vitro* using

267 fluorescent tool as thioflavin T, which binds to the beta sheet-rich structure characteristic of

268 amyloid-like structure (Groenning, 2010). PcOSIP1 does not assemble under amyloid

269 structure since no thioflavin T fluorescence signal was detected in any of the conditions of

270 temperatures and buffers tested (data not shown). We have shown that PcOSIP1 was rich in α-

271 helices, while amyloid is structurally dominated by β-sheets. Moreover, AFM revealed that it

272 did not form rodlets. These experimental data, coupled to sequence analysis, allowed us to

273 confirm that OSIP1 is a new self-assembling protein, that does not belong to the well-known

274 class of hydrophobins.

275 In the context of lignocellulosic biomass degradation, the structural property of OSIP1 may be

276 the key point explaining the way by which it participates in fungal stress resistance by

277 protecting the cell wall. In accordance, the comparative secretome analysis of *P. anserina*

278 grown on oak sawdust revealed that the *PaOSIP1*[Δ] mutant highly expresses WSC proteins

279 compared to the wild type in this condition. WSC proteins are localized to the cell wall and

280 the plasma membrane and act as sensors upstream of the cell-wall integrity pathway. In

281 particular, WSC-1 may function in regulating cell wall biogenesis through the MAK-1

282 pathway in *Neurospora crassa* (Maddi *et al*., 2012). Single deletions of the five wsc genes of

283 *Beauveria bassiana* resulted in significant, but differential, increases in cellular sensitivity to

284 cell wall perturbation, oxidation, high osmolarity, and metal ions (Tong *et al*., 2016b). In

285 *Aspergillus fumigatus*, deletions of *wsc1* caused an increased in sensitivity to caspofungin but

286 no change in cellular sensitivity to other cell wall perturbation, alkaline pH and high

287 temperature (Dichtl *et al*., 2012). In the nematode-trapping fungus *Monacrosporium*

288 *haptotylum,* a gene cluster of 5 secreted proteins that are adjacent in the *M. haptotylum*

289 genome (cluster 74) is highly (>10-fold) upregulated during infection (Andersson *et al*.,

290 2013). This cluster gathers two genes coding for WSC proteins, one gene containing the

291 DUF3129 domain and two SSP-coding genes (Meerupati *et al*., 2013). This suggests a

292 functional link between these proteins. Additionally to WSC proteins, the *PaOSIP1*[Δ] mutant

293 highly expresses DUF1996-containing proteins. In *B. bassiana,* DUF1996-containing proteins

294 localize in vacuoles and play significant roles in the response to cell-wall perturbation, high

295 osmolarity, oxidation, fungicidal and multiple metal stress (Tong *et al*., 2016a). The absence

296 of OSIP1 in *P. anserina* grown in presence of oak sawdust strongly affected the whole

297 secretome of the fungus, likely because of the cell wall weakness. Indeed, the functionality of

298 the cell wall integrity (CWI) and secretory systems are connected and coordinately respond to

299 exogenous stresses through the modulation of the cell periphery and secretion (Malavazi *et*

300 *al*., 2014).

301 Taking together, these data strongly suggest that OSIP1 proteins prevent cell wall stress.

302 Consequently, its absence affects the cell wall associated signaling pathway, leading to a

303 deregulation of the secretion process. These data could be of great interest for both the

304 improvement of protein secretion particularly in a context of lignocellulosic biomass

305 degradation, and the limitation of fungal pathogenicity, for which the fungal cell wall has a

306 crucial role (Gow *et al*., 2017).

307

308 **Experimental procedures**

309 **Growth conditions**

310 The *P. anserina* strain used in this study was derived from the S strain (Rizet, 1952; Boucher

311 *et al*., 2017). Standard culture conditions, media compositions and genetic methods for this

312 fungus have already been described (Rizet, 1941; Silar, 2013) and are available at

313 https://podospora.i2bc.paris-saclay.fr. Growth kinetics of the wild type and *PaOSIP1*$^\Delta$ strains

314 were done in M2-Agar medium and M2-Agar medium supplemented with caspofungin (500

315 ng/ml) and oak extractives (2 mg/ml) for 10 days at 27 °C. Oak (*Quercus petraea*) acetonic

316 extract preparation has been performed as described previously (Fernández-González *et al*.,

317 2018).

318

319 **Analysis of OSIP1 sequences**

320 OSIP1 sequences were searched within all fungal genomes available in the Joint Genome

321 Institute database (Mycocosm https://genome.jgi.doe.gov/programs/fungi/index.jsf) using

322 BlastP with a cut off of Evalue=10^{-5}. Sequences of OSIP1 of *Podospora anserina* ((PaOSIP1

323 (208230 JGI) and *Phanerochaete chrysosporium* (ProtID 2981896 JGI) have been used as

324 templates. Another sequence close to PaOSIP1 was added as a template (P209725 (ProtID

325 209725 JGI)). Evolutionary analyses were conducted in MEGA7 using the Neighbor-Joining

326 method (Kumar *et al*., 2016). The tree is drawn to scale, with branch lengths in the same units

327 as those of the evolutionary distances used to infer the phylogenetic tree. The evolutionary

328 distances were computed using the Poisson correction method and are in the units of the

329 number of amino acid substitutions per site. The analysis involved 628 amino acid sequences.

330 All ambiguous positions were removed for each sequence pair. There were a total of 467

331 positions in the final dataset. To carry out the clustering, the Laplacian eigenmap technique

332 (Belkin and Niyogi, 2003) was applied with Gaussian mixture model (Reynolds, 2015) as

333 follows. After sorting the sequences in alphabetical order, the similarity of each sequence pair

334 were obtained from the score provided during a pairwise sequence alignment using the

335 Needleman-Wunsch (Needleman and Wunsch, 1970) dynamic programming algorithm from

336 Biopython (Cock *et al*., 2009) module (pairwise2 function). Default values for gap open and

337 extend penalties were chosen with blosum62 matrix for amino acid substitution, leading to a

338 matrix M of integers. A similarity matrix S has been deduced by dividing each row by its

339 maximum, and by computing the identity matrix minus this one. The normalized Laplacian

340 associated with the similarity matrix has been computed as follows: $L = D^{-1}(D-S)$, where D is

341 the diagonal matrix whose element in position (i,i) is the sum of the i-th row in S. Eigenvalues

342 of L have then been computed and sorted in ascending order thanks to the numpy library

343 (Oliphant, 2006), and the N-th first eigenvalues have only be considered, where N is such that

344 the increase between the N-th and N+1-th eigenvalue is lower than 1%. Associated

345 eigenvectors have then been clusterized according to a Gaussian mixture model (Reynolds,

346 2015), and the model selection (number of Gaussians) has been performed according to the

347 Bayesian Information Criterion (BIC, (Schwarz, 1978)). To sum up, Laplacian eigenmap

348 allowed us to map the similarity matrix in a low dimensional space of points, each point being

349 associated to one amino acid sequence. This cloud points has been considered as the

350 superposition of a given number of gaussian trends (the clusters), this number being

351 determined thanks to the BIC criterion of parcimony. For further information about this

352 sequence clustering technique, see, e.g. Bruneau *et al*. (2018).

353

354 **Deletion of PaOSIP1 in *Podospora anserina***

355 To delete PaOSIP1 (Pa_5_3780), the "split marker" method was used (Silar, 2013). This

356 protocol is based on the generation of two DNA fragments carrying a resistance marker

357 flanked with either 5' or 3' non-coding sequence of the genes by two successive PCR

358 reactions. In the first step, a 832 pb-long 5'-non-coding region of PaOSIP1 and a 962 pb-long

359 3' region were PCR-amplified from the S strain DNA with the PaOSIP1-A/ PaOSIP1-B, and

360 PaOSIP1-C/ PaOSIP1-D primer pairs respectively. At the same time, the hygromycin

361 resistance marker was amplified with PaOSIP1-E and PaOSIP1-F from the pBC-hygro vector

362 (Silar, 1995). Primers sequences are given in Fig. S2. In a second step, the second round of

363 PCR using primers PaOSIP1-A and PaOSIP1-F, and PaOSIP1-D and PaOSIP1-E enabled to

364 merge the resistance marker with either the 5' or the 3' region. The two PCR products were

365 used to transform a mus51::phleoRstrain, in which the mus51gene encoding one of the

366 subunit of the non-homologous end joining dimer is replaced with a phleomycin resistance

367 gene. Three crossing-over events between the two cassettes and the *P. anserina* genome

368 enabled the deletion of PaOSIP1. Three hygromycin resistant transformants were selected.

369 They were crossed with the wild-type S strain, and one homokaryotic hygromycin resistant

370 and phleomycin-sensitive descendant was selected as the PaOSIP1::hygroRstrain or

371 *PaOSIP1*$^\Delta$. Its genotype was confirmed by Southern blot analyses using digoxigenin labeled

372 probes (Fig. S2). For functional complementation tests, PaOSIP1 coding sequence was cloned

373 into pAKS-Genet^R vector and expressed in *PaOSIP1*$^\Delta$. The presence of the gene was checked

374 by PCR and three transformants were selected for functional complementation tests. They all

375 restored the mutant phenotype, thus, only the results for one of them are presented.

376

377 **SEM imaging of *PaOSIP1*$^\Delta$ hyphal network**

378 **Cloning of PcOSIP1**

379 *Phanerochaete chrysosporium* mycelium was harvested from liquid cultures in TK medium

380 supplemented with oak extractives as previously described (Thuillier *et al*., 2014). Total RNA

381 was extracted and purified using the RNeasy plant minikit (Qiagen) according to the

382 manufacturer's instructions. RNA was treated with DNase I during purification as

383 recommended in the manufacturer's protocol. An additional purification step was performed

384 by precipitating RNA with 2 M LiCl. RNAs were reverse transcribed using the masterscript

385 kit (5 prime) following the manufacturer's protocol. The PCR reactions to amplify PcOSIP1

386 (Prot ID 2981896 in the Joint Genome Institute database v2.2 (previously identified as Prot ID

387 4474 in v2.0 of *P. chrysosporium* genome annotation)), have been performed with Herculase

388 Taq (Agilent technologies) for cloning into the pEt26b (Novagen) vector for His-tagged

389 protein production in *Escherichia coli*. The sequence was amplified without the predicted

390 signal peptide of secretion using the following primers (for:

391 CCCCCATATGGCTATTATCACGCCCGCG and rev:

392 CCCCGCGGCCGCTGCTTGGAGCTCCTCATC).

393

Heterologous expression of PcOSIP1 in *Escherichia coli* and purification of the recombinant protein

Expression of recombinant PcOSIP1 was performed in *E. coli* Rosetta2 (DE3) strain containing pLysS plasmid (F⁻ ompT hsdS_B(rB− mB−) gal dcm (DE3) pRARE2 (CamR)). The bacteria were cultivated in LB medium supplemented with 50μg/ml kanamycin and 50μg/ml chloramphenicol at 37°C. At OD_{600} of 0.6, the expression of the recombinant proteins was induced by adding 0.1 mM isopropyl ß-D-1 thiogalactopyranoside (IPTG) during 4h. Cells were harvested by centrifugation and resuspended in 30 mM Tris-HCl pH 8.0, 500 mM NaCl buffer and stored at -20°C. The purification of His-tagged PcOSIP1 was performed by affinity chromatography on IMAC columns (Sigma Aldrich) from the soluble fraction obtained after a 30 min centrifugation (27,000 x g) of cells lysed by sonication. The washing buffer was 30 mM Tris–HCl pH 8.0, 2 M NaCl in a first step and 30 mM Tris–HCl pH 8.0, 500 mM NaCl and 10 mM imidazole in a second step. The elution buffer was 30 mM Tris–HCl pH 8.0, 500 mM NaCl, 250 mM imidazole. Both proteins were dialyzed against a 30 mM Tris-HCl pH 8.0, 500 mM NaCl buffer by ultrafiltration on YM10 membranes, concentrated and loaded on Sephadex 75 16/600 column (AKTA purifier) equilibrated with 30 mM Tris-HCl, 200 mM NaCl. The purified protein was finally concentrated and analyzed on 15% SDS-PAGE gel to check the purity. The concentration of the protein was determined by BC assay (interchim).

Circular dichroism (CD)

Due to the incompatibility of Tris buffer, which absorbs between 180 and 260 nm, the PcOSIP1 spectrum was recorded exclusively in phosphate buffer. Directly after purification, PcOSIP1 was dialyzed in 50 mM phosphate buffer pH 8.0 using dialysis membrane (Spectra/Por, MWCO 6-8 000). Circular Dichroism spectra of PcOSIP1 was obtained in 50 mM phosphate buffer pH 8.0 at 25 °C in a quartz cuvette (1-mm path length) from 180 to 260

nm with a bandwidth of 1 nm using a Chirascan Plus spectropolarimeter (Applied

Photophysics, Ltd, UK). The mean residue ellipticity [θ]MR was calculated using Pro-Data

Viewer (Applied Photophysics, Ltd, UK) software and expressed in deg. $cm^2.dmol^{-1}$ per

residue.

Dynamic Light Scattering (DLS)

The homogeneity of solutions, the aggregation state and particle sizes were analyzed by

granulometry on a Zetasizer Nano-S model (Malvern Instruments, Malvern, UK). The protein

solution was analyzed by DLS at a final concentration of 4mg/ml either in 50 mM phosphate

buffer pH8.0 or 30 mM Tris-HCl, 200 mM NaCl buffer. The supernatant of each sample was

gently transferred into a quartz cuvette of 12 μl and the particle size measurements were

performed in triplicate at 37°C, with alight diffusion at 173°. The data were collected in

automatic mode and analyzed using the associated software DTS version 4.2 (Malvern

Instruments).

Atomic Force Microscopy (AFM)

PcOSIP1, either in 50 mM phosphate buffer (pH 8.0) or 30 mM Tris-HCl and NaCl 200 mM

buffer (pH 8.0), was analyzed at a starting protein concentration of 6 mg/ml. The protein

solutions were carefully dialyzed to remove NaCl and diluted 10 times just prior to AFM

observations. A glass coverslip was cleaned with a piranha treatment and washed in ultrapure

water, before being dried in a stream of nitrogen gas. A tiny droplet of each diluted protein

solution was deposited onto the glass coverslip heated at 20°C to promote a rapid drying

(within 2 minutes) while avoiding the formation of concentration gradients on the substrate

(Zykwinska *et al*., 2014). The sample was then immediately imaged by AFM. A

NanoWizard® Atomic Force Microscope (JPK, Germany) operating in intermittent contact

444 mode under ambient conditions was used to image the protein solutions deposited onto the

445 glass coverslip. A standard rectangular cantilever (Nanosensors NCL-W) was employed for

446 imaging (scan rate of 0.5 Hz), with a free resonance frequency of 174 kHz and a curvature

447 radius of the tip of 10 nm. In order to check the reproducibility of the observed morphology,

448 all samples were scanned at least on three different zones. Each sample was investigated using

449 fresh tips previously cleaned by UV-ozone treatment. The height measurements were done

450 using JPK Data Processing software (JPK, Germany).

451

452 **LC–MS/MS protein identification**

453 *P. anserina* wild type and *PaOSIP1*$^{\Delta}$ strains were cultivated in flasks containing 1 g of oak

454 sawdust and 10 ml of M2 medium without any carbon source for 1 month at 25°C. For each

455 strain, three independent cultures were pooled before protein extraction. Proteins from the

456 whole sample (sawdust containing mycelium and secretome) were extracted with 10 ml of 50

457 mM sodium acetate pH4.5 buffer for 1.5 h under shaking at 4°C. The sample was centrifuged,

458 concentrated with centricon filter membrane (5 kDa) until around 3 ml and precipitated with

459 cold acetone (80%). 10 µg of proteins was loaded on 12% SDS-PAGE gel. After a short

460 migration (0.5 cm) in the stacking gel, the gels were stained with Coomassie blue and each

461 electrophoresis track was cut into two 2-mm-wide strips. Proteomic identification was

462 performed at the Plate-forme d'Analyse Protéomique de Paris Sud-Ouest (PAPPSO, INRA,

463 Jouy-en-Josas, France; http://pappso.inra.fr/), according to a protocol described in Navarro et

464 al. (2010). Briefly, the digestion of the proteins contained in the gel strips was carried out

465 according to a standard trypsinolysis process, using modified trypsin (Promega,

466 Charbonnières-les-Bains, France). Peptide analysis was performed by Ultimate 3000

467 RSLCnano liquid chromatography (Thermo Fisher Scientific, Waltham, Massachusetts, USA)

468 coupled to a Q-exactive mass spectrometer (Thermo Fisher Scientific) using electrospray

469 ionization. Peptide attribution and protein annotation were performed by comparing mass

470 spectrometry data to predicted proteins in the genomes of *P. anserina* as well as an internal

471 contaminant database, using X!Tandem Cyclone software (X!Tandem, Jouy-en-Josas,

472 France). The protein annotation was completed manually by BlastP using both the NCBI

473 (https://blast.ncbi.nlm.nih.gov)   and   JGI   Mycocosm

474 (https://mycocosm.jgi.doe.gov/Podan3/Podan3.home.html) databases.

749 **Figure legends**

750 **Fig. 1: Comparative genomics of fungal OSIP1**

751 Sequences were retrieved from the whole fungal JGI database (Mycocosm from Joint

752 Genome Institute) using BlastP search tool with PcOSIP1, PaOSIP1 and P209725 as

753 templates. (A) A total of 1057 sequences have been retrieved (cut off of Evalue=10^{-5}) and

754 clustered as described in Experimental procedures part. The number of sequences found per

755 trophic mode is indicated by various colors for each cluster. (B) Sequence alignment of

756 ascomycete OSIP1 sequences from *P. anserina*, *Chaetomium thermophilum*, *Sordaria*

757 *brevicollis* and *Fusarium solani*. The signal peptide of secretion is colored in yellow, the

758 DUF3129 domain in blue gray. The eight conserved cysteinyl residues are highlighted (in red

759 those that are both conserved in basidiomycete and ascomycete sequences and in orange those

760 that are specifically conserved in ascomycetes sequences) (C) Evolutionary relationship of

761 OSIP1 and DUF3129 containing proteins. The evolutionary history of OSIP1 cluster

sequences and DUF3129 containing sequences retrieved from the Pfam database, was inferred using the Neighbor-Joining method. Basidiomycete sequences are highlighted in gray. The functionally characterized proteins are reported. Sc: *Saccharomyces cerevisiae*, Mg: *Magnaporthe grisea*, Pc: *Phanerochate chrysosporium*, Pa: *Podospora anserina*, Bg: *Blumeria graminis*, Cg: *Colletotrichum gloeosporioides*. Because some of DUF3129-containing proteins are annotated as GAS-like proteins in the pfam database, GAS1 (Glycolipid Anchored Surface) from *Saccharomyces cerevisiae* that has been well studied (Ragni *et al.*, 2007) and the GAS1 sequence of *P. chrysosporium,* were added to the analysis.

Fig. 2: Growth phenotype of *PaOSIP1^Δ* in presence of caspofungin.

Wild type, *PaOSIP1^Δ* mutant and a complemented strain (*PaOSIP1^Δ_PaOSIP1)* were grown in M2 medium as control (A) and M2 supplemented with caspofungin (500 ng/ml) (B) for 10 days at 27°C (n=3). The pictures show fungal growth after 10 days.

Fig. 3: SEM images of *PaOSIP1^Δ* and WT hyphal network.

Cryosections of mycelium were obtained as described in material and methods and visualized by scanning electron microscopy. Images shown in the figure correspond to the top left quarter of the whole images shown in supplemental data. The bar scale corresponds to 5 µm. The extracellular matrix has been manually colored in yellow, the merged images are shown in the middle panels. The single colored ECM is presented on the right panels.

Fig. 4: Self-assembly of PcOSIP1.

(A) Circular dichroïsm analysis of PcOSIP1 secondary structure. The spectrum was recorded in 50 mM phosphate buffer pH 8.0 with 66 µM of protein. PcOSIP1 spectrum shows signals at 190, 208 and 222 nm (B) Dynamic light scattering analysis of the oligomerization state of

787 PcOSIP1. The percentage of the various oligomers of PcOSIP1 in 30 mM Tris-HCl pH 8.0-

788 200 mM NaCl buffer (Tris-NaCl buffer) and 50 mM phosphate buffer pH 8.0 (Phosphate

789 buffer) is represented by black bars. Rh: hydrodynamic radii. (C) Atomic Force Microscopy

790 height images of PcOSIP1 in Tris-NaCl buffer and Phosphate buffer. Size of AFM images: 3

791 μm × 3 μm. (D) Macromolecular (1 and 2) and microscopic (3) views of the PcOSIP1 gel.

792

793 **Fig. 5: Growth phenotype of *PaOSIP1$^\Delta$* in presence of oak extractives.**

794 Growth kinetics of the wild type, *PaOSIP1$^\Delta$* mutant and a complemented strain

795 (*PaOSIP1$^\Delta$_PaOSIP1*) in M2 medium supplemented with oak extractives (2 mg/ml) (n=3). The

796 pictures show fungal growth after 10 days.

797

798 **Fig. 6: Secretome analysis of *PaOSIP1$^\Delta$* in comparison to the wild type strain in presence**

799 **of oak sawdust.**

800 (A) Global analysis of the amount of proteins specifically detected or more abundant ((PAI)

801 fold>2) in the secretome of each strain in presence of oak sawdust (the experimental set up is

802 described in the experimental section). (B) Percentage of the proteins found specific or more

803 abundant in *PaOSIP1$^\Delta$* within the total of the proteins identified for each functional class. (C)

804 Number of glycoside hydrolases (GH) of each family detected in the secretomes of *PaOSIP1$^\Delta$*

805 and wild type strains in presence of oak sawdust. The proportion of proteins detected as

806 specific or more abundant (PAI fold>2) in the mutant strain is represented as red bars, the

807 dark blue bars corresponding to the number of GH showing PAI fold<2 for the mutant

808 compared to wild type. (D) Protein Abundance Index (PAI) for each strain. A focus has been

809 made on cell wall-related proteins. ProtID are those from the JGI Mycocom database. Full

810 proteomic data are available in Table S2.

811

Fig S1: Sequence alignment of basidiomycete OSIP1 sequences from *P. chrysosporium,*

T. versicolor, Phlebiopsis gigantea, Punctularia strigosozonata and *Phlebia centrifuga.* The

signal peptide of secretion is colored in yellow, the DUF3129 domain in blue gray. The four

conserved cysteinyl residues are highlighted in red.

Fig. S2: Strategy for PaOSIP1 deletion. (A) Gene replacement strategy for deleting

PaOSIP1 in *Podospora anserina*. (B) Primers used for gene replacement and probe synthesis

as described in the experimental procedures section. (C) Southern blot showing the efficiency

of the gene replacement and insertion of the resistance cassette in a single copy within the

genome. Genomic DNA was digested by Pst1 restriction enzyme and hybridized with both

AB and CD digoxigenin labeled probes.
