1 **Impacts of land-cover changes on snow avalanche activity in the French Alps**

2 **Abstract**

3 Dendrogeomorphic analyses provide long and continuous chronologies of mass movements that are useful for the
4 detection of trends related to climate change. Socio-environmental changes can, however, induce non-
5 stationarities. This study addresses the following questions: (1) How does the evolution of forest cover induce non-
6 stationarities in tree-ring based reconstructions of snow avalanche activity? (2) How are trends inherent to tree-ring
7 approaches distinguishable from real fluctuations in avalanche activity? Using dendrogeomorphic techniques, we
8 reconstructed snow avalanches in six adjacent paths in the French Alps. Results show two distinct trends in process
9 activity between 1750 and 2016. In the southern paths, the frequency of snow avalanches increased sharply in the
10 1970s. The distribution of tree ages, as well as old topographic maps, allow an attribution of this trend to the
11 destruction of large parts of the forest stand by a large snow avalanche in the 1910-20s. This extreme event induced
12 a sudden change in the capability of newly colonizing trees to record subsequent snow avalanches. In the northern
13 paths, by contrast, progressive afforestation starting in the mid-19th century, as well as colonization of the release
14 areas after World War II, resulted in a strong reduction in snow avalanche activity since the 1930s. Even if global
15 warming remains a possible additional driver of snow avalanche activity at the study sites, the rural exodus and the
16 abatement of pastoral practices during the 19th and 20th centuries are the main explanations for the observed trends
17 in process activity. Results also illustrate a need to clarify the complex interrelations among forest evolution, global
18 warming, social practices, and the process activity itself when interpreting trends in mass movements.

20

21 **1. Introduction**

22 Climate warming in Europe has occurred since the end of the Little Ice Age (or LIA) around ~1850; this trend has
23 accelerated more markedly since ~1985 (IPCC, 2013). High mountain environments experience a stronger
24 response to climate change with even faster average warming as compared to the global mean (Mountain Research
25 Initiative EDW Working Group et al., 2015). This evolution has resulted in rapid changes in the cryosphere (Beniston
26 et al., 2018) and related changes in hydro-geomorphic process activity (Stoffel and Huggel, 2012). As a result of
27 ongoing warming, available *in situ* snow depth data indicate an elevation-dependent decreasing trend in snow
28 amounts, snow cover duration and snow water equivalent in the Alps (e.g. Bormann et al., 2018; Falarz, 2004;
29 Laternser and Schneebeli, 2003; Marty et al., 2017; Morán-Tejeda et al., 2013). At the same time, the abandonment
30 of traditional farming systems since the mid-19th century have affected many mountain regions across Europe, and
31 even more so after World War II. The abatement of traditional farming has favored grassland abandonment,

32 subsequent forest encroachment (Gellrich et al., 2007; O'Rourke, 2006), and the progressive disappearance of
33 mosaics of landscape features reflecting traditional mixed farming management (MacDonald et al., 2000).

34 Changes in snow cover characteristics often induce changes in spontaneous avalanche activity (Castebrunet et al.,
35 2012; Stoffel and Corona, 2018), including alterations in friction and flow regime (Naaïm et al., 2013; Köhler et al.,
36 2018). Tree-ring and historical archives enable inferences of longer-term changes of avalanche activity (Corona et
37 al., 2013; Giacona et al., 2017), and possibly detections of the impacts of climate change on snow avalanche
38 activity. In this regard, Ballesteros-Cánovas et al. (2018) reported increased avalanche activity on some slopes of
39 the Western Indian Himalaya over the past decades and related the changes in process behavior to the increased
40 frequency of wet-snow conditions. In the European Alps, studies have demonstrated negative correlations between
41 past changes in avalanche numbers and runout distance, as well as avalanche activity in forested areas, with
42 temperature changes. They have also shown positive correlations with snow depth changes (Eckert et al. 2013,
43 Teich et al., 2012). These studies also suggested that avalanche mass and run-out distance have decreased over
44 past decades, with a decrease of avalanches with a powder part since the 1980s, a decrease of avalanche numbers
45 below 2000 m, but an increase of snow avalanches at higher elevations (Eckert et al., 2013; Lavigne et al., 2015;
46 Gadek et al., 2017). At the same time, other studies have shown a positive trend in the proportion of avalanches
47 involving wet snow over the last decades and for the months of December through to February (Pielmeier et al.,
48 2013; Naaïm et al., 2016).

49 A large body of literature has documented interferences between snow avalanche activity and land cover changes
50 (e.g., Bebi et al., 2009; Germain et al., 2005; Héту et al., 2015; Kulakowski et al., 2006, 2011; Podolskiy et al., 2014;
51 Schneebeli and Bebi, 2004; Teich et al., 2012). Germain et al. (2005) showed that deforestation and landscape
52 heterogeneity should be carefully considered as tree removal—after clear-cuts and forest fires—affected snow
53 redistribution, which in turn would increase the frequency of events in existing and new avalanche paths. Similarly,
54 Kulakowsky et al. (2011) demonstrated a decreasing fragmentation of forest stands on avalanche paths resulting
55 from the modification of the disturbance regime interacting with land use changes and global warming over the last
56 45 years in Switzerland. Accordingly, changes in traditional agricultural systems are susceptible to affect avalanche
57 activity, as they can favor passive colonization of release areas with shrubs and trees, with potentially marked
58 consequences on avalanche frequency and on runout distances. Yet, to date, research has not considered the
59 impact of land abandonment and marginalization on mass-movement activity in a thorough manner. One exception
60 is the study of García-Hernández et al. (2017) who reported passive reforestation as the main driver of changes in
61 avalanche damage in the Spanish Pyrenees over the last fifty years. Similarly, Giacona et al. (2018) reported that
62 progressive land abandonment and decreased anthropogenic pressure have significantly reduced the exposure of
63 properties (i.e. high-altitude farms in particular) to the risk of avalanches in the Vosges massif.

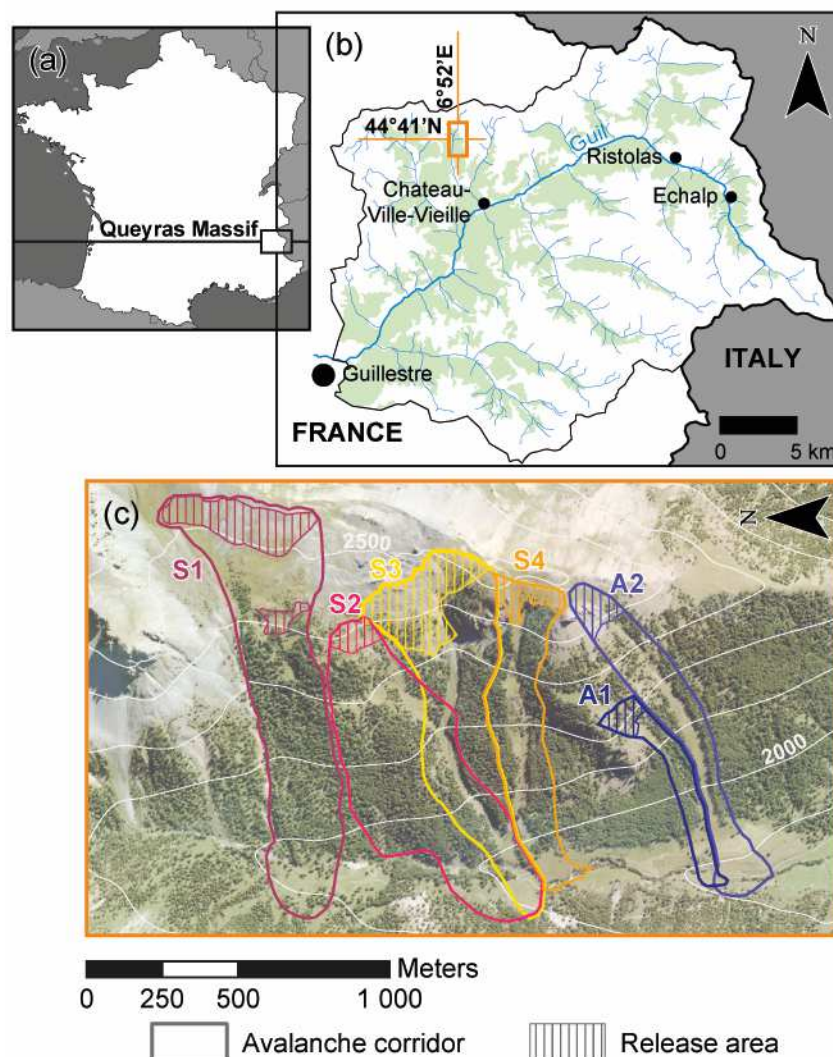

64 The lack of long-term studies is usually attributed to the scarcity of continuous records of past avalanche activity
65 (see Corona et al., 2012). On wooded paths, dendrogeomorphology (Alestalo, 1971) allows to identify and date of
66 growth disturbances induced by past mass-movement activity in ring-width series. It can therefore also provide
67 continuous, annually resolved snow avalanche reconstructions to complement historical sources.
68 Dendrogeomorphic approaches have repeatedly yielded reconstructions of multi-decadal to multi-centennial
69 chronologies of snow avalanche events over the last decades in numerous mountainous regions worldwide (see
70 Favillier et al., 2017 for a recent review). Yet, non-stationarities in process or site characteristics are likely to affect
71 dendrogeomorphic reconstructions that will then impact the resulting time series of past events and trends therein.
72 For this reason, Corona et al. (2012) proposed to adjust thresholds aimed at detecting past process activity in tree-
73 ring records to account for the reduced frequency of reconstructed events related to the decreasing number of living
74 trees back in time. Similarly, Favillier et al. (2018) attributed the over-representation of avalanche events in their
75 reconstructions since the mid-20th century to the difficulty to retrieve ancient hidden scars (Stoffel and Perret, 2006),
76 invisible on the stem surface, thus rendering the determination of suitable sampling positions a difficult task
77 (Trappmann and Stoffel, 2013). Finally, age- and diameter-dependent sensitivities of trees observed in hydro-
78 geomorphic processes are yet another factor to be considered (Tichavský and Šilhán, 2016). These sensitivities
79 thus represent a third source of non-stationarity in tree-ring reconstructions.

80 In this study, we deployed a dendrogeomorphic approach to study snow avalanches on a slope of the upper Guil
81 valley (Chateau-Ville-Vieille municipality, French Alps) in the Queyras massif. We addressed the following
82 questions: (i) How does the forest cover evolution induce non-stationarities in tree-ring reconstructions of snow
83 avalanche activity? (ii) How are trends inherent to tree-ring approaches distinguishable from real fluctuations in
84 avalanche activity? To answer these questions, we selected a slope comprising six different avalanche paths with
85 similar morphology (in terms of altitude of the starting zone and path length) but different forest cover (i.e. densely
86 forested paths upstream and corridors characterized by a marked transverse zonation downstream), thus allowing
87 comparison between reconstructions. To this end, we performed a diachronic analysis of historical maps, aerial
88 photographs and estimated tree ages to document the evolution of the forest stand within each path. We
89 hypothesized that potential non-stationarities in tree-ring reconstructions could result from (1) forest recolonization
90 after destructive avalanche events or (2) afforestation related to recent socio-environmental changes at the study
91 site.

92 **2. Study site**

93 The site under investigation is on the territory of Château-Ville-Vieille (Queyras massif, French Alps), 1.5 km to the
94 northwest of a hamlet called Souliers. The study site is locally known as Grand Bois (44° 47'N, 6° 46'E, Fig. 1) and
95 consists of a west-facing slope (135 ha) extending from the Crépaud ridge (2580 m asl) to the Souliers torrent (1900
96 m asl). Naturally triggered snow avalanches are common on the slope and release from several starting zones

97 located between 2300 and 2580 asl. We delineated six avalanche paths (S1-S4, A1-A2) based on the mapping of
 98 erosional and depositional avalanche features in the field as well as on the interpretation of aerial photographs. We
 99 derived the morphometric characteristics of each path from a 5-m Digital Elevation Model (DEM) extracted from the
 100 IGN RGE ALTI® database (Tab. 1). With respect to land cover, a preliminary analysis of aerial photographs shows
 101 a north-south gradient of afforestation on the selected paths, meaning that the forest cover increases from 31.2%
 102 at A2 to 65.1% at S2. Paths S3-S4 and A1-A2 have characteristic transverse vegetation patterns, as defined by
 103 Malanson and Butler (1984): dense shrubs with flexible stems colonize the inner zone of these paths, including
 104 European rowan (*Sorbus aucuparia* L.) or common juniper (*Juniperus comunis*); in the outer zones, European larch
 105 (*Larix decidua* Mill.) is dominant. Rhododendron (*Rhododendron ferrugineum* L.) and bilberries (*Vaccinium myrtillus*
 106 L.) form most of the understory vegetation. By contrast, transverse vegetation patterns were absent at S1-S2 and
 107 tree stand physiognomy (i.e. candelabra-shaped or broken-crown trees) was the main evidence of past avalanche
 108 occurrences. According to Saulnier (2012), residents exploited the Grand Bois de Souliers slope intensively for
 109 pastoralism since the mid-19th century. Despite a sharp decline in pastoral activities, forest exploitation remained
 110 in place over large parts of the 20th century and until pastoralism disappeared in 1971 (Saulnier et al., 2015).

112 **Figure 1.** Location of the studied paths: (a) overview of the Queyras massif (French Alps), (b) detailed view of the
 113 Chateau-Ville-Vieille locality within the Queyras massif and the study site (c) detailed view of the six avalanche
 114 paths delineated on the Grand Bois de Souliers slope.

115 At the meteorological station of Saint-Véran (44°41'N, 6°52'E, 2039 m asl), located 12 km southeast of Grand Bois,
 116 mean annual precipitation and temperature are 709.6 mm and 5.3°C (1981–2010), with a winter (Dec-Apr) mean
 117 temperature of -0.2°C and winter precipitation totaling 237 mm on average. Due to its remoteness and the lack of
 118 objects at risk, the northernmost portion (S1-S4) of the Grand Bois de Souliers slope has neither been included in
 119 the EPA (Enquête Permanente sur les Avalanches; Bourova et al., 2016; Mougin, 1922) database nor mapped in
 120 the CLPA (Carte de Localisation des Phénomènes Avalancheux; Bonnefoy et al., 2010). Conversely, in the case
 121 of paths A1-A2, CLPA maps exist for two events: one in 1972 covering the Souliers road and torrent over 80 m.
 122 The second record is from December 2008 when a powder-snow avalanche destroyed 50 m³ of wood. The 2008
 123 event occurred during an intense avalanche cycle that affected the Queyras between December 14 and December
 124 17, 2008 (Eckert et al., 2010b). During this period, southerly atmospheric fluxes progressively evolved into an
 125 easterly return causing important snowfall for three days. Cold temperatures and drifting snow aggravated the
 126 situation and caused the occurrence of 209 avalanches over a period of 5 days according to the EPA avalanche
 127 database. Some avalanches had very long runout distances and exceeded the historical limits recorded in the
 128 CLPA (Gaucher et al., 2009).

129 **Table 1.** Main characteristics of the studied avalanche paths. Numerical values correspond to the areas delineated
 130 in Fig. 1c and derived from crossed a 5-m DEM.

Avalanche path						Release area			
Path	Aspect	Length (m)	Mean width (m)	Area (ha)	Mean slope (°)	Forest cover in 2015 (%)	Release altitude (m)	Mean slope (°)	Area (ha)
S1	W	1231	250	39.1	22.4	45.92%	2390-2570	28.1	7.9
S2	W	990	350	35.6	24.8	65.13%	2350-2420	26.7	1.5
S3	W	1107	250	27.6	28	43.53%	2300-2515	31.1	7.5
S4	W	950	180	16.5	28.8	55.49%	2380-2490	29.6	2.1
A1	W-S	695	92	6.02	27	50.33%	2150-2250	34.4	1.2
A2	W-S	1105	160	15.6	28.4	31.20%	2375-2490	34.8	2

131

132 3. Material and methods

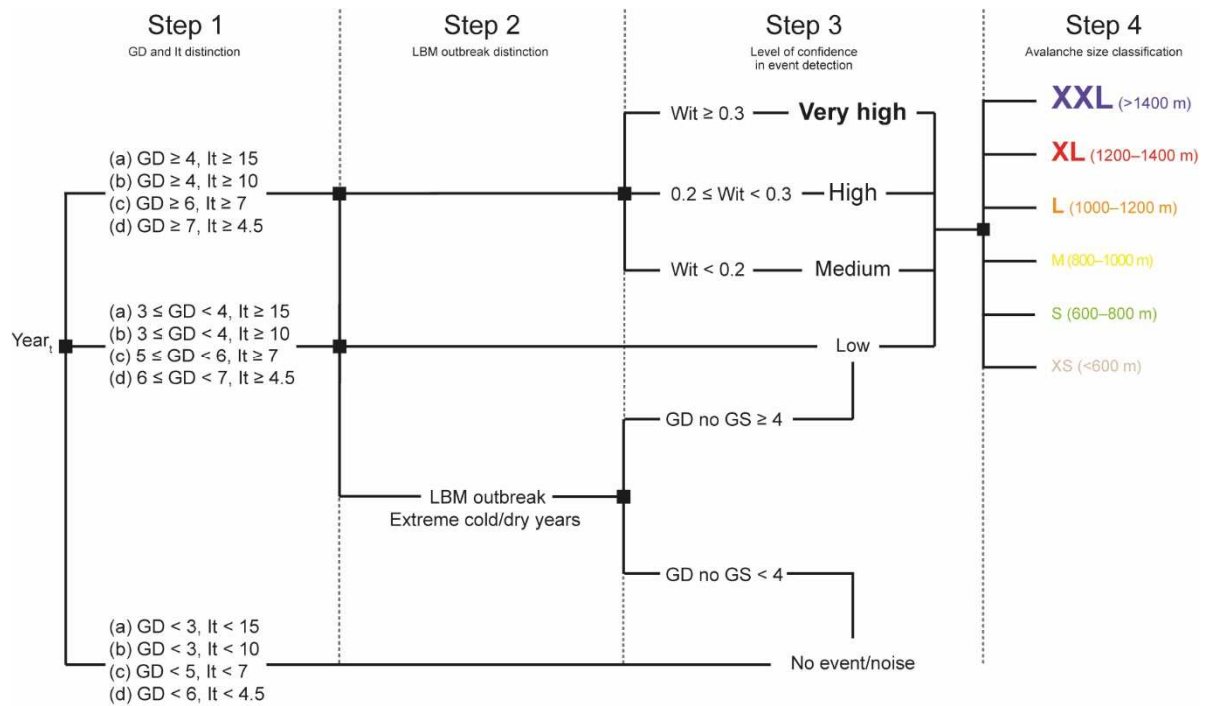

133 3.1. Sampling strategy, dating and classification of growth disturbances

134 The field work missions in summers 2011 (S1-S2) and 2016 (S3-S4, A1-A2) allowed collecting a total of 884
 135 increment cores from 825 European larch (*Larix decidua* Mill.) trees growing in the 6 avalanche paths. In the field,
 136 the sampling design followed the recommendations of Šilhán and Stoffel (2015) and Stoffel and Corona (2014),
 137 with particular attention paid to the number and the spatial distribution of sampled trees as well as to the balance

138 between older and younger trees. The use of a 1-m precision GPS device allowed recording the position of each
139 tree. In addition, we recorded a series of data including the diameter at breast height (DBH) and the nature of the
140 disturbance (type, height) in the field. In the lab, we applied standard dendrochronological procedures (Stoffel and
141 Bollschweiler, 2008) to process the samples. We used the Souliers and Echalp reference chronologies (Corona et
142 al., 2012; Saulnier et al., 2019) to cross-date growth disturbances (GD) identified in the tree-ring series and to
143 correct the tree-ring records of affected trees in case of missing or false tree rings. We considered injuries and
144 callus tissues (CT) (Stoffel et al., 2010), tangential rows of traumatic resin ducts (TRD) (Schneuwly et al., 2009a,
145 2009b), compression wood (CW) and sharp growth suppression (GS; Kogelnig-Mayer et al., 2013)—considered if
146 tree-ring width was $\geq 60\%$ smaller over ≥ 3 year compared to mean tree-ring width of the 5 years preceding the sharp
147 decrease—as the most reliable indicators of past avalanche activity. To emphasize features obviously associated
148 to snow avalanche activity, we classified GDs by intensity (Stoffel et al., 2013) based on their visual aspect and
149 according to the classification proposed by Kogelnig-Mayer et al. (2011) as follows: weak (intensity class 1), medium
150 (intensity class 2), strong (intensity class 3) reactions and clear evidence of injuries (intensity class 4).

151 *3.2. Detection of past avalanche events in growth disturbance series*

152 To detect past snow avalanche events in GD series, we employed the four-step procedure proposed by Favillier et
153 al. (2017); please refer to Fig. 2 for details. We restricted the avalanche reconstruction to the period for which at
154 least 10 trees were alive. In addition, we adjusted the minimum number of GDs and Shroder's It index (Shroder,
155 1978) in a way to account for changes in sample depth (Butler and Sawyer, 2008; Corona et al., 2012). Definition
156 of these thresholds depends on the nature of the avalanche path and the type of vegetation, and sometimes needs
157 to be adjusted to the study site. For this reason, we employed thresholds that were less rigid than those proposed
158 by Favillier et al. (2017) so as to (1) to maximize the frequency of reconstructed events while still (2) taking sufficient
159 care not to include noise in the reconstruction. To optimize the reconstruction, we considered preferentially trees
160 located in the release area and within the tracks for the reconstruction of snow avalanches. We added GDs
161 observed in ring series of trees located in the runout zone of more than one avalanche path (S2–S3; Fig; 3a) as
162 additional evidence of past events.

163

164 **Figure 2.** Synoptic diagram of the 4-step approach used for the detection of avalanche events in tree-ring series,
 165 adapted from Favillier et al. (2017). Growth disturbance (GD) and Shroder's It index (It) thresholds vary according
 166 to sample size: (a) <20 trees; (b) 20 to 49 trees; (c) 50 to 99 trees; and (d) ≥ 100 trees. We analyzed avalanche
 167 events occurring at the same time as larch budmoth outbreaks (LBM) or climatic events again and assigned
 168 confidence levels to this dating according to the weighted index factor (Wit).

169 In a second step (Fig. 2), we identified years with larch budmoth (LBM) outbreaks and climatic extremes (cold/dry
 170 years) as they could potentially bias the avalanche reconstruction. Saulnier et al. (2017) recorded LBM outbreak
 171 years at the study site. The homogenized temperature (1780-2014) and precipitation (1800-2002) records from the
 172 HISTALP grid points located nearest to the study site (Chimani et al., 2013; Efthymiadis et al., 2006) allowed the
 173 computation of extremely cold and dry summers. Table 2 presents the list of LBM events and extreme summers
 174 found at the study site. In case that potential avalanche events detected in step 1 coincide with LBM years or
 175 climatic extremes, we analysed tree-ring records again to avoid erroneous reconstruction of snow avalanches. In
 176 these years, we systematically excluded abrupt growth suppressions from the GD record. In addition, a minimum
 177 threshold of 3 GDs enabled the discrimination of avalanche from non-avalanche events (Fig. 2). In a third step, we
 178 assigned levels of confidence to each avalanche event based on the weighted index factor (Wit) proposed by
 179 Kogelnig-Mayer et al. (2011) accounting for GD type and intensity as follows: very high (vHLC, $Wit > 0.3$), high
 180 (HLC, $0.3 > Wit > 0.2$) and medium (MLC, $Wit < 0.2$) (Favillier et al., 2017). To increase the stringency of the
 181 approach further, we rated each event detected during step 1 and events coinciding with LBM or climatic events in
 182 step 2 with a low level of confidence (LLC) (Fig. 2). In a last step, we mapped avalanche events and associated
 183 GDs using the ArcGIS 10.2.1 Time Slider (ESRI, 2013; Kennedy, 2013). On the basis of the position of impacted

184 trees, we categorized avalanches with a length <600 m, 600-800m, 800-1000m, 1000-1200m, 1200-1400m, and
 185 <1400 m as eXtra-Small (XS), Small (S), Medium (M), Large (L), eXtra-Large (XL), eXtra- eXtra-Large (XXL)
 186 avalanches, respectively. Fig. 2 summarizes the thresholds employed in the four-step procedure with respect to the
 187 minimal number of GDs, their intensity and the minimum percentage of disturbed trees. At the scale of individual
 188 paths, we computed the annual probability for an avalanche event by dividing the number of reconstructed events
 189 by the period covered by the reconstruction.

190 **Table 2.** Larch budmoth years (in bold) and pointer years (in italics) – according to Saulnier et al. (2017) – as well
 191 as extremely cold (*) and dry summers (**) (Efthymiadis et al., 2006; Saulnier et al., 2011) recorded in the French
 192 Alps. A careful analysis of these years enables detection of possible interferences between snow avalanche
 193 damage in trees and LBM and/or climatic signals. Both LBM and climate events may induce growth reductions
 194 comparable to those observed after snow avalanches in the tree-ring series.

196 3.3. Documentation of forest dynamics

197 Time series of cartographic documents are reliable indicators of spatio-temporal dynamics of forest stands
 198 (cadastral, topographic maps, aerial photographs; Houghton et al., 2012). In France, the oldest map yielding data
 199 on evolution is the Napoleonic cadastral map from the early 19th century. Specifically created for taxation purposes
 200 (Eynard-Machet, 1993), this map offers a precise and detailed record of land ownership and use at the level of
 201 allotments (Coughlan, 2013). At Souliers, the Napoleonic cadastral map dates to 1827. We used it as a baseline
 202 for the documentation of forest cover changes. In addition, we analyzed pictures from 5 aerial flight campaigns from
 203 the French National Geographic Institute (IGN; <1:30,000) to detect forest changes, namely in 1945, 1971, 1981,
 204 2003 and 2015. Image interpretation was realized with standard photographic keys (i.e., tone, texture, pattern,
 205 shape, and size) and supplemented with secondary information on geomorphology, historical vegetation maps, and
 206 ground truth data. Based on these physiographic constraints, we realized visual interpretation and digitalization
 207 (Kennedy, 2013) at the path scale to generate maps of forest cover patterns for each of the dates, allowing

208 quantification of forest cover changes between 1945 and 2015 for each path and for 100-m elevation bands using
209 ArcGIS 10.2.1 (ESRI, 2013). In addition, this analysis also investigated data from 11 aerial flight campaigns with
210 lower-resolution images (>1:30,000) to detect evidence of high-magnitude snow avalanches that would have
211 destroyed the forested stands partially between 1945 and 2016.

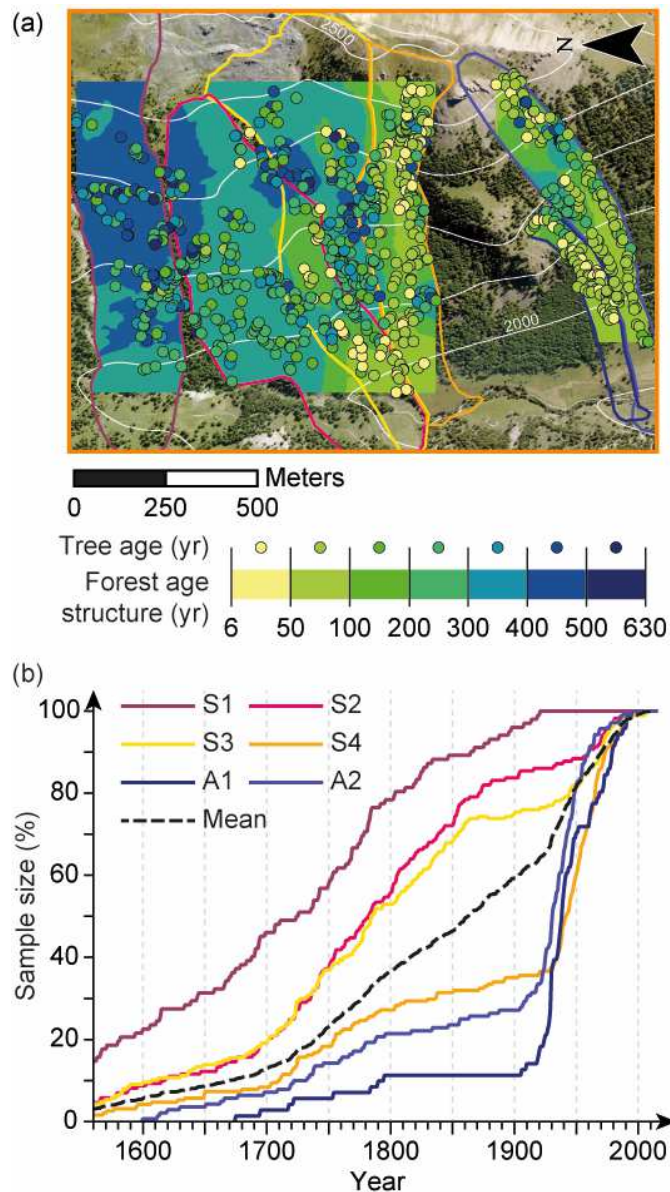

212 The age structure of the stand also served the assessment of forest dynamics for each path. For this purpose, we
213 approximated the number of tree rings in each of the selected trees. Whenever the pith was not present on a core,
214 we estimated the number of missing rings using the “*Estimate Distance and Rings to Pith*” function of the coo-
215 recorder 9.0 software (Larsson, 2016). In this study, sampling positions ranged from 0.2 to 1.5 m above ground
216 level. To compensate for the time elapsed from germination until a tree reaches sampling height, we added an age
217 correction factor (Bollschweiler et al., 2008; Bosch and Gutiérrez, 1999; Muntán et al., 2004). We estimated age at
218 sampling height in comparison to nearby *L. decidua* trees with according heights, for which the age could be easily
219 determined by counting branch whorls (Sorg et al., 2010).

220 **4. Results**

221 *4.1. Evolution of the forest cover*

222 Trees sampled in the six paths were, on average, 186.1 ± 126 years old. The oldest tree sampled in path S2 was
223 628 years old whereas the youngest tree (S3) reached sample height in 2010. Amongst the individuals sampled on
224 the Grand Bois de Souliers slope, 40.6% of the sampled trees were less than 100 years old and 26.7% had between
225 200 and 300 growth rings at sampling height. One-fifth of all trees was older than 300 years (19.2%) and 8.3% of
226 the sampled trees were at least 400-year-old. The spatial distribution of trees shows clear spatial patterns with three
227 homogeneous areas (Fig. 3a): (1) an old-growth forest stand mainly composed of >300-year old trees in the
228 northern part of the slope (S1-S2), (2) a cluster (S2-S3) where the distribution of tree ages ranges between 100
229 and 300 years but does not exceed 100 years at the margins of the main tracks, and (3) several clusters of
230 senescent trees above 2200-2300 m asl.

231 Tree-ring data also provide valuable information on forest dynamics for the last century (Fig. 3a). Tree ages are
232 significantly higher in paths S1 (306 ± 122 yrs), S2 (229 ± 122 yrs) and S3 (225 ± 128 yrs) than in S4, A1 and A2 where
233 tree ages averaged 137 ± 120 , 92 ± 70 and 128 ± 97 yrs, respectively. In paths S1-S3, sample depth exceeds 10%
234 after 1620 CE and steadily increased between 1730 and 1860 (Fig. 3b). In these three paths, >70% of the sampled
235 trees were present in 1860. Sample size evolved only moderately during the 20th century. By contrast, in paths S4
236 and A1-A2, sample size evolves moderately from 18.3, 5.5, and 14.3% in 1750 CE to 36.1, 16.9, and 33.6% in
237 1920, respectively. The number of sampled trees remains <40% before 1920 but sharply increases during the
238 interwar period to exceed 80% after World War II. Here, results suggest a rapid colonization of the central part of
239 the paths between the 1920s and the 1960s.

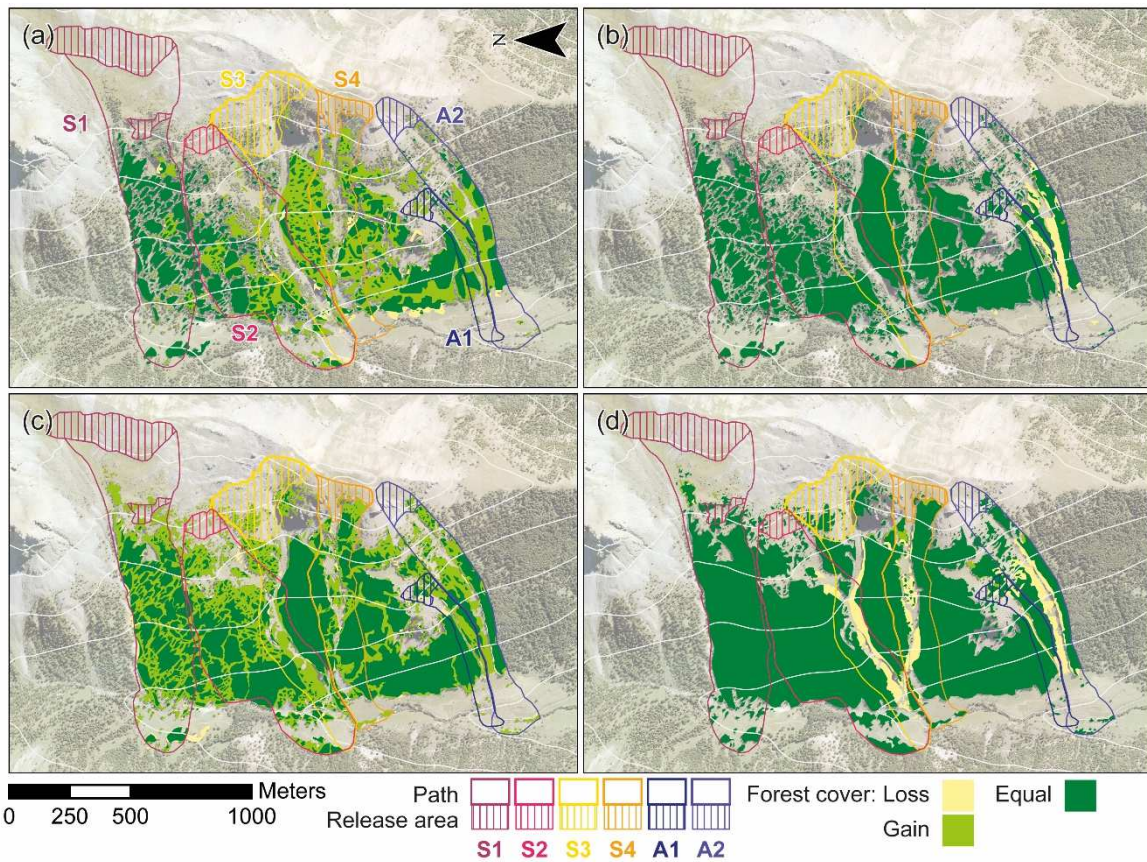

240

241 **Figure 3.** Age structure of the forest stand growing at Grand Bois de Souliers: (a) spatial distribution of individual
 242 tree and interpolated stand ages; (b) evolution of the sample size at the six avalanche paths. The black line
 243 represents the mean sample size evolution.

244 At the slope scale, historical maps and aerial photographs usefully supplement tree-ring data to document forest
 245 evolution since the mid-19th century. At the Grand Bois de Souliers slope, the Napoleonic Cadastral map from
 246 1827 shows a binary landscape with allotments (Getrille and Clos de la Chaussolle) between 2100 and 2300 m asl
 247 mainly occupied by larch stands, whereas rocks and scree covered with shrubs and herbs take over above 2300
 248 m asl. Landscape changes appears rather limited between 1827 and 1945, but resolution obviously differs between
 249 the cadastral map and the aerial photographs. Between 1945 and 1971 (Fig. 4), diachronic comparison of aerial
 250 pictures reveals rapid forest sprawl, mostly in paths S1-S3, and an increase of forested areas between 2100 and
 251 2300 m asl by 9 ha (+71.1%, Fig 5). In addition, the expansion of young trees on bare areas is clearly visible above

252 2300 m asl in S1-S3 (+0.72 ha). Between 1981 and 2015, forest colonization was ongoing above 2300 m asl (+9.6
 253 ha), i.e. in a zone where avalanches are usually released. Over the full period covered by aerial pictures (1945–
 254 2015), the forested surface has more than doubled at Grand Bois de Souliers (32.7 vs. 89.7 ha or +274.3%).

255

256 **Figure 4.** Diachronic evolution of the forest stands at Grand Bois de Souliers between 1945 and 2015: (a) 1945–
 257 1971, (b) 1971–1981, (c) 1981–2003, and (d) 2003–2015.

258

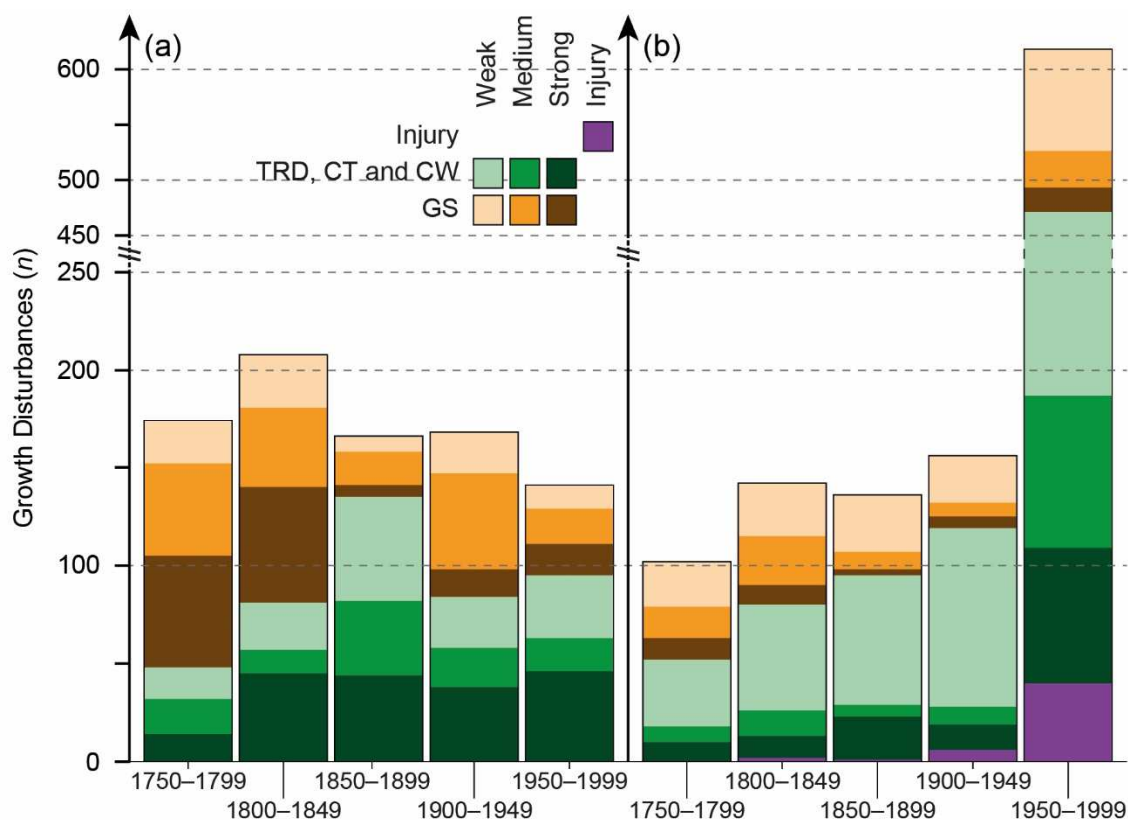

259 **Figure 5.** Evolution of the surfaces occupied by larch stands, computed for 100-m elevation bands, (a) at Grand
 260 Bois de Souliers; within (b) avalanche paths S1-S3; and (c) paths S4, A1 and A2 as delineated in Fig. 1.

261 *4.2 Past snow avalanche activity*

262 Comparison of the 16 additional aerial photographs available for the period 1945-2016 allowed retrieving signs of
 263 past avalanche events through the identification of avalanche-induced forest damage or avalanche deposits.
 264 Comparisons of aerial photographs of 1971–1974 and 2003–2009 allowed a delineation of the events listed in the
 265 CLPA for 1972 and 2008, respectively. We could not retrieve additional events in the 10 other photographs covering
 266 the periods 1945–1948, 1952–1971, 1974–2003, and 2009–2013 (Fig.4).

267 Analysis of the 825 trees sampled in the six paths allowed identification and dating of 2,460 GDs (1750-2016) with
 268 annual resolution. Table 3 summarizes the number and types of GDs identified at the slope and path scales. The
 269 mean number of GDs per tree is significantly lower in paths S1-S3 (1.85, 2.1, and 1.7 GD.tree⁻¹, respectively) as
 270 compared to paths S4, A1-A2 (3.7, 3.8, and 4.8 GD.tree⁻¹, respectively). Figure 6 shows types of GDs computed
 271 for the time windows 1750-1799, 1800–1849, 1850-1899, 1900-1949, and 1950–1999 in paths S1-S3 (Fig. 6a) and
 272 S4-A1-A2 (Fig. 6b). In paths S1-S3, the mean number of GDs progressively decreased from 41.6 GD.decade⁻¹
 273 (n=208 GDs) in 1800-1849 to 28.2 GD.decade⁻¹ (n=141 GDs) in 1950–1999. Conversely, in paths S4-A1-A2, we

274 detect a significant increasing trend from 20.4 GD.decade⁻¹ (n=102 GDs) in 1750-1799 to 122.4 GD.decade⁻¹
 275 (n=612 GDs) in 1950–1999. For all paths, a clear shift is visible in the spectrum of mechanical damage: the
 276 percentage of growth suppression in the spectrum of mechanical damage decreased inversely proportional to the
 277 percentage of callus tissue, tangential rows of traumatic resin ducts and compression wood. In addition, in paths
 278 S4 and A1-A2, the proportion of injuries increased during the 19th century. Based on the 4-step procedure, the
 279 reconstruction of past events includes 974 GDs (40%). At the opposite, the procedure excluded 1460 GDs (60%)
 280 from analysis as they were noise and were not related to past snow avalanche activity. Amongst the 974 GDs, 314
 281 had intensities of 3 or 4 are thus considered the more robust indicators of snow avalanching.

282
 283 **Figure 6.** Bar plots showing the distributions of GD types and intensities between 1750 and 2000 for paths (a) S1-
 284 S3 and (b) S4-A1-A2.

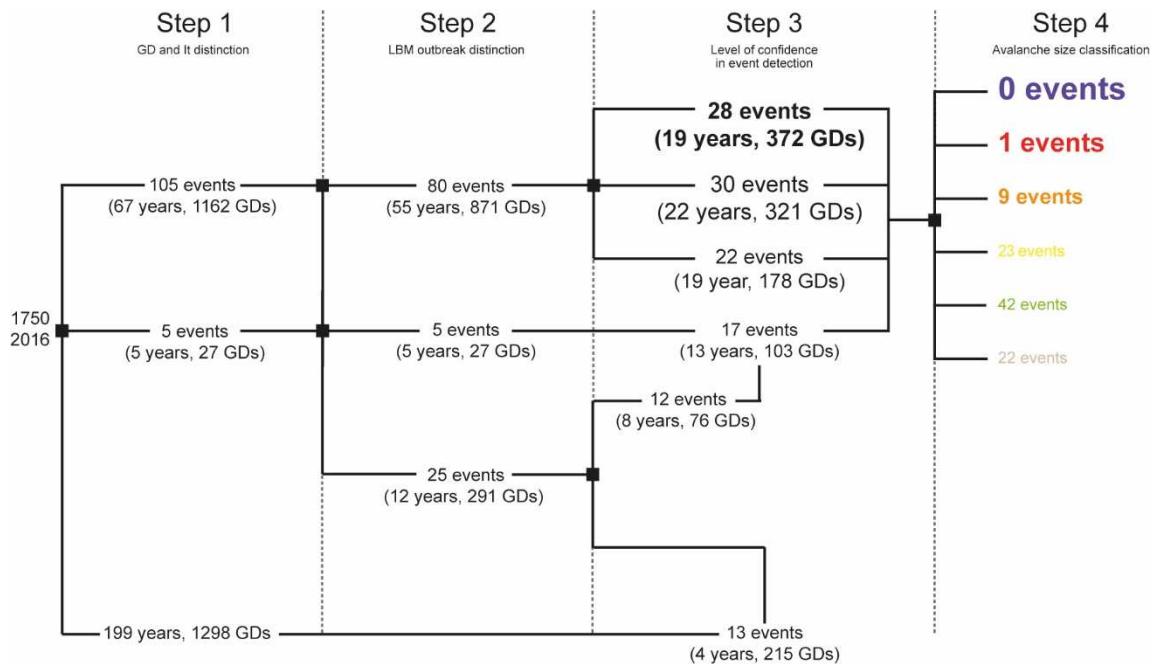

285 **Table 3.** Intensities of reactions and types of growth disturbances (GD) assessed in the 825 larch trees selected
 286 for analysis.

Path	Impact scars (n)	Mechanical disturbances			Growth suppression			Total
		TRD, CT, CW (n)			(n)			
		strong	medium	weak	strong	medium	weak	
S1	0 (0%)	45 (1.8%)	11 (0.4%)	21 (0.9%)	57 (2.3%)	42 (1.7%)	13 (0.5%)	189 (7.7%)
S2	0 (0%)	70 (2.8%)	48 (2%)	88 (3.6%)	81 (3.3%)	96 (3.9%)	54 (2.2%)	437 (17.8%)
S3	0 (0%)	46 (1.9%)	17 (0.7%)	22 (0.9%)	31 (1.3%)	49 (2%)	26 (1.1%)	191 (7.8%)
S4	48 (2%)	80 (3.3%)	44 (1.8%)	218 (8.9%)	43 (1.7%)	86 (3.5%)	182 (7.4%)	701 (28.5%)

A1	4 (0.2%)	31 (1.3%)	32 (1.3%)	128 (5.2%)	12 (0.5%)	12 (0.5%)	53 (2.2%)	272 (11.1%)
A2	17 (0.7%)	84 (3.4%)	65 (2.6%)	305 (12.4%)	33 (1.3%)	55 (2.2%)	111 (4.5%)	670 (27.2%)
Total	69 (2.8%)	356 (14.5%)	217 (8.8%)	782 (31.8%)	257 (10.4%)	340 (13.8%)	439 (17.8%)	2460 (100%)

287

288 Dendrogeomorphic analysis allowed the dating of 97 snow avalanches (Fig. 7) occurring in 67 different years.
 289 Except for path A1 where the number of trees is insufficient to reconstruct avalanches before 1908, the sample
 290 depth exceeds the minimal threshold ($n=10$) for the period 1750-2016. In total, we reconstructed 6, 11, 11, 23, 10,
 291 and 36 avalanche events in paths S1, S2, S3, S4, A1 and A2, respectively. The oldest event occurred in 1756 on
 292 S2 whereas the most recent avalanche occurred in paths A1-A2 in 2015. Based on possible interferences between
 293 avalanche activity, climatic, and LBM signals in the tree-ring record (step 2), and based on the Weighted Index
 294 Factor (Wit; step 3, Figs. 7-8), we assigned very high and high levels of confidence to 28 and 30 events,
 295 respectively. By comparison, we reconstructed 22 events with a $Wit < 0.2$, and characterized by a majority of weak
 296 and medium GDs, therefore rated with a LLC. We excluded 13 out of the 30 potential events coinciding with LBM
 297 outbreak episodes or extreme climatic years and we rated the 17 remaining events with an LLC (Fig. 7). At the
 298 annual scale, frequencies reached the highest values in the years 1808, 1908, 1933, 1971, 1972, 1984, and 2004,
 299 during which we reconstructed a snow avalanche on 3 out of 6 paths. Interestingly, we retrieved the two events
 300 mentioned in the CLPA for 1972 and 2008 with an LLC in S4-A1-A2 and with a vHLC in S4-A2, respectively.

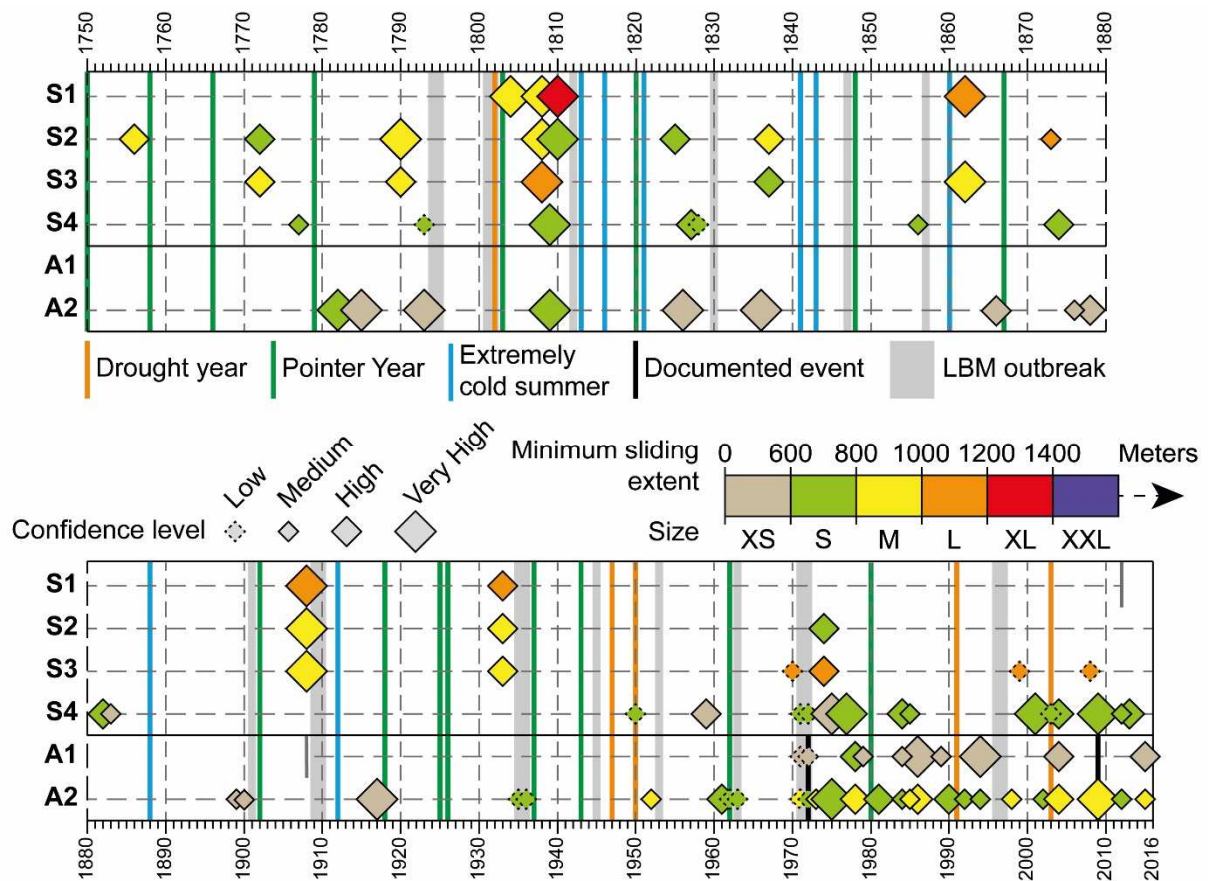

301

302 **Figure 7.** Synoptic diagram showing the characteristics of the reconstructed snow avalanche events and possible
 303 interferences with climate or larch budmoth outbreaks, level of confidence, and minimum slide extent.

304 Considering all reconstructed events, the mean recurrence interval of avalanches at Grand Bois de Souliers is 2.8
 305 years (or 3.6 events per decade) for the period 1750–2016. The recurrence interval is not constant over time but

306 shows a clear decrease from 5.9 years for the periods 1750–1850 and 1851–1950 to 2 years between 1950 and
 307 2015. Decadal frequencies reach their maximum between 1772 and 1793 (9 events), 1804–1810 (8 events), 1825–
 308 1837 (7), 1932–1937 (5), 1970–1986 (13), and 1999–2009 (10) (Fig. 8). Conversely, the number of reconstructed
 309 events decreased drastically between 1838 and 1861 (1), 1884–1900 (1), 1912–1930 (1), 1938–1959 (2), 1964–
 310 1969 (0), and 1987–1998 (5) (Fig. 8). At the path scale, the frequency of events sharply increased in A1 and A2
 311 since 1970. In these paths, the number of reconstructed events increased from 0 to 10 and from 6 to 18 for the
 312 periods 1924–1969 and 1970–2016, respectively. By contrast, tree-ring analyses in paths S1 and S2 did not
 313 evidence any events since 1933 and 1974 whereas GDs in tree-ring series revealed only 2 avalanches with LLC in
 314 S3 since 1974 (Fig. 8). Decadal frequency of events ranged between 0.3 (S1) and 0.68 events.decade⁻¹ (S4, A2)
 315 for the period 1750–1882 but is very heterogeneous between paths: while it is <0.2 event.decade⁻¹ in paths A1–A2,
 316 values exceeds 1 event.decade⁻¹ in S4 (1.1) and S2 (2.04) for the period 1883–2016.

317

318 **Figure 8.** Avalanche events reconstructed for the period 1750–2016 in six paths at Grand Bois de Souliers. Symbol
 319 sizes are proportional to the level of confidence. The color range highlights the minimum slide extent determined
 320 from the position of impacted trees. Grey bands represent years associated to LBM outbreaks. Vertical lines show
 321 snow avalanches documented in chronicles (black), as well as extremely dry (orange) and cold (blue) summers.

322 **5. Discussion**

323 The study we report here employs dendrogeomorphic techniques in six avalanche paths at Grand Bois de Souliers
324 with the aim to discuss interrelations between forests stand dynamic and snow avalanche activity as documented
325 by tree rings. To meet this objective, we used the detection procedure developed by Favillier et al. (2017) (1) to
326 disentangle snow avalanche signs in tree-ring records from signals induced by climatic or ecological disturbances
327 and (2) to qualify the robustness of our tree-ring based snow avalanche reconstruction. This procedure allowed the
328 reconstruction of 97 snow avalanche events in 67 different avalanche years back to 1750 CE. In parallel, a
329 diachronic analysis of cartographic documents and age estimates of the stand structure allowed quantification of
330 forest structure evolution, as well as the illustration of the afforestation process in the selected paths since the mid-
331 18th century. In detail, our study reveals a strong dichotomy between paths S1, S2, and S3 (Group 1, G1) where
332 the reconstructed chronology highlights the progressive disappearance of snow avalanche activity since the 1930s
333 on one side and paths A1, A2 and to a lesser extent S4 (Group 2, G2) for which the recurrence intervals drastically
334 increased since the 1970s on the other side. Forest cover evolution further reinforced this difference with a gradual
335 increase in paths S1, S2, and S3 since 1750, whereas it showed an abrupt extension only around the 1920s in the
336 other paths.

337 *5.1 Non-stationarity of the dendrogeomorphic reconstruction potential in paths A1, A2 and S4*

338 For the paths of Group 2, we attribute the increase in the avalanche frequency over the last decades to a non-
339 stationarity in the potential of dendrogeomorphic approaches to capture past snow avalanches. As such, we could
340 attribute this non-stationarity to the underestimation of hidden scars as reported by Stoffel and Perret (2006): as
341 conifers mask scars of past events effectively, the detection and/or positioning of old scars on the stem surface
342 remain complex, rendering determination of suitable sampling positions a difficult task. It is thus possible to miss
343 older events on increment cores of *L. decidua*, and older trees will tend to yield data on fewer impacts relative to
344 their age (Trappmann and Stoffel, 2013). Corona et al. (2012) evidenced that snow avalanche chronologies derived
345 from tree-ring series tend to underestimate process activity by roughly 60%. In a more recent study, however, de
346 Bouchard d'Aubeterre et al. (2019) demonstrated that paths covered by forests up to release zones allow to
347 reconstruct both exhaustive—up to 70% of the real snow avalanche activity—and reliable snow avalanche
348 chronologies over longer time periods. Accordingly, the number of reconstructed snow avalanche events must be
349 considered as a minimum frequency in our study. As geomorphic characteristics and forest cover of the studied
350 paths are similar to those of the Ravin de la Salce (de Bouchard d'Aubeterre et al., 2019), we consider that the
351 reconstructed activity in our study is close to real snow avalanche activity.

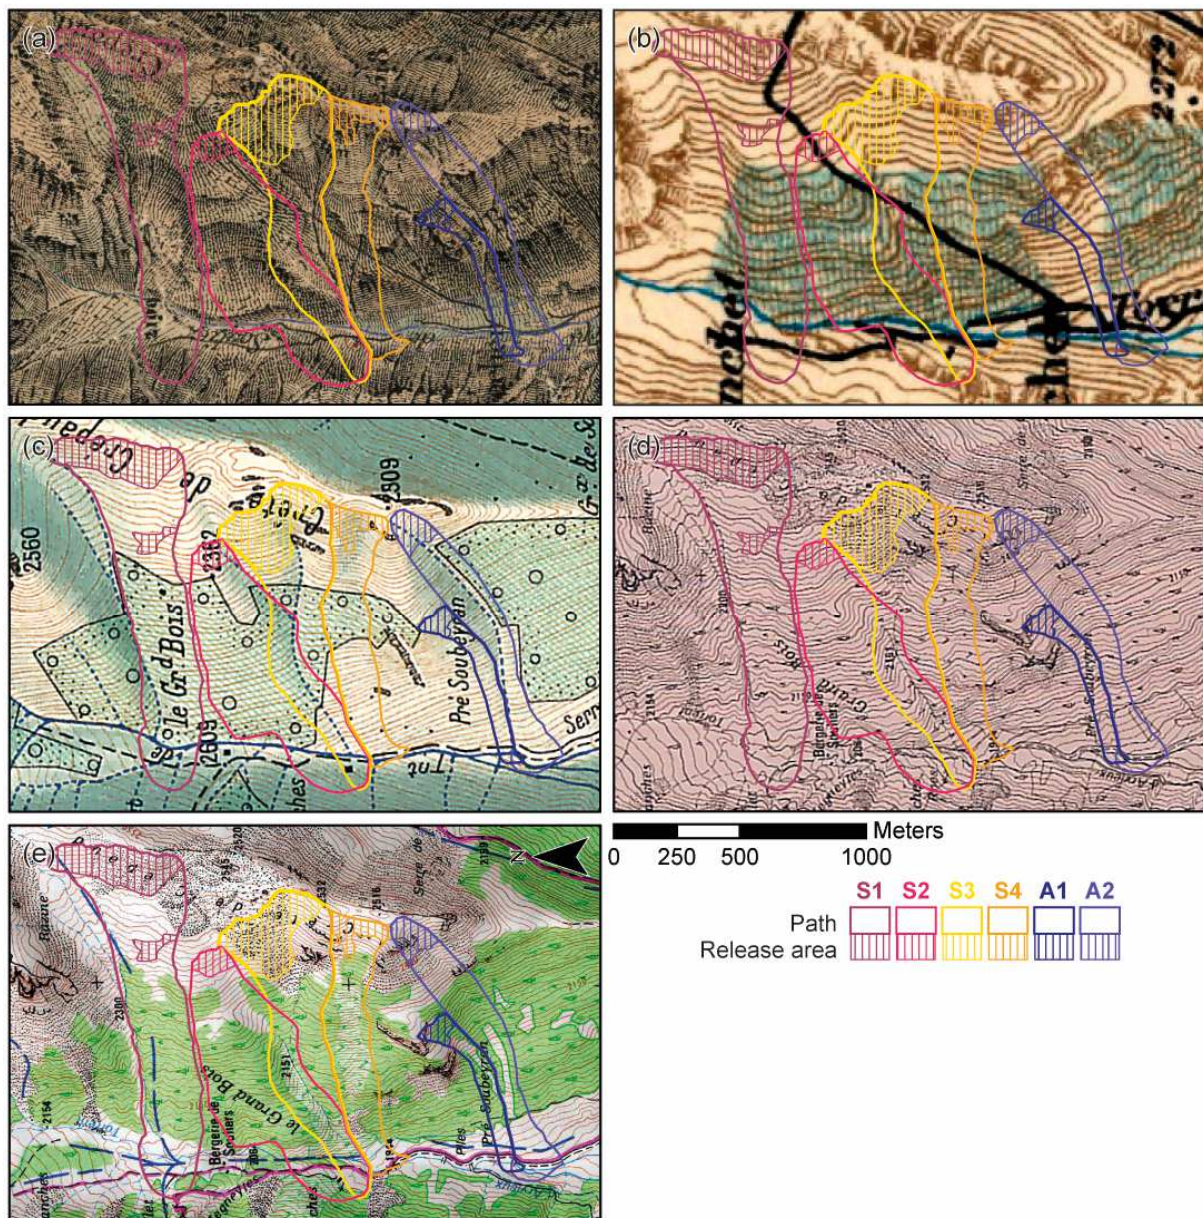

352 Secondly, we could also attribute the tipping point observed in the reconstructions of Group2 paths in the 1970s to
353 forest recolonization after an avalanche event destroying large parts of the forest stands, thereby removing
354 evidence of past and subsequent events (e.g. Bryant et al., 1989; Carrara, 1989, 1979; Corona et al., 2012; Dubé
355 et al., 2004; Germain et al., 2005; Kogelnig-Mayer et al., 2011, Larocque et al., 2001; Rayback., 1998). We could

356 not retrieve evidence for such an extreme event from GDs detected between 1880 and 1920 in trees from paths
357 S4, A1 and A2. Yet, the distribution of tree ages in paths A1-A2 and S4, showing a sharp increase in sample depth
358 during the 1930s and signs of forest recolonization on topographic maps between 1896 and 1933 (Fig. 9b, c),
359 supports the occurrence of such an event. On the site cleared by powder-snow avalanche in 2008, *L. decidua*
360 seedlings tend to recolonize avalanche paths at Grand Bois de Souliers within only a few years after a geomorphic
361 event. One may therefore reasonably assume that an avalanche that would have occurred in the early 1910–1920
362 could have given rise to a new forest stand in the 1930s, and that this growing forest would have recovered its
363 complete “dendrogeomorphic potential” in the 1970s. This assumption and the lags are in line with observations of
364 a sharp increase in avalanche activity observed at Täsch (Swiss Alps; Favillier et al., 2018). Here the increase in
365 reconstructed avalanche activity in the 1960s was the result of an extreme avalanche event that destroyed a
366 400×800 m forest strip in 1920. It thus seems reasonable to suggest that a forest stand will need up to 40–50 years
367 to reach its full “dendrogeomorphic potential” after an extreme event. Obviously, the above-mentioned time period
368 is strongly dependent of the intensity of the destructive event, the altitude of the forest stands and the recruitment
369 rate of the considered tree species.

370 *5.2 Non-stationarity of the snow avalanche activity related to slope afforestation*

371 In the paths of Group 1, the frequency of GDs and avalanche events detected in the tree-ring series decreased
372 since the 1930s. In these three paths, the oldest trees are more than 500 years old and most of the sampled trees
373 exceed 200 years. In addition, forests continuously expanded since ca. 1540, and especially during the 18th century.
374 The presence of multi-centennial trees in avalanche paths suggests the absence of extreme events since the mid-
375 16th century as otherwise extreme avalanches would have destroyed the forest stand. Furthermore, evidence for
376 more moderate snow avalanching as compared to Group2 exists via the more limited number of GDs (n=857)
377 identified and dated in the tree-ring series from the 461 trees sampled in this sector and via the absence of injuries
378 (intensity 4 damage). By contrast to Group1, the dendrogeomorphic potential in the paths of Group2 appears to be
379 constant over time and reconstructions should thus properly reflect the natural fluctuations of avalanche activity.
380 Yet, we should not dissociate conservation of the forest from human activity at Souliers. Saulnier (2012) reports
381 that specific silvicultural rules existed since “immemorial times” at Grand Bois de Souliers to maintain the protective
382 function of the forest stand. Interestingly, Roman (1887) and Gadoud (1917) indicate a multiplication of protective
383 regulations between the 13th and 15th centuries in the Queyras massif aimed at preventing forest overexploitation
384 or destruction. The proclamation of these regulations coincides with the age of the oldest trees in paths S1 and S2.
385 From a perspective of process dynamics, our reconstruction shows a moderate, yet continuous avalanche activity
386 in paths S3 and S2—and to a lesser extent in S1—between the mid-18th century to the 1930s that decreased
387 sharply thereafter. This evolution is most likely related to the afforestation of several release areas that is clearly
388 visible through the analysis of aerial photographs since 1945. Indeed, the presence of trees is a decisive factor

389 stabilizing snowpack by (1) increasing terrain roughness (2) intercepting falling snow, (3) modifying radiation and
 390 temperature regimes and by (4) reducing near-surface wind speeds (de Quervain, 1978; Leitinger et al., 2008;
 391 McClung, 2003; Salm, 1978). Schneebeli and Bebi (2004) demonstrated that these effects considerably limit
 392 avalanche formation to the steepest slopes (>35°).

393
 394 **Figure 9.** Diachronic comparison of topographical maps of (a) 1866, (b) 1896, (c) 1933, (d) 1971, and (e) 2015.
 395 According to the labelling system of each map, forest cover is represented by green polygons on the maps dated
 396 to (a) 1866, (b) 1896, (c) 1933 and (e) 2015, and with conifers like pictograms on (d) the 1971 map. Germination
 397 dates of sampled trees suggest that a devastating avalanche in the 1910s or 1920s cleared the forested surface in
 398 paths S1-A1-A2. Topographic maps support this interpretation by showing the absence of a forest (c) in 1933 and
 399 an almost complete (re)colonization (d) in 1971 and (e) in 2015.

400 Even if the interrelations between a decrease of snow avalanche activity and forest expansion are undoubted, the
401 causes for this evolution are less easily understood. Indeed, one should keep in mind that forest colonization in
402 paths S1-S3 dates to Medieval times as testified by the age structure of sampled trees and that the forest expanded
403 continuously, especially during the 18th and 19th centuries. This trend is in line with the forest expansion observed
404 at Chateau-Ville-Vieille (and at the scale of the Queyras massif), where forested areas increased from 357 ha (4400
405 ha in the Queyras massif) in 1747 to 2,325 ha (16,000 ha) in 1908 (Gadoud, 1917). The anthropogenic global
406 warming cannot reasonably explain pre-industrial afforestation. According to Touflan et al. (2010) and Chauchard
407 et al. (2010), forest and grazing management induced significant recruitment of *L. decidua* during the 18th and the
408 19th centuries. Larch is not only an early successional species, but also favored by shepherds because of its
409 compatibility with grazing activities. The deciduous foliage of larch, with its soft needles and its low tree density,
410 ensures high grass productivity and offers shelter from rain and intense sunlight to both cattle and sheep (Carrer
411 and Urbinati, 2001; Chauchard et al., 2010; Motta and Lingua, 2005). In addition, larch is probably more resistant
412 to trampling as compared to swiss stone pine or silver fir and its wood is also more valued for its natural decay
413 resistance, high density and aesthetic value (Chauchard et al., 2010). In addition, the strong decrease of livestock
414 from 6808 units (LU) in 1836 (Granet-Abisset, 1994), to 3015 LU in 1961 (Leynaud and Georges, 1965), and 1994
415 LU in 2010 (AGRESTE, 2012), resulting from a rural exodus (Chauchard et al., 2007; Didier, 2001; Motta and
416 Garbarino, 2003), is an imprint of the progressive abatement of livestock grazing in the Queyras. The reduced
417 livestock pressure and rural exodus certainly explains part of the upward shift of larch trees at Souliers as it
418 coincides with the demographic evolutions in (1) the Chateau-Ville-Vieille municipality where the number of
419 inhabitants decreased from 1440 in 1763 to 766 in 1911 and (2) in the Queyras massif where the 1911 census
420 population (4094 inhabitants) was lower to the one of 1700 (5310 inhabitants) (Blanchard, 1915).

421 Finally, we cannot exclude potential influences of decreasing trends in snow cover depth (Beniston et al., 2018;
422 Durand et al., 2009; Reid et al., 2016) and snow cover duration (Beniston, 1997; Uhlmann et al., 2009) on
423 avalanche-forest interactions through direct impacts on avalanche frequency (Eckert et al., 2010c; Ballesteros-
424 Cánovas et al., 2018) and the nature (Pielmeier et al., 2013; Naaim et al., 2016) of snow avalanches. At Grand Bois
425 de Souliers slope, it is therefore possible that the increase in the tree-line in the 20th century was a mere bounce-
426 back to a level without depression by previous anthropogenic activity (Gehrig-Fasel et al., 2007), rather than a
427 climatically induced advance of the tree-line. Similarly, (i) the absence of clear trends in avalanche frequency in
428 Group2 since the 1970s, (ii) the rather weak decrease in snow amounts and snow cover duration documented so
429 far in the Southern French Alps (Durand et al., 2009; Castebrunet et al., 2014) at the altitudes at which the
430 avalanche release areas are located, and (iii) the rather limited changes documented over the last decades in
431 avalanche occurrence numbers around the study area (Eckert et al., 2013; Lavigne et al., 2015) further suggest
432 limited impacts of global warming.

433 **6. Conclusion**

434 In summary, this study provided answers to the two research questions posed: (i) how does past forest cover
435 evolution induce non-stationarities in tree-ring reconstructions of snow avalanche activity? (ii) How are trends
436 inherent to tree-ring approaches distinguishable from real fluctuations in avalanche activity?

437 First, two distinct types of non-stationarities were identified in the reconstructed avalanche activity. In the three
438 paths located in the southern part of the slope, a strong increase in avalanche frequency occurred since the 1970s.
439 The distribution of tree ages retrieved from dendrogeomorphic analyses, in combination with old topographic maps,
440 allowed attributing this non-stationarity to rapid afforestation of the snow avalanche paths. In the northern paths,
441 the frequency of reconstructed events decreased in S1 during the 1930s and in S2-S3 after World War II. This non-
442 stationarity is related to the densification of the forest stands in these paths since the 18th century and to the
443 colonization of the release areas during the 20th century.

444 Second, the rapid afforestation evidenced in the three southern paths of the slope is related to a forest recolonization
445 process induced by a snow avalanche that destroyed the forest stand before the 1930s. On the three northern
446 paths, the identified non-stationarity indicates a decrease in snow avalanche activity induced by forest colonization
447 processes. Even if global warming may still play a role in this evolution—by speeding up forest colonization or
448 weakly decreasing available snow amounts in S1-S3—, both dynamics are explainable by socio-environmental
449 factors. Their impact on forest cover dynamics, namely through forest and grazing management during the 18th
450 century, and the rural exodus and abatement of grazing throughout the 20th century, is particularly evident.

451 These results demonstrate the necessity for a more careful inclusion and consideration of socio-environmental
452 factors—such as the pastoral decline or rural exodus—to better understand and explain ongoing trends in mass-
453 movement activity. More widely, this study calls for more systemic approaches in tree-ring reconstructions to tackle
454 the complex interrelations among forest evolution, global warming, social practices and process activity adequately
455 in the future.

759 Captions

760 **Figure 1.** Location of the studied paths: (a) overview of the Queyras massif (French Alps), (b) detailed view of the
761 Chateau-Ville-Vieille locality within the Queyras massif and the study site (c) detailed view of the six avalanche
762 paths delineated on the Grand Bois de Souliers slope.

763 **Figure 2.** Synoptic diagram of the 4-step approach used for the detection of avalanche events in tree-ring series,
764 adapted from Favillier et al. (2017). Growth disturbance (GD) and Shroder's It index (It) thresholds vary according
765 to sample size: (a) <20 trees; (b) 20 to 49 trees; (c) 50 to 99 trees; and (d) ≥ 100 trees. We analyzed avalanche
766 events occurring at the same time as larch budmoth outbreaks (LBM) or climatic events again and assigned
767 confidence levels to these events according to the weighted index factor (Wit).

768 **Figure 3.** Age structure of the forest stand growing at Grand Bois de Souliers: (a) spatial distribution of individual
769 tree and interpolated stand ages; (b) evolution of the sample size at the six avalanche paths. The black line
770 represents the mean sample size evolution.

771 **Figure 4.** Diachronic evolution of the forest stands at Grand Bois de Souliers between 1945 and 2015: (a) 1945-
772 1971, (b) 1971-1981, (c) 1981-2003, and (d) 2003-2015.

773 **Figure 5.** Evolution of the surfaces occupied by larch stands, computed for 100-m elevation bands, (a) at Grand
774 Bois de Souliers; within (b) avalanche paths S1-S3; and (c) paths S4, A1 and A2 as delineated in Fig. 1.

775 **Figure 6.** Barplots showing the distributions of GD types and intensities between 1750 and 2000 for paths (a) S1-
776 S3 and (b) S4-A1-A2.

777 **Figure 7.** Synoptic diagram showing the characteristics of the reconstructed snow avalanche events and possible
778 interferences with climate or larch budmoth outbreaks, level of confidence, and minimum slide extent.

779 **Figure 8.** Avalanche events reconstructed for the period 1750–2016 in six paths at Grand Bois de Souliers. Symbol
780 sizes are proportional to the level of confidence. The color range highlights the minimum slide extent determined
781 from the position of impacted trees. Grey bands represent years associated to LBM outbreaks. Vertical lines show
782 snow avalanches documented in chronicles (black), as well as extremely dry (orange) and cold (blue) summers.

783 **Figure 9.** Diachronic comparison of topographical maps of (a) 1866, (b) 1896, (c) 1933, (d) 1971, and (e) 2015.
784 According to the labelling system of each map, forest cover is represented by green polygons on the maps dated
785 to (a) 1866, (b) 1896, (c) 1933 and (e) 2015, and with conifers like pictograms on (d) the 1971 map. Germination
786 dates of sampled trees suggest that a devastating avalanche in the 1910s or 1920s cleared the forested surface in

787 paths S1-A1-A2. Topographic maps support this interpretation by showing the absence of a forest (c) in 1933 and
788 an almost complete (re)colonization (d) in 1971 and (e) in 2015.

789 **Table 1.** Main characteristics of the studied avalanche paths. Numerical values correspond to the areas delineated
790 in Fig. 1c and derived from crossed a 5-m DEM.

791 **Table 2.** Larch budmoth years (in bold) and pointer years (in italics) – according to Saulnier et al. (2017) – as well
792 as extremely cold (*) and dry summers (**) (Efthymiadis et al., 2006; Saulnier et al., 2011) recorded in the French
793 Alps. A careful analysis of these years enables detection of possible interferences between snow avalanche
794 damage in trees and LBM and/or climatic signals. Both LBM and climate events may induce growth reductions
795 comparable to those observed after snow avalanches in the tree-ring series.

796 **Table 3.** Intensities of reactions and types of growth disturbances (GD) assessed in the 825 larch trees selected
797 for analysis.
