**Abstract** Single cells represent the basic building units of life, and thus their study is one of the most important areas of research. However, classical analysis of biological cells eludes the investigation of cell-to-cell differences to obtain information about the intracellular distribution since it only provides information by averaging over a huge number of cells. For this reason, chemical analysis of single cells is an expanding area of research nowadays. In this context, metallomics research is going down to the single-cell level, where high-resolution high-sensitive analytical techniques are required. In this chapter, we present the latest developments and applications in the fields of single-cell inductively coupled plasma mass spectrometry (SC-ICP-MS), mass cytometry, laser ablation (LA)-ICP-MS, nanoscale secondary ion mass spectrometry (nanoSIMS), and synchrotron X-ray fluorescence microscopy (SXRF) for single-cell analysis. Moreover, the capabilities and limitations of the current analytical techniques to unravel single-cell metabolomics as well as future perspectives in this field will be discussed.

## 22 Abbreviations

23	ALOD	Absolute limit of detection
24	AP-MALDI	Atmospheric pressure matrix-assisted laser desorption
25		ionization
26	CE	Capillary electrophoresis
27	cryo-XT	Cryo nanoscale X-ray tomography
28	CyTOF	Cytometry by time-of-flight
29	ESI-MS	Electrospray ionization mass spectrometry
30	fs-LI-O-TOFMS	Femtosecond laser ionization orthogonal time-of-flight mass
31		spectrometry
32	HECIS	High-efficiency cell introduction system
33	HPCN	High performance concentric nebulizer
34	ICP-AES	Inductively coupled plasma atomic emission spectrometry
35	ICP-MS	Inductively coupled plasma mass spectrometry
36	ICP-SFMS	Inductively coupled plasma sector field mass spectrometry
37	ICP-TOFMS	Inductively coupled plasma time-of-flight mass spectrometry
38	LADE	Liquid-assisted droplet ejection
39	LA-ICP-MS	Laser ablation inductively coupled plasma mass spectrometry
40	LB-HPCN	Large-bore high performance concentric nebulizer
41	MALDI	Matrix-assisted laser desorption ionization
42	$\mu$ DG	Micro-droplet generator
43	M-DIS	Micro-droplet injection system
44	$\mu$ FI	Micro-flow Injection
45	$\mu$ XRF	Micro-X-ray fluorescence
46	NPs	Nanoparticles
47	PBS	Phosphate-buffered saline
48	PDMS	Poly(dimethylsiloxane)
49	PFH	Perfluorohexane
50	QDs	Quantum dots
51	RR	Ruthenium red
52	SC-ICP-MS	Single-cell inductively coupled plasma mass spectrometry
53	SIMS	Secondary ion mass spectrometry
54	SNMS	Secondary neutral mass spectrometry
55	SOD	Superoxide dismutase
56	SP-ICP-MS	Single particle inductively coupled plasma mass spectrometry
57	SR-nXRF	Synchrotron radiation nano-X-ray fluorescence
58	SXRF	Synchrotron X-ray fluorescence
59	TEM	Transmission electron microscopy
60	TOF-SIMS	Time-of-flight secondary ion mass spectrometry

## 10.1 Introduction

61

An integrated approach of biometal sciences called metallomics is now a well-established research field aimed at understanding the biological functions of metal ions and their chemical structures in biological systems and how their usage is fine-tuned in biological species and in populations of species with genetic variations. In fact, chemistry and biology are expected to come together in investigations of biometals because neither establishing only structures nor finding only functions is sufficient (Maret 2016).

62  
63  
64  
65  
66  
67  
68

Cells are the basic building blocks of all living organisms; they provide structure for the bodies, take in nutrients, convert them into energy, and carry out specialized functions. Thus, study of these “basic units of life” can be considered one of the most important areas of research helping understand how organisms function and how cellular components work together to carry out life functions and enable organisms to meet their basic needs.

69  
70  
71  
72  
73  
74

Most known biological processes depend on metals, and, as a result, the entirety of metal ions present in a cell, including, e.g., Mg, Ca, Mn, Fe, Cu, and Zn, determines its life functions; cells use the physicochemical properties of metal ions to control essential processes. Complexation with metals is a basic functionalization reaction of cell components such as proteins (proteome), metabolites (metabolome), and nucleic acids (genome). Based on their physicochemical properties, metals are recognized, classified, and localized by living cells and then distributed to organelles – such as nuclei and mitochondria – to enable them to perform their functions.

82  
83

Metallomics on the level of single cells seems to be an ultimate goal in the development of the field. Although the establishment of metallomics as a stand-alone scientific field had at its beginnings the study of individual cells (salmon eggs) by Haraguchi et al. (2008), technical limitations have been hampering more advanced investigations at this level due to small size of cells of interest in biological studies; the work with tissue homogenates (or slices in elemental imaging) has been privileged. However, it has to be underlined that cell disruption during sample preparation process (homogenization) results in loss of individual cell properties and mixing cell compartments in a way that is not likely to occur in Nature. For these reasons, development of analytical strategies for characterization of metallome homeostasis at cellular level is necessary for full understanding of life processes. Moreover, studies of individual cells in their integrity undoubtedly possess a philosophical appeal of the fundamental primary approach to explore a microcosm encapsulating the essence of life.

97

The first step in this direction is the determination of total element contents in individual cells. It has been suggested that correlating gene mutations, physiological status, and stress response with the trace element pattern should be carried out on the single-cell level because due to the variability of cells bulk analysis may be not meaningful (Schmid et al. 2010). The technical feasibility of such determination requires a combination of high metal detection sensitivity combined with ultrafast

103

104 data acquisition. Its realization, based on the concept similar to that proposed by  
105 Tanner's group (Bandura et al. 2009) in their mass cytometry scheme of inductively  
106 coupled plasma time-of-flight mass spectrometry (ICP-TOFMS) investigation of  
107 individual cells containing metal-labeled species, has been facilitated by new instru-  
108 mental developments in ICP-MS. They include systems originally designed for the  
109 analysis of nanoparticles by single-particle ICP-MS as well as miniaturized on-chip  
110 sample introductions setups. Multielemental (and multiisotopic) capability of  
111 ICP-MS allows a holistic view of cell microcosms with a perspective to study isoto-  
112 pic distribution and fractionation variability which is expected to bring new insights  
113 into metal utilization by the Nature.

114 The total element analysis is complemented by the development of intracellular  
115 metallome imaging techniques such as nanoSIMS (secondary ion mass spectrome-  
116 try), synchrotron X-ray fluorescence microscopy (SXRF), and, to some extent, laser  
117 ablation (LA)-ICP-MS. NanoSIMS analysis can be performed at lateral resolution  
118 down to 50 nm thus allowing imaging at subcellular level. This methodology, based  
119 on the coaxial design of the ion gun and the secondary ion extraction, allows the  
120 analysis of up to seven ions with multicollection and recently developed oxygen  
121 probe made possible the detection of most of the metals (Nuñez et al. 2018; Pett-  
122 Ridge and Weber 2012). Another powerful tool for measuring element localization  
123 is SXRF based on a spectroscopic analysis of the emission of characteristic fluores-  
124 cence from a material that has been excited by bombarding with high-energy X-rays.  
125 A new (third) generation synchrotron sources, providing high brilliance at high pho-  
126 ton energies and highly advanced X-ray focusing systems, make it possible to visu-  
127 alize intracellular element localization at the sub-100 nm scale. In the case of  
128 nanoSIMS, only square-element mapping is possible (depending on the implementa-  
129 tion energy – up to a few nanometers), while in the case of SXRF, the whole depth  
130 of the cell (up to few  $\mu\text{m}$ ) is accessible. Another, by far more robust and easier  
131 accessible option, is laser ablation ICP-MS offering, however, worse resolution of  
132 down to several  $\mu\text{m}$  (Gundlach-Graham and Günther 2016).

133 Although the ultimate goal of all-species-of-all elements on a single-cell level  
134 seems still to be distant, the first reports on single-cell metabolomics and proteomics  
135 (Rubakhin et al. 2011) open a way to the characterization of metal-containing mol-  
136 ecules at cellular levels. The success in this field is highly dependent on the develop-  
137 ment in small-scale high-resolution molecular mass spectrometry.

138 The present chapter summarizes the developments in metallomics studies on the  
139 level of individual cells highlighting novel approaches and, at the same time, dis-  
140 cussing the current limitations and presenting perspectives of future progress.

## 10.2 Detection and Quantitative Distribution of Metals and Metal Nanoparticles at the Single-Cell Level

141

142

In order to fully understand a biological system such as a cell, it is necessary to determine the trace metals within the system, due to their essential roles in biological or physiological functions. In contrast with stochastic average analysis by bulk measurements, the quantitative analysis of individual cells leads to a more sensitive representation of cell-to-cell variations of content of elements (Miyashita et al. 2017). In this context, single-cell elemental analysis is considered one of the major research fields in metallomics in the next decade (Haraguchi 2017a).

143

144

145

146

147

148

149

However, elemental analysis of individual cells must not be restricted to the investigation of intracellular metal ions. Engineered nanoparticles are already present in our daily life in a number of consumer and industrial products from where they are directly released and incorporated into the environment. As a result, analytical methods to study their uptake by biological systems and, more specifically, by cells are needed.

150

151

152

153

154

155

In recent years, detection and quantitative multielement analysis in a single biological cell has been carried out using various measurement systems. Different applications reported in literature are shown in Table 10.1.

156

157

158

One of the first multielemental analyses in single biological cells was reported by Haraguchi et al. (2008). In this study, two or three salmon eggs were decomposed with HNO<sub>3</sub> by using a microwave-assisted acid digestion method and subsequently analyzed by ICP Atomic Emission Spectrometry (ICP-AES) and ICP-MS. In the experiment, 78 elements were the target of analysis. Sixty-six elements out of these 78 were determined in salmon egg cells, whereas other 7 elements (Li, Zr, Nb, Hf, Ir, Bi) could be only detected close to their detection limit as a result of their low abundance in the sample. The other 5 elements (F, Rh, Te, Ta, Re) were below their detection limit and they could not be determined or detected in this study. However, all these elements except F were detected in a recent experiment by using High Resolution ICP-MS (Haraguchi 2017b). The results supported the concept of the extended all present theory of the elements in a single biological cell, i.e., “cell microcosm,” which postulates the existence of all elements in a single biological cell (Haraguchi 2004). Nevertheless, it has to be taken into account that the size of salmon eggs is bigger than the normal biological cells of study (mm vs μm), which requires the use of higher sensitive techniques.

159

160

161

162

163

164

165

166

167

168

169

170

171

172

173

174

More recently, Umemura et al. (2017) recently reported a multielement quantitative determination (more than 30 elements) of prokaryotic and eukaryotic cells and subcellular organelles, by microflow injection (μFI)-ICP-MS. Preliminary studies performed by ICP-MS in time-resolved mode only allowed the determination of a few major elements, such as P, Mg and Fe, whereas the signal of the other elements

180 could not be distinguished from the single produced by the background. As a result,  
 181 an alternative approach was proposed, based on traditional solution-based ICP-MS  
 182 after microwave-assisted acid digestion of less than 10 mg of dry weight sample.  
 183 The concentration determined by ICP-MS was normalized as number of atoms per  
 184 cell or organelle.

### 185 **10.2.1 Time Resolved ICP-MS Analysis**

186 In recent years, time-resolved ICP-MS, known as single-cell ICP-MS (SC-ICP-MS),  
 187 has attracted a great deal of interest for multielemental analysis of single cells as an  
 188 alternative of classical bulk analysis of large amounts of cells with a lysis, extrac-  
 189 tion, or digestion (Miyashita et al. 2014a, 2017; Mueller et al. 2014; Wang et al.  
 190 2017a). This technique is able to detect and quantify metallic elements in individual  
 191 cells with high sensitivity, with the advantage of obtaining information about cell-  
 192 to-cell variations instead of the average information from large cell populations  
 193 obtained by conventional bulk measurements.

194 SC-ICP-MS is based on the well-established technique of single-particle  
 195 ICP-MS (SP-ICP-MS), whose theoretical basis was outlined by Degueldre and  
 196 Favarger (2003) and further developed by Laborda et al. (2014), that has shown that

information about the particle size and particle number concentration can be derived from the time-resolved signals. Briefly, a cell suspension is introduced into the plasma (via conventional concentric nebulizers or other dedicated introductions systems as it will be discussed later) where droplets containing cells are vaporized and the intrinsic metals inside the cell are atomized and ionized, producing an ion plume that is detected by the ICP-MS as a short transient signal or a spike signal (also called cell event).

Each individual cell produces its own ion plume with a typical duration in the range of 100–500  $\mu\text{s}$  (Miyashita et al. 2017). If the acquisition time (i.e., dwell time) of the detector is longer than the duration of the ion plume generated, signals corresponding to individual cells can be detected as high spikes, whose signal is proportional to the amount of metals in the cell. Therefore, the spike intensity distribution can be correlated with the mass distribution of the metal in the cells. On the other hand, if the dwell time is shorter than the duration of the ion plume, cells events are recorded as transient signals. In SC-ICP-MS an essential requirement is that each cell event corresponds to the signal generated by an individual cell, so that cells must be well separated in time and space in the ICP.

One of the first studies on single-cell introduction into ICP in time-resolved mode was performed by Nomizu et al. (1994). They used a previously developed airborne particle analyzer (Nomizu et al. 1992, 1994) to determine the calcium content in some single mammalian cells with diameters from 10 to 20  $\mu\text{m}$  by ICP-AES. Droplets containing cells were dried in a drying chamber, and cells were directly introduced into the plasma and the calcium signal produced by each cell registered by the analyzer. For quantitative purposes, the system was calibrated with monodisperse calcium acetate aerosols generated by a vibrating orifice aerosol generator, assuming that a cell and a particle behave the same way in the plasma and thus the pulse signals derived from both produced the same pulse height if the calcium content is the same. Through this approach, they determined the calcium content in mouse fibroblasts, human pancreas, and human umbilical vein endothelial cells, with measured contents ranging from 0.057 to 0.27 pg of Ca per cell. The detection limit was reported at  $\sim 0.01$  pg of Ca in a cell. However, other major elements present in cells, such as Mg, K, and Na, could not be detected due to the system that was not sensitive enough, a problem that authors thought could be overcome by using ICP-MS as detection method. In addition, the introduction efficiency of dried cells into the ICP was less than 0.1%.

The direct analysis of a single bacteria cell by SC-ICP-MS was reported for the first time by Houk's group (Li et al. 2005). *Bacillus subtilis* (*B. subtilis*), grown in a spiked uranium medium, were introduced by a microconcentric nebulizer, and the U signal incorporated intrinsically into single cells was registered by a magnetic sector instrument (ICP-SFMS) operating at the fastest integration time (4 ms). The study showed that bacteria cells behave more like large particles rather than wet droplets.  $\text{U}^+$  spikes were observed when introducing the sample as dry and wet bacterial aerosols. On the other hand, they also showed that the U response is different for lysed and unlysed bacteria, observing a 30% increase when bacteria are lysed by

241 sonication. The quantification of U was possible by using an inorganic U standard  
242 but applying a correction factor that has to be known.

243 Ho and Chan (2010) used a conventional pneumatic V-groove nebulizer to per-  
244 form a single-cell analysis of a unicellular alga (*Chlorella vulgaris*, 1–6  $\mu\text{m}$ ) using  
245 single quadrupole ICP-MS at its lowest integration time (10 ms). This model alga  
246 was chosen as a model due to its high magnesium content. By monitoring this major  
247 element and counting the number of spikes, the number density of the cells was  
248 determined. The sample uptake rate and the algae number density were optimized  
249 to ensure that each magnesium spike corresponded to one cell. However, the trans-  
250 port efficiency was estimated at 0.54% due to an inefficient sample introduction  
251 system. On the other hand, they demonstrated the feasibility of a quantitative deter-  
252 mination of Mg in the algal cells by using MgO particles for calibration. Alternatively,  
253 a semiquantitative measurement was also possible by using aqueous standards for  
254 calibration. The use of MgO particles for calibration reduces the error due to a dif-  
255 ferent diffusion loss of Mg atoms coming from cells with respect to those coming  
256 from aqueous standards. Apart of the presence of a major element like Mg ( $10^8$   
257 atoms per cell), they were able to detect other trace elements in the algal cells, like  
258 Mn and Cu ( $5 \times 10^6$  atoms per cell). The method was also applied to a kinetic study  
259 of the sorption rate of Cr onto algal cells without separation of the cells from the  
260 original suspension.

261 The same group used a similar approach to obtain valuable biologically relevant  
262 info about the uptake of bismuth-based drugs in single cells (Tsang et al. 2011). The  
263 magnesium and bismuth content in *Helicobacter pylori* was monitored at the single-  
264 cell level in order to track the presence of individual cells and the metaldrug  
265 uptake. For quantitative purposes, MgO particles were used as calibration standards  
266 as in their previous work (Ho and Chan 2010). A magnesium content of about  $2.9 \times$   
267  $10^7$  atoms per cell was determined in wild-type bacteria, whereas the bacteria treated  
268 with the bismuth-based drug deposited nearly  $1 \times 10^6$  atoms per cell. The study  
269 showed that tracking the changes of bismuth content in single bacteria cell with  
270 time provides a snapshot of bismuth uptake. Moreover, the competitive effect of  
271 ferric ions against the bismuth uptake by cells was demonstrated.

272 Zheng et al. (2013) applied SC-ICP-MS to determine intracellular quantum dots  
273 (QDs) in single mouse leukemic monocyte macrophage cells (RAW 246.7) after  
274 different exposure times. They used a microconcentric nebulizer to directly intro-  
275 duce the cells after exposure with carboxyl CdSeS of 7 nm, and the cadmium signal  
276 was monitored with a dwell time of 5 ms by using a single quadrupole ICP-MS. The  
277 method was applied to study uptake kinetics of QDs by incubating the cells for  
278 2–12 h. A transport efficiency of 2.9% was obtained for this study. The CdS uptake  
279 was quantified by using a semiquantitative approach based on the introduction of a  
280 cadmium standard solution for calibration, assuming that ions from QDs and dis-  
281 solved ions from standard solution behave alike in the plasma. A suspension of QDs  
282 of the same diameter could be not be used for calibration purposes, since 7 nm is  
283 below the size detection limit of the technique. The results were validated by flow  
284 cytometry and cell digestion methods.

The same system was used to determine the uptake of  $\text{Gd}@C_{82}(\text{OH})_{22}$ , a new nanomaterials antitumor agent, and cisplatin in single cells (Zheng et al. 2015). Cancer cells (HeLa) and normal cells (16HBE) were incubated with  $\text{Gd}@C_{82}(\text{OH})_{22}$  and cisplatin at different doses for 2 and 24 h and directly introduced into the ICP after treatment, monitoring the gadolinium and platinum signals. Standard solutions of Pt or Gd were used to quantify the number of atoms per cell after each exposure dose and exposure time. Metal contents ranging from 0.03 to 2.4 pg and from 0.15 to 25 pg were obtained for Pt and Gd, respectively. Results showed that  $\text{Gd}@C_{82}(\text{OH})_{22}$  has higher bioavailability.

SC-ICP-MS was used to analyze at the single-cell level the contents and distribution patterns of essential mineral elements (Fe, Cu, Zn, Mn, P, and S) in two types of cancer cells (HeLa and A549) and one type of normal cells (16HBE) (Wang et al. 2015). Analyses were performed by using a concentric PFA-ST nebulizer which resulted in low cell transport efficiency (~0.2%). In order to fulfill the criteria that each spike signal corresponds to one cell event, dwell time and cell number density were optimized. As expected, different distribution patterns of the elements among the three types of cells were observed, which led the authors to the conclusion that these discrepancies can be used to distinguish between normal and tumor cells in mixed populations. The quantitative analysis of the elements in single cells was performed by the use of standard solutions.

Amable et al. (2017) used SC-ICP-MS to investigate the uptake of cisplatin by ovarian cancer cells, by tracking the platinum content in individual cells over time, which could be used as a predictor of the effectiveness of the treatment. The platinum content increased over time, signifying increased cisplatin uptake. Moreover, the same authors used the same analytical approach to study the uptake rate of gold nanoparticles (AuNPs) at two different concentrations by three different ovarian cell lines and to determine the intrinsic copper and zinc contents in one ovarian cell line. In the later study, the use of a short dwell time (50  $\mu\text{s}$ ) allowed to reduce the background signal while keeping the signal-to-background ratio constant.

One of the major drawbacks of SC-ICP-MS is the high sample consumption (as a consequence of inefficient cell transport efficiency) in conventional sample introduction systems, usually based on a concentric nebulizer and a spray chamber. As we have seen in the previous studies reported, the cell transport efficiency was <5%. In order to try to overcome this problem, some groups have developed special sample introduction devices.

Groombridge et al. (2013) developed a high-efficiency cell introduction system (HECIS), which was based on a total consumption sample introduction device, to determine trace elements in single yeast cells (*Saccharomyces cerevisiae*). The sample introduction system consisted of a modified high performance concentric nebulizer (HPCN) and a 15 mL on-axis spray chamber utilizing a sheath gas glow to prevent sample deposition. Besides, a solution of NaCl at low concentration was added to the cell suspension in order to reduce cell adsorption. The modified nebulizer was able to generate aerosols below 10  $\mu\text{m}$  in size by working at 10  $\mu\text{L min}^{-1}$ , which leads to a lower background noise level. With the developed system, a cell transport efficiency of  $75.0 \pm 4.7\%$  into the plasma was achieved for the analysis of

330 single yeast cells. The signals of Mg, P, Ca, Mn, Fe, Cu, and Zn were obtained by  
331 single quadrupole ICP-MS at a dwell time of 10 ms. They also conducted a prelimi-  
332 nary investigation into the potential for multielement correlation analysis within  
333 cells by using ICP-TOFMS. The time-resolved profiles of six elements (Mg, P, Mn,  
334 Fe, Cu, and Zn) were simultaneously obtained in one measurement at a dwell time  
335 of 1 ms. Results show a relatively strong correlation for the spectra between P and  
336 Zn (correlation factor, 0.69), between P and Mg (0.63), and between Mg and Zn  
337 (0.63). Despite the successful application of the HECIS, the cell transport efficiency  
338 was not close to 100%, probably due to cell loss during introduction, according to  
339 the author (Miyashita et al. 2014b). Therefore, the same group modified the HPCN  
340 in order to improve the efficiency of single-cell analysis by reducing the loss of  
341 cells, as well as to accept a wider range of size cells (from 2.0 to 6.4  $\mu\text{m}$ ) (Miyashita  
342 et al. 2014b). The modified system consisted of an HPCN with a large-bore center  
343 capillary tube (LB-HPCN) and a 15 mL on-axis spray chamber still with a sheath  
344 gas flow but with a longer total length and shorter inner tube length. Besides, an  
345 external ion pulse counting unit allowed improving the data acquisition frequency  
346 (0.05–1 ms). The system was tested by monitoring a wide range of biologically  
347 important elements (C, Mg, Al, P, S, K, Ca, Cr, Mn, Fe, Zn) in unicellular microbes  
348 of different sizes: yeast (*Saccharomyces cerevisiae*), cyanobacterium (*Synechocystis*  
349 sp. *PCC 6803*), red algae (*Cyanidioschyzon merolae 10D* and *Galdieria sulphura-*  
350 *ria*), and green alga (*Chlamydomonas reinhardtii* CC-125). The cell introduction  
351 efficiencies determined ranged 86% to ca. 100% for microbes with cell diameter of  
352 6.4  $\mu\text{m}$  and 2.0–3.0  $\mu\text{m}$ , respectively.

353 A sample introduction system based on micro-droplet generator ( $\mu\text{DG}$ ) was  
354 developed by Shigeta et al. (2013a) and coupled to a sector field ICP-MS instru-  
355 ment, operating in fast scanning mode (shortest dwell time of 100  $\mu\text{s}$ ). Uniformly  
356 sized droplets down to 23 nm were achieved thanks to the use of triple pulse mode  
357 of the droplet generator. The generated droplets were injected into a low-temperature  
358 desolvation system, using He as drying gas. The system was successfully applied  
359 for the detection of trace elements (Na, Mg, Fe, Cu, Zn, Se) in single selenized yeast  
360 cells (*Saccharomyces cerevisiae*) with 100% transport efficiency (Shigeta et al.  
361 2013b). The single yeast cells with a diameter of roughly 6  $\mu\text{m}$  were embedded into  
362 droplets and introduced into the plasma, with a fixed droplet generation rate of  
363 50 Hz, producing equidistant signals that allowed the discrimination between sig-  
364 nals produced due to background from those produced by the analyte. Signal inten-  
365 sities from single cells were measured for Cu, Zn, and Se from the histograms for  
366 about 1000 cell events. In addition, they performed open vessel digestion of washed  
367 yeast cells for multielement analysis, determining absolute amounts per single cell  
368 for Na (0.91 fg), Mg (9.4 fg), Fe (5.9 fg), Cu (0.54 fg), Zn (1.2 fg), and Se (72 fg).

369 Ishihara et al. (2015) developed a desolvation system for micro-droplet injection  
370 system (M-DIS) in order to detect trace metals in the unicellular alga  
371 *Pseudococcomyxa simplex* by ICP-AES. In the M-DIS system, the cell solution is  
372 not nebulized but introduced at the center of the ICP as a single micro-droplet with  
373 a diameter between 30 and 70  $\mu\text{m}$ . The desolvation system readily removed the  
374 water vapor by placing a cooling part to the introduction route downstream of the

heating, allowing the decrease of the solvent load in the droplet and thus improving the sensitivity of the elements present in the cell. The modified M-DIS system equipped with the desolvation system was coupled to ICP-AES, and the emission spectra of Ca, Mg, and Fe contained in a single cell were recorded; however, the emission spectra corresponding to the metals Mn, Zn, and Mo could not be detected.

Verboket et al. (2014) proposed a novel droplet microfluidic sample introduction system for ICP-MS. The system is based on a liquid-assisted droplet ejection (LADE) chip made entirely of poly(dimethylsiloxane) (PDMS), which produced droplets in a stream of perfluorohexane (PFH). A membrane desolvator is used prior the injection into the plasma to reduce the droplet size. The chip was able to generate highly monodisperse droplets in the size range from 40 to 60  $\mu\text{m}$ , which remain intact during the ejection and can be transported and directly injected into the ICP with >50% efficiency. The system was tested by introducing calf red blood cells suspended in phosphate-buffered saline (PBS) and monitoring the  $^{56}\text{Fe}$  signal. However, the transport efficiency of cells was low (4.5%) as a result of losses in the transport assembly. The amount of Fe per cell was calculated by calibrating the instrument with droplets consisting of a multielement solution.

Recently, Wang et al. (2017b) fabricated a droplet chip which produced droplets with an average diameter of 25  $\mu\text{m}$ , online with an ICP-MS via a microflow nebulizer. The single cells encapsulated in the droplets generated by the chip remained intact during its transportation from the outlet of the droplet chip to the microflow nebulizer. The developed droplet chip was applied for the quantification of Zn and zinc oxide nanoparticles (ZnO NPs) uptake/adsorption in single HepG2 cells by SC-ICP-MS. ZnO NPs were used for the quantification of Zn in single cells. The cell transport efficiency was low (2.96%) compared with other systems, but the frequency of droplet generation was high ( $3\text{--}6 \times 10^6$  droplets per minute).

Mass cytometry, usually in combination with a time-of-flight analyzer, can offer the capability of single-cell analysis on the basis of specific metal-based cell markers. Tanner's group introduced in 2008 for the first time a specialized system for the multiparametric analysis of single cell at high throughput (Bandura et al. 2009, Tanner et al. 2008). The developed system was used for the analysis of human cells through an approach based on multiatom elemental antibody tagging. The mass cytometer was later introduced to the market as "CyTOF" by DVS Sciences Inc.

More recently, Guo et al. (2017) used CyTOF for label-free detection and quantification of Ag in single bacterial (*Pseudomonas putida*) cells of different physiological states. Cells were treated with silver ions or 10 nm silver nanoparticles (AgNPs). The amount of Ag per cell was determined via the intensity of the mass cytometric signal for Ag. The information about the amount of Ag per cell was combined with an approach using ruthenium red (RR) staining as a marker for all cells of a population and cisplatin staining for live/dead cell discrimination. They found that the treatment with AgNPs caused higher frequencies of dead cells, higher frequencies of Ag-containing cells, and higher per-cell silver quantities.

417 **10.2.2 Other MS-Based Approaches**

418 Apart of its capabilities to obtain information about the intracellular distribution of  
419 metal and metal nanoparticles, as it will be discussed in the next section, LA-ICP-MS  
420 is able to provide quantitative information. In this context, LA-ICP-MS allows the  
421 quantification of inorganic nanoparticles without losing spatial information of the  
422 nanoparticle distribution at the cell level, overcoming the disadvantages of ICP-MS  
423 elemental analysis after cell digestion or extraction.

424 One of the major problems to achieve an accurate quantification of metals and  
425 metal nanoparticles by LA-ICP-MS is a lack of suitable single-cell standards. In  
426 order to overcome this problem, different approaches have been investigated.

427 Drescher et al. (2012) used LA coupled to a sector field ICP-MS to study the  
428 uptake of AuNPs (with a diameter of 25 nm) and AgNPs (with a diameter of 50 nm)  
429 in single eukaryotic cells (mouse fibroblasts). The number of nanoparticle per cell  
430 after incubation was determined on the basis of a matrix-matched calibration using  
431 nitrocellulose membranes spiked with nanoparticle suspension. The limit of detec-  
432 tion and the limit of quantification for AgNPs were 20 and 60 particles and for  
433 AuNPs were 190 and 550 particles, respectively. Results showed a strong depen-  
434 dency of particle uptake on concentration and incubation conditions. In the case of  
435 AgNPs, increasing nanoparticle concentration and incubation time was shown to  
436 lead to an increase of the silver intensity inside the cells, which was directly corre-  
437 lated with an increasing number of nanoparticles.

438 The same group used LA-ICP-MS for a quantitative comparison of the uptake of  
439 uncoated AgNPs and AuNPs, silica-coated AgNPs, and silica nanoparticles with a  
440 plasmonic (Au or Ag) core (BrightSilica) by single mouse fibroblasts and macro-  
441 phages (Drescher et al. 2014). The use of nanoparticles with thicker shells (silica-  
442 coated AgNPs) provided the possibility to compare the uptake of relatively large  
443 nanoparticles with smaller ones (BrightSilica with thin shells) at an identical size of  
444 the plasmonic cores. Since the uptake of nanoparticles by cells is size dependent,  
445 the signal intensity obtained was about six times higher for BrightSilica(Ag) with a  
446 diameter of 57 nm than for the 126 nm silica-coated AgNPs. Results also showed a  
447 smaller uptake by fibroblast cells of BrightSilica NPs in comparison with uncoated  
448 AgNPs and AuNPs of almost the same size.

449 Wang et al. (2013) quantified the gold mass in single mouse leukemic monocyte  
450 macrophage cells (RAW 246.7) exposed to 30 nm AuNPs by LA-ICP-MS. For cali-  
451 bration purposes an inkjet printer producing dried residues of picoliter droplets was  
452 used in order to simulate matrix-matched calibration standards. Under controlled  
453 conditions, the droplets dispensed from the printer were almost identical with less  
454 than 1% mass variations. Through this calibration approach, a limit of quantification  
455 of 1.7 fg Au was achieved. A log-normal distribution, ranging from 1.7 to 72 fg Au  
456 per cell, corresponding to 9 to 370 AuNPs per cell, was obtained in single cells  
457 exposed to AuNPs for 4 h.

458 Van Malderen et al. (2016a) presented an interesting quantitative approach in  
459 order to overcome the limitations in precision, accuracy, and efficiency of current

calibration strategies in LA-ICP-MS. For this purpose, they designed and proposed the use of high-density microarray plates for multiple matrix-matched standards. A calibration curve with good linear correlation was obtained within the range of 5–200  $\mu\text{g g}^{-1}$ , exhibiting a detection limit of 3 fg Cu. The system was applied for the quantification at the single-cell level of Cu in the marine microalgae *Scrippsiella trochoidea* after copper exposure.

Büchner et al. (2014) studied the accumulation of AuNPs in fibroblast cells during cellular uptake, processing, and mitosis. Cells were exposed to 14 nm AuNPs with different incubation times and analyzed by LA-ICP-MS. Results showed that AuNPs form aggregates of different sizes, and the gold signal intensity can be compared for the different incubation times. As an indicator for the aggregation of nanoparticles inside the cells, the authors determined the number of spots per cell with a gold signal intensity >50,000 cps. The number of spots with gold intensity >50,000 cps showed a different trend that was attributed to a change in the intracellular particle distribution over time.

Finally, Gao et al. (2013) proposed an approach based on high irradiance femto-second laser ionization orthogonal time-of-flight mass spectrometry (fs-LI-O-TOFMS) to determine the elemental composition of single paramecium cells, with the size of several tens of micrometers. After a simple preparation procedure, based on heating and drying the cells, a series of elements (Na, Mg, Al, P, S, Cl, K, Ca, Mn, Fe, Cu, Zn, I, Cs) were determined in paramecium at the pg per cell level. Salts of these elements were used in order to increase the element concentration. This approach allowed the measurement of nonmetallic elements like P, S, or Cl difficult to analyze with single quadrupole ICP-MS instruments. An absolute limit of detection (ALOD) at the femtogram level was achieved.

### 10.3 Subcellular Distribution Analysis of Metal and Metal Nanoparticles in Single Cells by Imaging Techniques

As it has already been mentioned, classical studies of biological cells consist on the digestion of a cell suspension and thus averaging over a huge number of cells. With this approach, not only the intrinsic individual variation but also the information about intracellular distribution of metals is lost. Nevertheless, each cell is subdivided into different compartments with specific reactions, and thus chemical elemental imaging is critical to elucidate the biochemical processes that take place in each of them.

The determination of the metal distribution at the subcellular level in individual cells is challenging and requires analytical methods with high sensitivity and high spatial resolution. In the last years, the advances in analytical techniques like LA-ICP-MS, SIMS, or SXRF have opened a number of possibilities for imaging at the single-cell level. Different applications reported in literature are shown in Table 10.1.

500 **10.3.1 LA-ICP-MS**

501 LA-ICP-MS is an established quantitative elemental analysis and mapping technique, which provides spatially resolved information on element distribution (qualitative and quantitative) in biological samples (Mueller et al. 2014). Rapid response  
502  
503 LA-ICP-MS systems greatly benefit throughput and sensitivity, which are key  
504 parameters in 2D and 3D imaging at high lateral resolution (Van Malderen et al.  
505 2016b). The novel capabilities of laser ablation as a sample introduction technique  
506 in ICP-MS are being increasingly applied for advanced imaging mass  
507 spectrometry.  
508

509 LA-ICP-MS was used by Managh et al. (2013) for tracking single macrophage  
510 cells labeled with 50 nm AuNPs in different tissues of immunodeficient mice. Since  
511 the cell diameter (~10  $\mu\text{m}$ ) was much smaller than the laser spot diameter (25  $\mu\text{m}$ ),  
512 a single cell was completely ablated in each laser shot.

513 Jakubowski's group (Drescher et al. 2012, 2014) showed the capabilities of  
514 LA-ICP-MS for spatially resolved bioimaging of the intracellular distribution of  
515 nanoparticles in single eukaryotic cells in two different studies. Scan speed, ablation  
516 frequency, and laser energy were optimized in order to achieve a laser spot size of  
517 4  $\mu\text{m}$  or 8  $\mu\text{m}$  so that the laser spots are widely overlapping each other and the signal  
518 of the sample is generated by the difference in the ablated area. By using this laser  
519 ablation scan mode, the lateral resolution in scan direction is much smaller than the  
520 laser spot diameter, obtaining a high-resolution image. In a first study, they used the  
521 optimized ablation system to investigate the intracellular distribution of AuNPs and  
522 AgNPs in cellular substructures of single mouse fibroblasts (Drescher et al. 2012).  
523 The subcellular mapping obtained enabled the differentiation of nanoparticles in the  
524 cytosol from those in the cell nucleus region.

525 In a different study, the same group combined LA-ICP-MS with cryo nanoscale  
526 X-ray tomography (cryo-XT) to investigate the intracellular distribution at the sub-  
527 cellular level with 3D resolution of silica nanoparticles with a plasmonic (Au or Ag)  
528 core (BrightSilica) in 3 T3 fibroblast cells and J774 macrophage individual cells  
529 (Drescher et al. 2014). Taking advantage of the absorption of soft X-rays by the  
530 silica material, the study confirmed that BrightSilica nanoparticles enter cells by an  
531 endocytotic mechanism.

532 Büchner et al. (2014) detected Au nanoaggregates at subcellular level in single  
533 fibroblast cells by LA-ICP-MS micromapping. They achieved high sensitivity at  
534 high spatial resolution and complete cell ablation by optimizing the laser ablation  
535 parameters as previously described in the study performed by Drescher et al. (2012).  
536 By using an 8  $\mu\text{m}$  diameter beam, they showed that the nanoaggregates accumulated  
537 in localized, perinuclear regions of the cells, but it was also demonstrated that reor-  
538 ganization occurred during mitosis.

539 However, these LA-ICP-MS micromapping studies were performed in fibroblast  
540 cells, which can be considered relatively large in size ( $\geq 50 \mu\text{m}$  in diameter).  
541 Therefore, the application would benefit from improved spatial resolution for the

investigation of the distribution of nanoparticles within smaller cells (Van Malderen et al. 2016a).

Van Malderen et al. (2016a) demonstrated the capabilities of LA-ICP-MS to study the intracellular transition metal distribution in single cells of model marine microalgae. Microimaging of *Scrippsiella trochoidea* exposed to 20  $\mu\text{g g}^{-1}$  indicated an important organelle acting as preferential storage of Cu. These conclusions were corroborated by images obtained by SXRF in a cross-validation approach (Vergucht et al. 2015), showing the potential of LA-ICP-MS for subcellular level imaging.

While the use of LA-ICP-MS for single-cell imaging is just at its beginning, other SXRF microscopy and secondary ion mass spectrometry showed already that the imaging of biological trace metals at nm scale is possible (Qin et al. 2011).

### 10.3.2 NanoSIMS 554

SIMS is an analytical technique based on the use an accelerated primary ion beam that bombards a solid surface and generates secondary ions, which are subsequently analyzed by a mass spectrometer (Boxer et al. 2009). In the case of nanoSIMS, the primary ion beam is scanned over the surface of the sample, and ejected secondary ions are analyzed by a double sector mass spectrometer (Schaumlöffel et al. 2016).

Current nanoSIMS instruments are equipped with two different primary ions sources: a thermal ionization cesium positive ion source that generates negative secondary ions (Storms et al. 1977) and a duoplasmatron oxygen negative ion source that generates positive secondary ions (Benninghoven et al. 1987). Its high spatial resolution (better than 100 nm) has opened numerous research application fields, such as the detection of chemical elements at the subcellular level in biological samples.

Slaveykova et al. (2009) demonstrated the capabilities of nanoSIMS to investigate Cu distribution in single micrometer-sized algal cells. The microalga *Chlorella kesslerii* was exposed to nanomolar and micromolar copper concentrations, representative of natural and heavily contaminated waters, and the subcellular distribution of copper in individual cells was mapped by measuring  $^{63}\text{Cu}^-$  and  $^{65}\text{Cu}^-$  secondary ions. A cesium source was used to generate  $\text{Cs}^+$  primary ions that were accelerated as a tightly focused ion beam with a probe working diameter of approximately 50 nm. Results showed that the quantity of Cu in the cell wall and membrane was lower than that in the cell interior.

Smart et al. (2010) used nanoSIMS with dedicated sample preparation methodologies to study the distribution of nickel and other elements in single cells from a nickel hyperaccumulator plant (*Alyssum lesbiacum*), with spatial resolutions of better than 100 nm. A  $^{58}\text{Ni}^-$  signal distribution was obtained by using the primary  $\text{Cs}^+$  ion beam, whereas the primary  $\text{O}^-$  ion beam allowed them to obtain maps showing the distribution of the positive secondary ions  $^{23}\text{Na}^+$ ,  $^{40}\text{Ca}^+$ ,  $^{39}\text{K}^+$ ,  $^{24}\text{Mg}^+$ , and  $^{58}\text{Ni}^+$  from the same area analyzed with the  $\text{Cs}^+$  beam. They demonstrated a significant

583 sequestration of nickel in the epidermal cell vacuoles together with a uniform distri-  
584 bution throughout the cell walls. However, despite the sample preparation method-  
585 ology applied in this study helped to minimize the redistribution of soluble elements,  
586 the in vivo distributions of highly diffusible ions ( $^{23}\text{Na}^+$ ,  $^{24}\text{Mg}^+$ ,  $^{39}\text{K}^+$ , and  $^{40}\text{Ca}^+$ ) were  
587 significantly altered during chemical fixation.

588 Wolfe-Simon et al. (2011) used nanoSIMS to study the intracellular arsenic in a  
589 bacterium (strain GFAJ-1 of the *Halomonadaceae*) that is able to substitute arsenic  
590 for phosphorus to sustain its growth. Bacteria was grown in an arsenic-enriched  
591 medium, using radiolabeled  $^{73}\text{AsO}_4^{3-}$  to obtain more specific information about the  
592 intracellular distribution of arsenic in single GFAJ-1 cells.

593 Wedlock et al. (2011) investigated the subcellular distribution of gold in situ in  
594 human breast cancer cells treated with an antitumor Au(I) complex. A  $\text{Cs}^+$  primary  
595 ion beam was used for imaging the negative secondary ion  $^{197}\text{Au}^-$ . Different beam  
596 currents were applied to obtain primary beam diameters of  $\sim 110$  nm (low-resolution  
597 images) or  $\sim 50$  nm (high-resolution images). NanoSIMS maps for  $^{197}\text{Au}^-$  signal in  
598 single cells after treatment showed that the subcellular distribution of gold was  
599 associated with sulfur-rich regions in the cytoplasmic, nuclear, and perinuclear  
600 regions.

601 The intracellular distribution of copper oxide nanoparticles (CuO NPs) in HepG2  
602 cells was studied by Audinot et al. (2013) by nanoSIMS imaging.  $^{63}\text{Cu}^-$  maps were  
603 acquired with a  $\text{Cs}^+$  ion primary beam, and a probe diameter in the range 80–100 nm  
604 in single cells was exposed to CuO NPs ( $25 \text{ mg mL}^{-1}$ ) for 24 h.

605 The detection of many trace elements at the single-cell level by nanoSIMS  
606 requires the generation of secondary positive ions with high yield by an oxygen  
607 primary ion source. However, the commonly used duoplasmatron oxygen source  
608 cannot achieve the same lateral resolution as the cesium primary source due to a  
609 larger primary ion beam size (down to 50 nm for the Cs source and 200 nm for the  
610 duoplasmatron oxygen source) (Schaumlöffel et al. 2016). In order to overcome this  
611 problem, Malherbe et al. (2016) designed a new rf plasma oxygen source that was  
612 fitted and characterized on a nanoSIMS instrument. This new oxygen ion source  
613 was applied for the localization of trace metals (Na, Ca, Fe, Mn, Cu) in individual  
614 cells of two model organisms: a unicellular alga (*C. Reinhardtii*) and flowering plant  
615 (*Arabidopsis thaliana*). The new rf plasma oxygen primary ion source showed  
616 higher achievable lateral resolutions and higher apparent sensitivities for electro-  
617 positive elements compared to the commonly used duoplasmatron source. The  
618 images produced for positive secondary ions with the rf plasma source showed simi-  
619 lar lateral resolution to those obtained for negative secondary ions with the cesium  
620 source.

### 621 10.3.3 Synchrotron-Based X-ray Fluorescence

622 SXRF (also abbreviated as  $\mu\text{XRF}$ ) is among the most powerful techniques for the  
623 investigation of metal accumulation at the cell level and can be used for imaging  
624 element distribution at high spatial resolution ( $<100$  nm) (Roudeau et al. 2014).

This technique is based in the X-ray fluorescence energy emitted by an atom that has been previously irradiated by X-ray photons produced by synchrotron radiation (Schaumlöffel et al. 2016). The irradiated atom ejects a core electron with a characteristic binding energy. In SXRF, the sample is moved by a nano-positioner stage, and spectra are recorded pixel by pixel which enable to provide images of the distribution of metals in single cells. SRXF has been widely applied in different investigation of the metal distribution at the single-cell level. Some interesting applications of SXRF will be explained below.

Vergucht et al. (2015) reported a new imaging approach based on the combination of optical tweezer technology with synchrotron radiation confocal XRF. The method allowed elemental imaging in a 2D projection mode in single marine microalgae (*Scrippsiella trochoidea*) cells in their natural, in vivo state. The elemental distributions showed that significant amounts of Mn, Fe, Cu, and Zn were detected within the Zn-exposed algae. In addition, the in vivo areal concentrations of accumulated metals in single cells could determine in a semiquantitative way, showing larger differences (Cu > Ni > Zn).

Elemental imaging by synchrotron  $\mu$ XRF was used by Isaure et al. (2017) to investigate Cd in fungal hyphae at the subcellular level. Aquatic fungus *H. lugdunensis* was exposed to 50  $\mu$ M Cd and  $\mu$ XRF maps obtained after 5 and 7 days. Results showed that the hyphal tip cells were depleted in Cd and that the metal was stored in older cells. S and P localization was also determined.

Penen et al. (2017) studied the Cd distribution in single microalga (*Chlamydomonas reinhardtii*) cells. Three different *C. reinhardtii* strains were exposed to 70  $\mu$ M Cd and analyzed by  $\mu$ XRF.  $\mu$ XRF maps from the three strains demonstrated that Cd level was highly heterogeneous between cells.

In an interesting approach, the redistribution of transition metals in mouse fibroblast cells during the individual stages of mitosis was investigated (McRae et al. 2013). Results showed similar mechanisms for the inheritance of Zn and Cu, but not Fe. Moreover, SXRF maps provided first clues toward a mechanism that might involve compartmentalized transport and possibly a role of the Golgi apparatus.

Leonardo et al. (2014) studied the subcellular location of silver and cobalt in a newly discovered unicellular microalga (*Coccomyxa actinabiotis*) by synchrotron radiation nano-X-ray fluorescence (SR-nXRF). The microalga was exposed to different concentrations of silver and cobalt, and the subcellular distribution after exposure was investigated. They found that cobalt was homogeneously distributed outside of the chloroplast, whereas silver was localized in the cytosol at low concentration and in the whole cell excluding the nucleus at high concentration.

Mathieu et al. (2017) studied the intracellular distribution of manganese in single human intestinal epithelial cells. Cells were incubated with  $MnCl_2$  or the manganese complex Mn1 mimicking superoxide dismutase (SOD), a protein involved in cell protection against oxidative stress, and manganese was mapped on cryofixed freeze-dried cells using SXRF with a resolution of 200 nm. The intracellular manganese content in a single cell was higher after incubation with the manganese complex than that in the control cell, but  $MnCl_2$  was more efficiently taken up. Moreover, SXRF maps demonstrated a diffuse distribution of manganese with higher amounts where the cell is the thickest.

671 Szyrwił et al. (2015) used SXRF to map the intracellular nickel in human fibro-  
672 sarcoma cells. Cells were incubated with Ni<sup>2+</sup> or a newly Ni<sup>2+</sup>-branch peptide com-  
673 plex (NiA), designed to deliver Ni<sup>2+</sup> to the cell nucleus. SXRF images demonstrated  
674 the nuclear location of Ni in cells treated with the NiA complex. However, in cells  
675 treated with nickel ions, effective metal uptake was not observed.

676 Ceko et al. (2015) determined the intracellular selenium distribution in single  
677 bovine ovaries by SXRF imaging. The approach allowed localizing Se to the granu-  
678 losa cell layer of large (>10 mm) healthy follicles.

679 Moreover, the use of SXRF has also been reported for the investigation of metal  
680 localization in plant cells (Zhao et al. 2014).

681 Roschztardt et al. (2011) studied the intracellular location of iron in single pea  
682 (*Pisum sativum*) cells by  $\mu$ XRF. The results revealed that, unexpectedly, the iron  
683 concentration found in the nucleus was higher than in the expected iron-rich organ-  
684 elles such as plastids or vacuoles. Furthermore, they showed that within the nucleus,  
685 the iron concentration in the nucleolus is the highest encountered among the intra-  
686 cellular compartments. This study raised the important question of the role that  
687 nucleolar iron plays in plant cells.

688 Isaure et al. (2015) used  $\mu$ XRF to investigate the distribution of cadmium in  
689 leave cells of two plants: the hyperaccumulator *Arabidopsis halleri* and the non-  
690 accumulator *Arabidopsis lyrata*. Images were obtained after 3 weeks of cadmium  
691 exposure. In the leaves of *A. halleri*, cadmium was found inside the cell and at the  
692 rim of the cell. However, the cellular distribution in *A. lyrata* leaves could not be  
693 obtained, since the lateral resolution and the cadmium were too low.

#### 694 10.3.4 Other MS Approaches

695 The intracellular distribution of nanoparticles has also been studied through other  
696 analytical approaches based on mass spectrometry techniques.

697 For instance, Haase et al. (2011) tested the capabilities of laser postionization  
698 secondary neutral mass spectrometry (laser-SNMS) for the study of the intracellular  
699 distribution of peptide-coated 20 nm AgNPs inside individual human macrophages  
700 cells, comparing the results with the established confocal Raman microscopy and  
701 transmission electron microscopy (TEM). Although confocal Raman microscopy is  
702 fastest and requires a much simpler sample preparation, laser-SNMS provides a  
703 much greater sensitivity and 3D resolution limits, being capable of detecting metal  
704 atoms with a spatial resolution of down to 100 nm. The images obtained demonstrated  
705 significant accumulation of silver particles under the form of aggregates inside the  
706 cells. Laser-SNMS was used in combination with TOF-MS to follow subtle bio-  
707 chemical alterations related to nanoparticle treatment.

708 Finally, TOF-SIMS 3D analysis proved to be able to localize silica micro- and  
709 nanoparticles with sizes down to 150 nm in single rat kidney epithelial cells  
710 (Hagenhoff et al. 2013). The approach followed by Hagenhoff et al. (2013) allowed

the discrimination between extracellular and intracellular localization of nonluminescent, unlabeled nanoparticles, otherwise hard to localize by other analytical techniques. TOF-SIMS provided images of their prominent distribution around the cell nucleus.

## 10.4 Molecular Analysis and Perspectives

715

The development of new analytical methods has opened the door to the identification of metabolites in single cells. One of the most interesting approaches is the coupling of high-resolution separation by capillary electrophoresis (CE) with high sensitivity and selectivity detection by electrospray ionization mass spectrometry (ESI-MS) (Týčová et al. 2017). For instance, Comi et al. (2017) developed an approach based on CE-ESI-MS to identify several amino acids as well as dopamine in single pancreatic islet cells.

716  
717  
718  
719  
720  
721  
722

On the other hand, no metalloproteomic and metallometabolomic data exist for single cells. However, in order to fully understand the cellular specificity and complexity of cells, it is necessary to measure molecular signatures with single-cell resolution (Wang and Bodovitz 2010). The future development of single-cell metallomics clearly depends on the developments in small-scale molecular mass spectrometry accompanied by custom-designed sample preparation methods. High-resolution mass spectrometry imaging, necessary for this purpose, requires a smaller region of sample for each pixel, but this sampling reduction is translated into a decrease of ionization efficiency and sensitivity (Dong et al. 2016).

723  
724  
725  
726  
727  
728  
729  
730  
731

SIMS is an ideal technique for mass spectrometry imaging thanks to its high surface sensitivity and submicron resolution (Passarelli and Ewing 2013). However, recent technical advances in the field of matrix-assisted laser desorption ionization (MALDI) have pushed its spatial resolution from the 20–100  $\mu\text{m}$  range to the 1–10  $\mu\text{m}$  range (Passarelli and Ewing 2013), reaching the point where single-cell mass spectrometry can be accomplished, although continued technology development is needed (Murray et al. 2016). For instance, Zavalin et al. (2012) developed a transmission geometry ion source which enabled to perform high-throughput MALDI MS imaging, achieving higher sensitivity. They demonstrated the capabilities of the developed method by mapping the distribution of lipids and peptides in mammalian cells with 1  $\mu\text{m}$  spatial resolution opening a way to single-cell mass spectrometry imaging such as single-cell proteomic (and, in future, metalloproteomic) imaging, even though the sensitivity is still a challenge.

732

734  
735  
736  
737  
738  
739  
740  
741  
742  
743  
744

The analysis of large metabolites in single cells remains a challenging task. TOF-SIMS is able to provide submicrometer spatial resolution for imaging of metabolites in single cells, whereas MALDI offers a high mass resolution. However, single-cell analysis by mass spectrometry imaging is limited in mass resolution range to  $m/z < 500$  in the case of TOF-SIMS and in spatial resolution (pixel size in the range of 50–200  $\mu\text{m}$ ) in the case of MALDI. Therefore, the analysis of metabo-

745  
746  
747  
748  
749  
750

751 lites and – in perspective – metallometabolites in individual cells with high spatial  
 752 resolution and high mass accuracy simultaneously remains a challenge.

753 However, in an interesting approach, Schober et al. (2012) have already devel-  
 754 oped a high-resolution mass spectrometry single-cell imaging method. They dem-  
 755 onstrated for the first time the combination of high spatial resolution (7  $\mu\text{m}$ ) with  
 756 high mass accuracy (<3 ppm) and high mass resolution ( $R = 100,000$  at  $m/z = 200$ )  
 757 in imaging analysis of human cervical cancer (HeLa) cells. Analyses were per-  
 758 formed with a high-resolution atmospheric pressure MALDI (AP-MALDI) coupled  
 759 to an Orbitrap mass spectrometer. The developed method allowed them to identify  
 760 larger metabolites in intact single cells thus giving a direction to future investiga-  
 761 tions of metal-binding species.

762 Finally, and in other to sum up, the different analytical techniques discussed in  
 763 this chapter, together with the relevant information obtained, are summarized in  
 764 Fig. 10.1.

**Fig. 10.1** Schematic representation of analytical information obtained by different analytical techniques at the single-cell level
