## 36 37 38 **Abstract**

39  
40 Level 4.1 from the Abri du Maras (Ardèche, France) is chronologically attributed to the beginning of MIS 3  
41 and is one example of late Neanderthal occupations in the southeast of France. Previous work on the faunal  
42 and lithic remains suggest that this level records short-term hunting episodes of reindeer associated with  
43 fragmented lithic reduction sequences. During fieldwork, the high density of the material did not allow  
44 identification of clear spatial patterning of these activities. In order to try to decipher the palimpsest of  
45 these short-term occupations, we combined contextual micro-stratigraphic analysis with interdisciplinary  
46 and methodological approaches to obtain high-resolution intra-site spatial data. The former was performed  
47 by studying microfacies variability of occupation layers at meso to microscales. A combination of spatial  
48 techniques based on GIS and kernel density analysis, along with faunal and lithic refitting was used and  
49 focused on the horizontal distribution of the whole archaeological assemblage.

50 The results demonstrate that quantitative approaches, associated with the interdisciplinary empirical  
51 processing of data, are suitable and adequate methods for describing the spatio-temporal formation of the  
52 archaeological assemblage. This integrated approach allowed us to identify a temporal succession of  
53 occupational events marked by distinctive anthropic imprints in the host matrix in well-preserved activity

54 areas. The analysis of their spatial patterns reveals differential treatment of lithic and faunal remains. We  
55 describe the possible organization of the settlement patterns dynamics of these specialized short-term  
56 occupations.

57

58 **Keywords:** Middle Palaeolithic, late Neanderthal, Abri du Maras, France, fauna and lithic refits, spatial  
59 pattern analysis, short-term occupations

60

## 61 1. Introduction

62

63 The interpretation of lithic and faunal assemblages in terms of human settlement patterns is one of the  
64 main issues in Prehistoric Archaeology for reconstructing behavioural strategies. Most Middle Palaeolithic  
65 assemblages are viewed as palimpsests formed from successive episodes of occupation that cannot be  
66 individually identified (Bailey 2007). They originate from the convergence into a single space of  
67 anthropogenic events with depositional, erosional and post-depositional processes (Lucas 2005, 2012)  
68 which is exclusively defined by stratigraphic criteria (Vaquero 2008). Even in archaeological contexts of high  
69 temporal resolution, each stratigraphically-expressed palimpsest is acknowledged to integrate successive  
70 occupation events (i.e. Julien et al. 1992; Vaquero 2008, Malinsky-Buller et al. 2011; Henry 2012; Vaquero et  
71 al. 2012a; Chacón et al. 2015; Machado et al. 2013, 2019; Mallol et al. 2019; Real et al. 2019).

72

73 A variety of methods have been used to attempt to identify behaviourally significant spatial patterns in  
74 terms of activities performed by Neanderthals (i.e. Adler and Conard 2005; Henry 2012; Bargalló et al. 2016;  
75 2020; Chacón et al. 2015; Dibble et al. 2018; Ekshtain et al. 2019; Marín et al. 2019). The critical issue of the  
76 palimpsest relevance has been more specifically approached by refitting analysis of lithics and faunal  
77 remains and spatial analysis (Henry 2012) in order to reconstruct the archaeological assemblage formation  
78 from a spatio-temporal perspective. Quantitative approaches, particularly using geostatistical tools, have  
79 recently provided a more refined analysis of human occupational patterns (Romagnoli and Vaquero 2016;  
80 Gabucio et al. 2018; Marín et al. 2019)

81

82 Previous interdisciplinary studies on the Maras 4.1 archaeological assemblage have provided solid data to  
83 recognize distinctive events of short-term and specialized occupation (Moncel et al. 2010, 2014; Hardy et al.  
84 2013, 2020; Vettese 2014, Richard et al. 2015; Vettese et al. 2017; Daujeard et al. 2019a). The combination  
85 of zooarchaeological, cementochronological and tooth microwear analyses reveals a single-species  
86 dominated spectrum, with catastrophic mortality and repeated autumnal deaths during a cold and humid  
87 phase of MIS 3. This integrated approach points to short-term hunting episodes of reindeer herds. The  
88 technological analysis strategies indicate the fragmentation of the reduction processes in a local and semi-  
89 local perimeter around the cave. The lithic procurement shows a flexible Neanderthal strategy combining  
90 forethought and planning. Results on micro-wear traces and residues point to mainly non-specialized  
91 activities. Considering the abundance of flint sources in the area, Neanderthal mobility appears to have  
92 been organized around the procurement of other important resources, including fauna and plants for food  
93 or tools as well.

94

95 Our objective here is to apply an integrated approach to the lithic and faunal materials based on refitting  
96 and spatial distribution in order to more fully understand the behaviours, activities and duration of the  
97 occupations of late Neanderthals in south-eastern France. We intend to interrogate our previously  
98 proposed circulating model of regional mobility that strongly depended upon a detailed knowledge of the  
99 regional micro-topography and the seasonally available resources (Daujeard and Moncel 2010; Moncel and  
100 Daujeard 2012; Daujeard et al. 2012; Daujeard et al. 2016). We also aim to challenge our initial hypothesis  
101 of reindeer mass hunting strategies (Daujeard et al. 2019a), in order to refine our interpretation of the site  
102 function for the level 4.1 occupation phase.

103 This should also help us to better understand the topographical constraints of this widely opened shelter  
104 adjacent to a small, narrow valley on the types of occupation, their spatial pattern and their duration in  
105 comparison to other examples of short-term Middle Paleolithic occupation (i.e. Vallverdú et al. 2005;  
106 Costamagno et al 2006; Hovers et al. 2011; Sánchez-Hernández et al. 2014; Bargalló et al. 2016; 2020; Castel  
107 et al. 2017; Villaverde et al. 2017; Mallol et al. 2019; Real et al. 2019; Mora Torcal et al. 2020; Picin et al.  
108 2020; Bargalló et al. 2020).

109 Moreover, the chronological attribution of the level 4.1 at the beginning of the MIS 3 between  $46 \pm 3$  ka and  
110  $40 \pm 3$  ka (Richard et al. 2015) places the occupation among the most recent Neanderthal occupations in  
111 Western Europe (Higham et al. 2014). The Abri du Maras is not isolated in the area and it is close to other  
112 late Middle Palaeolithic occupations, such as Le Figuier, Mandrin Cave (Vandeveldt et al. 2017), Baume  
113 Néron (Defleur et al. 1994), Saint Marcel (Moncel et al. 2008; Szmids et al., 2010) and Abri des Pêcheurs.

114 Likewise, the nearby Chauvet cave with its Aurignacian painting attests to the presence of Modern Humans  
115 in the region at 32-36 ka (Nomade et al. 2016). It is now well established that the replacement of  
116 Neanderthal by Modern Humans between 50 and 40 ka was characterized by a regionalization of lithic  
117 traditions, as shown for instance by various “transitional industries”. Technological strategies and land use  
118 patterns varied greatly in different regions (Quina/Levallois technologies for instance in southwestern  
119 France (Delagnes and Rendu 2011, Rendu et al. 2012), or “bout coupé” in England (Ruebens and Wragg  
120 Sykes 2016). Therefore, the level 4.1 from the Abri du Maras site could provide one of the latest traces of  
121 Neanderthals in the area.

122  
123

## 124 **2. The Abri du Maras site and the level 4.1**

125

### 126 **2.1 The site**

127 The site of Abri du Maras (170 m a.s.l.) is located on the right bank of the Middle Rhône Valley (**Fig. 1**), in a  
128 small dry valley of the Ardèche River, at the outer edge of the gorges. This rockshelter opens to the south-  
129 east and is the relict of a large cave at the end of the small valley (Debard 1988; Moncel et al. 2010, 2015).

130

131 The first archaeological investigations at Abri du Maras revealed a stratigraphic sequence of about 3 m  
132 including eight levels with Middle Palaeolithic deposits and a Levallois laminar debitage (upper part of the  
133 sequence, level 1) (Gilles 1950; Combiér 1967; Debard 1988; Moncel et al. 1994). The new excavations that  
134 started in 2006 have since provided a wide exposure of the succession of occupation layers. The excavations  
135 were conducted with classical methodologies, using a square meter grid and plotting each object with a  
136 total station. A GIS database recorded the spatial distribution (vertical and horizontal) information.  
137 Sediments were regularly dry and wet screened for microvertebrates, micro-flakes and shells.

138

139 The new excavations include the middle and lower parts of the sequence partially excavated during past  
140 fieldwork (previously assigned levels 4 to 8). Six large units or layers have been identified but their  
141 relationship with previously assigned levels is unclear due to loss of overlying infill. Stratigraphic layers 6  
142 and 5 are at present the oldest units currently known. They lie on the limestone substratum, visible on  
143 different parts of the excavated areas far from the actual shelter overhang. The overlying layer 4 is a 0.5 to 1  
144 m thick, silty to sandy-silty loessic deposit, mostly of aeolian origin. The coarse components come from frost  
145 shattering and gravitational fall of the limestone walls of the rock shelter. The loessic fine fraction originates  
146 primarily from the wind erosion of the fluvio-glacial terraces of the Middle Rhône valley during the cold and  
147 dry conditions of MIS 3 (Puaud et al. 2015). The initial loessic deposits have been weakly affected by gentle  
148 runoff and pedogenic transformations that are essentially expressed by an intense earthworm bioturbation  
149 and moderate redistribution of calcium carbonate along root channels (Puaud et al. 2015). The excavation  
150 has revealed the occurrence of two archaeological levels, 4.2 and 4.1, clearly separated by a sterile loessic  
151 layer, which have been exposed over 50 m<sup>2</sup> in the front of the remaining shelter (Moncel et al. 2014). The  
152 two distinctive occupation phases both have a high density of artefacts, the lack of *in situ* combustion  
153 evidence, the occurrence of patchy greyish to reddish-brown microaggregate lenses that have been  
154 suspected to be hearth remains during the excavation. Rare artefacts have been encountered in the  
155 overlying layers (3, 2, and 1). U/Th dating applied to bones from the top of unit 5/bottom of layer 4 yielded  
156 ages of 72 ± 3 ka, 87 ± 5 ka, 89 ± 4 ka, and 91 ± 4 ka (Moncel et al. 1994; Moncel and Michel 2000). New  
157 preliminary ESR-U/Th dating of ungulate teeth confirmed the chronology of layer 5 (90 ± 9 ka) but gave  
158 more recent ages for layer 4, attributed at the most to MIS 3. At present, the upper part of layer 4 defined  
159 as level 4.1 can be framed between 46 ± 3 ka (n=2) and 40 ± 3 ka, while 4.2 level would range from 55 ± 2 ka  
160 (n=3) to 42 ± 3 ka, therefore both belonging to the MIS 3 (Richard et al. 2015). This chronological  
161 attribution is consistent with Heinrich events H5 and H4, correlated to the D-O #12 event, a record in the  
162 Villars speleothems (Genty et al. 2010) of a woody steppe with a relatively warm and humid climate in  
163 contrast to the earlier periods.

164

### 165 **2.2 Layer 4 and level 4.1**

166

167 At the upper part of the large layer 4, the excavation of sub-level 4.1 (34 m<sup>2</sup> surface) (**Fig. 2, 3**) exposed a  
168 dense accumulation of archaeological remains throughout the 20 cm thick deposit. Its meticulous  
169 excavation has not revealed the occurrence of any significant change in colour, structure or texture that  
170 would be closely associated with the occurrence of the archaeological items, emphasizing the homogeneity  
171 of the clayey-sandy silt sedimentary matrix (see **Fig. S1**). The accumulation of the archaeological materials  
172 was observed to correlate with increased amount of coarse components issued from the pedogenic  
173 weathering of the limestone cliff together with the presence of collapsed limestone slabs for levels 4.1 and  
174 4.2. This repeated joint occurrence has allowed us to associate each phase of human presence with specific  
175 environmental conditions that were favourable to vegetation colonization of the limestone cliff and soil  
176 development on the uppermost limestone plateau.

177  
178 In contrast, the fine silt texture typical of intact aeolian dust, the weak effect of pedogenesis and the lack of  
179 coarse limestone fraction in the sterile deposit that accumulated between 4.1 and 4.2 levels indicates that  
180 the site was not occupied when the climate was colder and drier. Microvertebrate remains, and pollen  
181 grains are very rare at the site due to poor preservation, whereas charcoals are commonly encountered  
182 throughout the two occupation layers showing in general a good preservation independently of a highly  
183 variable abundance. The number of charcoal fragments in level 4.1 is low with a dominance of *Pinus*  
184 *sylvestris* type and *Betula* sp. (Daujeard et al. 2019a). A lack of preferential orientation of the archaeological  
185 materials, confirmed by statistical tests on the trends in orientation of the materials shows the minimal  
186 effect of post-depositional processes (**Fig. S2**). Moreover, the occurrence of some herbivore bones found in  
187 close anatomical association, with no evidence of post-fragmentation and broken bones *in situ* by post-  
188 depositional factors, along with the abundance of small lithic and faunal microremains ( $\leq 1$ cm) confirm the  
189 very low impact of post-depositional processes (**Fig. 3**).

190  
191

#### 192 **2.2.1 The faunal assemblage of level 4.1**

193  
194 The small and large mammal assemblage that is dominated by reindeer (88% of the NISP, representing 16  
195 individuals) with a minor occurrence of horse, bison, giant deer, red deer, ibex and lagomorphs, highlights  
196 open landscapes under cold and arid climate. There are no carnivore remains (Daujeard et al. 2019a).

197 For reindeer, long bones largely dominate the accumulation and, among them, the richest elements in meat  
198 and marrow, indicate primary carcass processing on the kill site with subsequent selective transport of the  
199 carcass elements. The scarcity of the axial skeleton and of the limb extremities is interpreted as  
200 abandonment at the kill site and/or an *in situ* differential and/or spatial preservation or treatment of spongy  
201 bones (bone grease extraction). Presence of cut and percussion marks on the remains of all types of species  
202 indicates that all the steps of the carcass treatment were processed *in situ*: skinning, dismembering and  
203 removing tendons, periosteum, flesh, marrow and possibly bone grease extraction.

204 The high number of reindeer individuals, catastrophic mortality profile, restricted season of death and  
205 intensive butchery may correspond with a planned mass hunting strategy of a particular species, with  
206 repeated autumnal deaths. The zooarchaeological data highlight diverse subsistence activities managed at  
207 the site, including the use of bones for fuel, with the high rates of carbonised bone fragments (majority less  
208 than 25 mm long) and the *in situ* consumption of meat and marrow. The presence of non-specialised  
209 activities differs from other Neanderthal reindeer-dominated assemblages, often connected with  
210 specialised sites such as hunting camps, with evidence of food storage and no or scant use of fire, i.e.  
211 Salzgitter-Lebenstedt (Gaudzinski and Roebroeks 2000; Gaudzinski-Windheuser, 2006), Pech de l'Azé IV  
212 (Niven 2013), Jonzac (Niven et al. 2012), Roc de Marsal (Castel et al. 2017) and Les Pradelles (Costamagno et  
213 al. 2006). Here, the data rather suggest the recurrent use of the site as a dwelling camp.

214  
215

#### 216 **2.2.2 The lithic assemblage of level 4.1**

217 The lithic material in level 4.1 totals 2041 items (excavations from 2006-2018 seasons) (**Table 1, Tables S1-**  
218 **S4, Fig. S2**). The applied technical strategies indicate the fragmentation of the "chaîne opératoire" into local  
219 and semi-local perimeters around the site (*i.e.* Moncel et al. 2014). Flint is the main raw material followed  
220 by quartz and occasionally basalt, limestone, granite, sandstone, quartzite and schist. The assemblage is

221 mainly composed of flakes and fragments of flakes, including 4.3% Levallois flakes (n=88). Laminar products  
222 (blades and bladelets) total 208 pieces (10.2%), including 58 Levallois blades. Points total 81 pieces (3.9%),  
223 including some clear Levallois points (n=44). There are 51 cores (2.5%), Levallois, discoidal-type, on flake  
224 and others. Only 22 cores can be related to the Levallois concept (preferential flake, unipolar convergent  
225 removals for points and centripetal). The other cores are unifacial unipolar, discoid, Kombewa, trifacial,  
226 orthogonal or crude. Most of them are not exhausted. The original form is possibly a flake for some of  
227 them, and for the others a nodule, a pebble, a fragment of slab or undetermined.  
228 Pebble tools are rare (one in quartz), while we total 32 entire or broken pebbles in various stones. Flake  
229 tools are rare as well (n = 46, 1.1%). They are mainly scrapers and denticulates, including one Quina scraper  
230 made on a thick and large flint flake. Levallois products are not retouched.  
231 The presence of cortical products (both backed and unbacked) suggests that a part of the debitage has been  
232 performed on the site with an introduction of already prepared cores. This is also the case for the blades  
233 with both cortical and non-cortical blades and points (**Fig. 4**). There are also backed blades and bladelets. If  
234 we compare the ratio of blades and points, there is an over-representation of these products compared to  
235 cores. Cores are mainly smaller and few exhausted on nodules or flakes except the Levallois and some  
236 centripetal cores made on flakes. A deep reduction would be necessary to be flaked again. The largest  
237 products could not be produced on the site and any large by-products are present.  
238 The largest flint flakes, Levallois blades (both cortical and non-cortical, mainly with unipolar schemes) and  
239 points were produced elsewhere, to the north and south of the site (up to 20-30 km and then brought to the  
240 shelter (**Fig. 4**). We total 55 pieces between 60 and 105 mm long (25 blades, 20 flakes and 10 points).  
241 According to geological analysis applied to a sample of more than 200 pieces, 13 raw material types were  
242 identified, with several types still unknown. They may have been collected from the Rhône Valley coming  
243 from the Alps Mountains. The main flint types so far identified attest to: (1) flint procurement on the  
244 plateau to the north of the site at a distance of 3 to 30 km (local to semi-local Barremian formations) from  
245 secondary flint outcrops and conglomerates, (2) secondary collection to the south, on a plateau located  
246 between 2 and 20 km from the site, involving crossing the Ardèche River (Ludian and Lutecian formations).  
247 The diversity of types is due to frequent gathering from conglomerates and indicates the indiscriminate use  
248 of all kinds of existing flint in each outcrop. Neanderthals collected flint while performing other activities, in  
249 a perimeter of 30 km around the site as an anticipation of future domestic needs.  
250 In terms of tool use, evidence of impact fractures suggests that some points, blades and flakes, could have  
251 been used as projectile tips, possibly as part of a complex projectile system (Hardy et al. 2013).  
252 Neanderthals exploited a wide range of resources including large mammals, fish, birds (possibly waterfowl  
253 and raptors), rabbits, plants, wood, and possibly mushrooms. Twisted fibres on stone tools provide evidence  
254 of making string or cordage (Hardy et al. 2020). Most of the stone tools were used for cutting, whatever  
255 their size and shape (including the Quina scraper). Imported artefacts and artefacts made on the site were  
256 used for the same range of activities and materials (butchery, plant and woodworking - Moncel et al. 2014).  
257

### 258 **3. Materials and methods**

#### 259 **3.1 Contextual stratigraphic analysis**

260 This methodology focuses on the attributes of the sedimentary matrix immediately associated with the  
261 artefacts in order to examine the three-dimensional spatial relationships among objects and deposits  
262 (Goldberg and Berna 2009). The aim is to identify at the finest scales the stratigraphic reality of human  
263 occupation episodes of level 4.1 with their distinctive microfacies assemblage resulting from the  
264 interference of depositional events and anthropic activities (Courty 2001).  
265

266 \*\*

267 As previously debated (Daujeard et al. 2019a), the contrast between the homogeneity at macroscale of the  
268 level 4.1 and the dense accumulations of archaeological remains makes interpreting the imprints of human  
269 occupation on the sedimentary matrix difficult. Also, the common occurrence of burnt bone fragments and  
270 the abundance of dispersed charcoals but no evidence of *in situ* heating makes a link occupation with fire-  
271 related activities unclear. The occurrence of greyish to reddish-brown thin lenses contrasting from the  
272 embedding loessic sediment by their granular structure were suspected to be possible remains of  
273

274 combustion deposits (Daujeard et al. 2019a). This suggested that the level 4.1 homogeneity could either  
275 express weak impact of human activities on the host sediment during short occupation events or complete  
276 alteration of anthropic attributes by post-depositional processes.  
277 In the absence of a distinctive microstratification throughout level 4.1 or of clear living-floors, contextual  
278 stratigraphic analysis was performed in the field by testing the link between any noticeable changes of  
279 microfacies and the occurrence of human artefacts. All subtle variations of microfacies identified by  
280 contrasting structure, texture or colour from the homogeneous host sediment have been exhaustively  
281 sampled to perform a systematic analysis of the microresidues from the bulk sediment samples. A sample of  
282 bulk matrix has also been systematically collected with each burnt bone or charcoal fragment that was  
283 exposed during the excavation. The same strategy was adopted for the polymer compounds that are similar  
284 to the previously identified ones in similar Neanderthal contexts (Courty et al. 2012). The polymer films,  
285 filaments and aggregates were identified with the naked eye during the excavation with their host matrix.  
286 . The exposure in square I6 of a 5 cm thick microstratified sublayer showing a succession of three greyish  
287 brown microaggregate lenses interwoven with abundant humified plant fragments and layered faunal  
288 remains with anatomical connections has provided a unique chance to perform a high resolution  
289 microfacies analysis during the excavation (**Fig. 5**).  
290 At an early stage of the excavation, a continuous column of undisturbed sediment blocks was sampled in a  
291 benchmark section for the fabrication of thin sections for micromorphological study. The column sampling  
292 was performed in an area with low density of human artifacts.  
293 All the bulk samples collected along the course of the excavation were water-sieved to obtain the total  
294 dispersion of the weakly resistant aggregates, clean grain surfaces and separation by sized-fractions (>2 mm,  
295 2-1 mm, 1mm-500  $\mu\text{m}$ , 500-250  $\mu\text{m}$ , 250-100  $\mu\text{m}$ ) after separation of light components by flotation. A  
296 morphological and mineralogical classification of the water-sieved residues was performed under the  
297 binocular microscope in order to perform a microfacies analysis of layer 4.1 and to identify unusual  
298 elements which would contrast from the bulk components. A selection of these unusual elements was  
299 subjected to scanning electron microscope and microprobe analyses (SEM-EDS).

300

### 301 **3.2 Spatial pattern analysis**

302

303 Level 4.1 is possibly a palimpsest of several occupations. The density and thickness of the material (Moncel  
304 and Daujeard 2012; Daujeard et al. 2019a). makes it difficult to distinguish all occupational events and the  
305 intensity or duration of each one (i.e. Mora Torcal et al. 2020). Based on previous results of archaeological  
306 assemblage studies, we decided to test spatial patterning focused on the horizontal distribution of all the  
307 remains from level 4.1 (Moncel et al., 2014; Daujeard et al. 2019a). The spatial patterning of the lithic and  
308 faunal remains is then compared with the data from lithic and faunal refitting and RMU lithic analysis  
309 (Bargalló et al. 2016; 2020; Romagnoli and Vaquero 2019; Fernández-Laso et al. 2020; Spagnolo et al. 2020a,  
310 2020b). These analyses provide insight into some spatial behaviours of Neanderthal groups occupying the  
311 rock shelter. Moreover, they provide a key to improving our knowledge of their cultural capabilities  
312 (Vaquero and Pastó 2001). However, given the limited extent of currently excavated surface, the analyses do  
313 not consider the entire area occupied by Neanderthals at the site. GIS analysis was carried out using ArcGIS  
314 10 software (ArcMap 10.4) (ESRI 2014). Nearest Neighbour Analysis and Kernel density analyses were used  
315 to identify the distribution pattern statically and visually. The research radius in the Kernel density analysis  
316 was defined as half standard deviation of our data.

317

### 318 **3.3 Faunal refits**

319

320 Bone fragments are less often included in refitting program than lithic materials. However, to discuss both  
321 the synchronic and diachronic components of transport and carcass processing events, bone refitting is  
322 essential (Rosell et al. 2012, 2019; Bargalló et al. 2016; Romagnoli and Vaquero 2019). Faunal remain  
323 refitting is one of the last steps of the zooarchaeological analyses, after taxonomic and anatomical  
324 determinations and taphonomic studies and can aid in the understanding of the taphonomic dynamics of  
325 the assemblage. Bone refitting can be complex because of species diversity within faunal assemblages and  
326 the quantity of bone fragments. Furthermore, material weakness increased the post-depositional  
327 fragmentation which may add to the perimortem fragmentation (Poplin 1976; Soulier 2013).

All the three-dimensionally recorded archaeological remains (n= 1946) and the  $\leq 1-1.5$  cm material non-recorded collected by sieving (n= 242) are taken into account.

In our work, mechanical and anatomical refitting (articulation and bilateral pairs) focused mostly on long bones and teeth of large- and medium-size ungulates (Morín et al. 2005; Lyman 2008; Enloe 2010; Fernández-Laso 2010). Spongy undetermined fragments were excluded in systematic refitting but undetermined shaft fragments ( $\geq 2$ cm) were included. Green bone or dry bone fracture edges help determine the homogeneity of assemblages through the identification of the *in situ* fragment movements (vertically and horizontally, intra- and inter-levels) (Enloe and David 1989; Villa and Mahieu 1991). Some refits were found during zooarchaeological analyses while other were notices during excavation. However, due to the scarcity of the long bone epiphyses and other elements of axial skeleton and carpals and tarsal, the anatomical refitting yielded few results compared to mechanical refitting, especially the bilateral pairs, which is quite impossible to identify in archaeological context. The identification of refits and anatomical connections during the excavation of level 4.1 revealed a weak pre- and post-depositional spatial disturbance of the archaeological material and offered us the possibility of distinguishing possible areas of activity (Rosell et al. 2012, 2019; Vettese 2014). Due to these numerous refits and the good spatial conservation of the elements, we established a systematic refit protocol for the long bones of Level 4.1 (Vettese 2014, Vettese et al., 2017; Daujeard et al. 2019a):

- (1) Selection and sorting of the identified remains by anatomical parts (ex. humerus, radio-ulna...taking account all the remains  $\geq 2$ cm);
- (2) Sorting by portions and sides (anterior, medial, posterior and lateral) (Fig. 2, Vettese et al. 2017);
- (3) Classification of all the remains by lateral side (right, left or undetermined);
- (4) Comparison of all the remains between right and left side and also with the undetermined ones, square by square and between squares;
- (5) Spatial distribution analysis of the bone refits and connections to identify the fauna-linked activity areas;
- (6) Cross-comparisons with the lithic refits and other disciplines in order to reach a comprehensive view on the type of occupation based on multiple resources.

### 3.4 Lithic Raw Material Units (RMU) and refit lithic analysis

The Raw Material Units (RMU) and the refit analysis allowed the reconstruction of the temporal formation of the lithic assemblage and identification of specific events of technical activity. This is defined as an activity episode related to the manipulation of lithic resources that is performed continuously, without location changes or temporal interruption (Roebroeks 1988; Vaquero 2008).

Refits are the most direct evidence to identify pieces belonging to the same RMU. However, other kinds of data must be considered. First, the macroscopic characteristics of the raw materials, including colour, grain, size, texture, inclusions and type of cortex. The technical categories, the size of the pieces, together with their spatial pattern are also used to integrate different artefacts in the same RMU (Machado et al. 2011, 2013; Vaquero et al. 2012a, 2012b; Chacón et al. 2015). In addition, RMU have been characterized by considering two main features: introducing events defined by the mode of introduction and knapping events referring to the intentional modification performed inside the site. We have also used petrographic analysis to group some RMUs on patinated flint due to the very high percentage of patinated flint material (around 58 %) in level 4.1 (Moncel et al. 2014).

For the refit analysis, we used the methods and terminology proposed by Cziesla (1990) and Sisk and Shea (2008). This methodology has been already used in other Middle Paleolithic sites with very good results to reconstruct the formation and composition of the lithic assemblages (among others: El Salt, Abric del Pastor, Abric Romaní, Teixoneres cave - Roebroeks 1988; Vaquero 2008; Chacón et al. 2015; Machado et al. 2011, 2013, 2019; Vaquero et al. 2012a, 2012b, 2019; Picin et al. 2020).

Three kinds of connections are distinguished: production-sequence, breakage and retouch refits. For production and retouch refits, connection lines have been defined according to the chronological order of

382 detachments, starting with the first refitted flake to the core or tool. For the refits of broken artefacts, the  
383 connection lines have been established by considering the contacting surface (Vaquero et al. 2012b). The  
384 refitting procedure allows us to distinguish two forming processes: (1) sets of artefacts splitting from each  
385 other by controlled conchoidal fracture (e.g., a flake whose ventral side joins to the surface of a core or the  
386 dorsal surface of another flake); and (2) conjoins: fragments of artefacts broken by forces other than  
387 conchoidal fractures (e.g., natural flaws, bending fractures, burning, etc.) (Sisk and Shea 2008).  
388

389 A total of 2050 lithic items recorded for level 4.1 were considered for this study, discarding the badly  
390 preserved pieces (with patina or thermal alteration) and pieces  $\leq 1$  cm long. The amount is not the same  
391 that in **Table 1** (n=2041) because some microflakes from the sieving materials were identified as parts of  
392 RMUs due to their macroscopic attributes.  
393

394 As a final step for the faunal and lithic refits, their spatial distribution together with the one of the RMU  
395 groups has been analysed. The results obtained are interpreted by integrating the multidisciplinary analysis  
396 of the different resources in order to identify the activity events (technical or related to the exploitation of  
397 carcasses) and their relevance in terms of occupation type for level 4.1.  
398  
399

## 400 **4. Results and interpretation**

### 401 **4.1 Contextual stratigraphic analysis**

402  
403  
404  
405 The micromorphological study performed on the benchmark section covering the entire level 4.1 confirms  
406 its homogeneity throughout the 20 cm thick deposit with a well-developed biogenic microstructure showing  
407 dense packing of earthworm pellets. The absence of distinctive vertical channels and the uniform  
408 composition of the microaggregated fine mass indicate an accumulation of biogenic reworked soil-materials  
409 rather than post-depositional effects of bioturbation. This extensive deposition of previously bioturbated  
410 soil-materials suggests that the limestone cliff was extensively colonized by woody vegetation with dense  
411 roots that trapped the loessic sediment. Incipient *in situ* redistribution of secondary carbonates along the  
412 packing porosity of the biogenic microaggregates has acted as a weak cementing agent of the deposits, thus  
413 favouring their intact preservation following their accumulation at the surface. In addition to the major silt  
414 component of aeolian origin, level 4.1 also displays an abundant subrounded calcareous coarse fraction (20  
415 to 40 %) of local origin and a minor population of angular quartz fine sands. The surface corrosion of the  
416 local coarse components that is typical of the microbial weathering occurring in root-colonized soil materials  
417 contrasts with the fresh angular sands, thus suggesting a possible exogenous origin. The random  
418 distribution of the limestone components and the lack of any freeze-thaw pedofeatures in the fine mass  
419 indicate that level 4.1 did not suffer from significant effects of frost during its accumulation.

420 These microstructural characteristics are coherent with the close association of the archaeological materials  
421 with the large slabs that collapsed from the limestone walls and partially fragmented *in situ* due to  
422 weathering by root colonization, as noticed during the excavation. The formation of level 4.1 can thus be  
423 concluded to have occurred under a mild temperate climate that allowed the formation of a dense  
424 vegetation cover protecting the limestone cliff from the direct effect of rainfall thus offering a dry shelter to  
425 the occupants. In contrast, the fine silt texture, the weak effect of pedogenesis and the lack of coarse  
426 limestone fraction in the sterile loessic deposits that bracket level 4.1 indicates that the site was not  
427 occupied when the limestone cliff was no longer protected by a dense vegetation cover and therefore  
428 directly exposed to winds and rainfall.  
429

430  
431 A few diffuse, cm-thick discontinuities that are marked by a more open micro-aggregation have been  
432 identified in the thin sections. These have sub-horizontal biochannels, well-preserved humidified organic-  
433 fragments, slight depletion of the calcitic fine mass and of the coarse fraction, and higher abundance of the  
434 angular quartz sands. This particular microfacies is typical of soil surface that was covered for a while by

435 biogenic crusts most probably due to moisture increase, thus inducing microbial activity (Courty et al.  
436 1989). However, the scarcity of microartefacts (bone and charred residues) and the absence of a distinctive  
437 trampled-linked microstructure do not allow us to consider these subtle discontinuities as residual living  
438 floors (Gé et al. 1993).

439 These discontinuities differ from the greyish to reddish-brown microaggregate lenses by their diffuse  
440 characteristics and the lack of distinctive attributes for relating them to human activities.

441 In contrast, the greyish to reddish-brown microaggregate lenses have been clearly identified in the field  
442 along the course of excavation by their sharp contact with the host homogeneous sediment, their loose  
443 microstructure and the common occurrence of microartefacts (**Fig.5a, b**).

444  
445 Their microfacies analysis reveals a dense packing of coarser aggregates (5 mm in average) that have a high  
446 structural stability and a marked hydrophobicity as compared to the homogeneous level 4.1. A great  
447 diversity of abundant millimetre-sized microresidues with clean, hydrophobic surfaces have been retrieved  
448 from the fine mass (**Fig.6a**). They comprise a high amount of the angular quartz sands that are similar to the  
449 ones in the weak discontinuities, along with abundant polymer components, siliceous sandstones, glassy  
450 breccia, metal films, fine charcoal, vitreous chars, shell fragments, flint micro-flakes, humified plant  
451 fragments, whitish ash grains, burnt, calcined or pyrolyzed bone fragments and elements of flying insects.

452  
453 The analysis of the water-sieved residues from the matrix associated with charcoals and chars that were  
454 collected throughout level 4.1 revealed similar translucent polymer films and coloured filaments, often in  
455 the form of twisted bundles.

456  
457 Within these diverse microresidues, the SEM-EDS analyses showed a common occurrence of  
458 nanostructured deposits of native metals which are either filling micro-cavities, forming aligned droplets, or  
459 being attached as twisted films to vesicles of the microdebris (**Fig.6**). All these exotic components have been  
460 previously identified in Neanderthal hearths at the Abric Romani (Courty et al. 2012) and have been since  
461 shown to be traces of flash-pyrolysis by-products that are issued from lightning-triggered aerosol  
462 transformation during periods of enhanced atmospheric electrification (Courty 2017). The occurrence of  
463 these flash pyrolysis by-products in the chars and charcoals of level 4.1 indicates the use of wood fuel that  
464 accumulated lightning-formed refractory components of enhanced conductivity in the plant tissues during  
465 tree growth (Courty et al. 2020).

466  
467 The microfacies of the microaggregate lenses with their heteroclite microresidues does not match any type  
468 of firing by-products which have been encountered so far in present or past fires of human or natural origin  
469 (Courty et al. 1989; Courty 2012; Macphail and Goldberg 2018). Furthermore, only part of the micro-  
470 residues displays burning traces whereas other are unburnt, although showing metal encrustations. In  
471 addition, the sharp contact of these distinctive microfacies with the surrounding and underlying sediment  
472 and the lack of large earthworm channels indicate that the microaggregation was not formed by *in situ*  
473 reworking of combustion deposits. In contrast to the adjacent bioturbated matrix of level 4.1, the  
474 abundance of human-related microresidues refutes an origin of soil materials falling from the limestone cliff.  
475 Therefore, the microaggregate microfacies must be an earth-made anthropogenic material mixed with fire  
476 residues and lightning-formed organo-mineral components. The observation during the laboratory  
477 treatment by moderate heating at 80°C of a new generation of sticky polymer films bounding the water-  
478 sieved residues showed that active catalyzers are still present in the microaggregates and are still reactive.  
479 Similar kinds of highly reactive catalyzers have been observed in recent situations of lightning impact at the  
480 ground along to highly stable polymers and metal pulverisation (Courty 2017; Courty et al. 2020). Compared  
481 to the reference data base, their great abundance in the microaggregate lenses of level 4.1 at the Abri du  
482 Maras helps to establish their anthropogenic deposition from use of lightning-impacted organic materials.  
483 This correlation is confirmed by the good match between the vertical distribution of the archaeological  
484 objects and the depth of the microaggregate lenses shown by the archeostratigraphic profiles.

485  
486 The contextual stratigraphic analysis of level 4.1 provides solid support to establish the multiplicity of  
487 occupation episodes for a short duration, which coincides with periods of enhanced lightning in response to  
488 atmospheric increase of ionized aerosols (Courty 2017; Courty et al. 2020). The absence of a continuous

489 particle-size range between the coarse and fine components of the artefacts clearly shows the lack of  
490 mechanical fragmentation which would have been caused by intense trampling of long-used surfaces. This  
491 moderate mechanical effects of human activity is confirmed by the microstructural properties of the  
492 successive level 4.1 occupation phases. The weak anthropogenic impact associated with the abundance of  
493 lightning-related microresidues suggests that the successive short-time occupation episodes share in  
494 common a set of activities linked to the use of lightning products.

495  
496 The highest density of lithic remains in the main part of the excavated area indicates that the occupations  
497 were preferentially located at a certain distance from the shelter wall, probably at the edge of the shelter  
498 roof (**Fig. 7**). As suggested by Combier (1967) and Debard (1988), at the time of level 4.1 deposition, the  
499 shelter was already largely collapsed and therefore limited to the right side of the small valley. There is no  
500 clear concentration of artefacts within the site, except a higher density of lithic remains close to the areas  
501 with the microaggregate greyish to brown-reddish lenses at the Northeast part and at the centre of the  
502 excavated area.

#### 503 504 **4.2 Spatial patterning**

505  
506 Level 4.1 has been excavated over a surface of 34 m<sup>2</sup> and a total thickness of 20 cm. Due to the dense  
507 accumulation of archaeological remains over the entire surface, it was presumed that level 4.1 did not  
508 present well preserved living floors (Daujeard et al. 2019a, b). After the study of the total archaeological  
509 assemblage (fauna, lithics and others; **Fig. S4-8**) from different methodological approaches, we decided to  
510 apply some spatial geostatistics in order to identify, from a quantitative point of view, the possible existence  
511 of accumulation areas that could correspond with domestic activity areas (following the definition of  
512 Stevenson 1991; Vaquero and Pastó 2001).

513  
514 The Nearest Neighbour Analyses of all the remains, including faunal and lithic materials, show that the  
515 spatial distribution is significantly clustered (all: score z: -55.38, p-value<0.001; bone: z-score: -40.33, p-  
516 value<0.001; lithic: z-score: -31.04, p-value<0.001). To visualize the clusters, we applied a Kernel-density  
517 analysis and the results show some clear accumulations of remains. These clusters are associated with the  
518 higher density of archaeological remains (fauna and lithics) and the microaggregate greyish to brown-  
519 reddish lenses (**Fig. 8**). The general pattern of level 4.1 shows four main accumulations areas (A to D) and  
520 three secondary ones (E to G), whereas the other remains are dispersed throughout the entire occupied  
521 surface. Some remains dispersed within the first interval (0–7%, lower concentration of remains) were  
522 located on the areas with few artefacts present, possibly in sectors where the level is residual.

523  
524 The spatial patterning of the faunal (**Fig. 9**) and lithic remains (**Fig. 10 and 11**) shows significant differences  
525 despite a broadly similar general distribution. The lithics show a larger dispersion of remains (from lines 5 to  
526 8) that the faunal ones (from lines 5 to 7). Thus, a greater quantity of artefacts was produced by knapping  
527 activities than the exploitation of carcasses and their normal dispersion is usually ≤ 1.5-2 m around the  
528 knapping locations (see refits section). In addition, the lithics present a higher number of clusters than for  
529 the faunal remains, especially for the main largest/dense accumulations areas (**Fig. 8**).

530  
531  
532 Lithic refits show pieces that connect two accumulations (n=7 refits) whereas faunal refits show only one  
533 (see section 4.3 and 4.4.2 – **Fig. 9 and 11**).

534  
535 Considering the general distribution of the remains and the morphology of the shelter over time, the main  
536 activities areas that are now identified are located just at the centre towards the outside part of the site.  
537 The geological study and the previous excavations showed that the slanted topography of the limestone  
538 substratum with a series of steps encouraged the occupants to settle a bit far from the shelter wall  
539 (Combier 1967). Therefore, the successive occupations followed the shortening of the roof in order to  
540 always settle at the best place, some meters away from the shelter wall. This open, well-lit area was also  
541 conducive to subsistence activities. This pattern is similar to the ones found in other Middle Paleolithic sites  
542 and can also be found in numerous ethnographic accounts (Binford 1978, 1996; Henry et al. 1996, 2004;

543 O'Connell 1987; Stevenson 1991; De la Torre et al. 2012; Modolo et al. 2015; Ekshtain et al. 2019;  
544 Fernández-Laso et al. 2020; Spagnolo et al. 2020a, 2020b).

545

### 546 4.3 Bone refits

547

548 Based on 2188 remains analysed, we identified 222 remains (10%), split into 88 bone refits in level 4.1.  
549 Mechanical refits represent the most frequent type, with 46 green bone fracture refits and 21 dry bone  
550 fracture refits, whereas there were only 21 anatomical refits. The most numerous refits are those  
551 composed of 2 remains (n=64 refits), followed by 3 remains (n=13 refits). Refit groups with more remains  
552 (between 3 and 8) are less frequent (n=11 refits) (**Table 2**). The longest refit is anatomical and connects  
553 eight elements (including seven complete ones).

554

555 Regarding all refits, 134 connection lines were identified (anatomical refits (n=47), green bone fracture  
556 refits (n=62), dry bone fracture refits (n=25)). The longest distance recorded was 2.51 meters for a green  
557 bone fracture connecting two bones (**Table 3**). However, the distance of most of the remains refitted was  
558 equal to 0 (52 % of the refits).

559

560

561 At taxonomic level, *Rangifer tarandus* showed the largest number of refits (61 refits) incorporating 547  
562 remains (**Table 4**), reflecting its dominance at the site. *Equus ferus* was the next most common with a  
563 majority of anatomical refits (3/6). We also found refits of non-taxonomically identified elements (20.5 %).  
564 Most of the bone refits were the partial reconstruction of long bone remains, mostly forelimbs (**Table 5**). All  
565 the bone refit of the head were anatomical refits.

566

567 In horizontal distribution, the bone material followed the pattern observed with the clusters resulted of the  
568 analysis of all the remains. However, areas C and D are grouped together. Most of the refits are in the main  
569 cluster areas defined from the Kernel density (**Fig. 8 and 9**). These zones are not connected, except for one  
570 mechanical refit, a green bone fracture, connecting the main area D with the secondary area E.

571

572

### 573 4.4 RMU and lithic refits

574

575 As we previously mentioned (see materials and method section), the percentage of patinated flint material  
576 for level 4.1 is high (around 58 %). A total of 2050 lithic items were considered for this study. Patinated,  
577 thermally altered, and pieces  $\leq 1$  cm long were excluded from this study. Nevertheless 52 RMU and 22  
578 refitting groups were recognized.

579

#### 580 4.4.1 RMU analysis

581

582 The 52 RMU identified total 593 pieces (26.3 % of the lithic assemblage, **Table 6**), mainly in flint and quartz.  
583 Each RMU corresponds to individual technical events and they were categorized as representing either  
584 introduction to the site (introducing events - IE) or modification performed on the site (knapping events -  
585 KE).

586

587 Some RMUs indicate several complete or almost complete knapping sequences produced on-site. All the  
588 technical categories are observed in the same RMU, including the production of the first cortical flakes and  
589 the different phases of reduction sequences and cores. Others show the fragmentation of the reduction  
590 sequences. The smallest RMUs are composed of a single object (isolated artefacts). These pieces were  
591 introduced to the site already knapped and are interpreted as part of tool kits transported by the human  
592 groups while moving throughout their territory. These tools demonstrate the fragmentation of some  
593 reduction processes and the existence of planned behaviour strategies in relation to (1) raw material  
594 constraints and, (2) specific needs in relation to the activities performed within and outside the site. **Table 7**  
595 synthesizes and describes each identified RMU.

596

597 The IE are mainly knapping products (flakes, blades and points) of different sizes, produced by both  
598 Levallois and discoidal strategies (e.g. Isol-Fl 1 to 11, Isol-Qtzite 3, Fl-1 – **Table 7 and Fig. 10b-d**). Some cores  
599 are introduced in an advanced state of reduction and are abandoned at the site after yielding a small  
600 number of flakes (around 2-3) (e.g. RMU Fl-16b, **Table 6**).

601  
602 The KEs demonstrate the co-existence of different core technologies, with a predominance of centripetal  
603 bifacial strategies (e.g. RMUs Fl-5b, Fl-13, Fl-16d to f, Qtz-1). Levallois technology only employs flint and  
604 limestone with unipolar recurrent and recurrent centripetal methods most common. For other stone types  
605 (i.e. quartz) the most frequent methods are orthogonal and discoidal. Nodules, angular fragments and large  
606 flakes form the basis of cores.

607  
608 The high degree of reduction often produces cores that are over-exhausted, making it difficult to identify  
609 the method, but the knapping products present the typical attributes necessary to describe the core  
610 technologies.

611  
612 The technological analysis of the whole assemblage (Moncel et al. 2014), as well as the RMUs analysis,  
613 shows a high degree of fragmentation of the lithic reduction processes (i.e. Vaquero et al. 2012b; Turq et al.  
614 2013; Vaquero et al. 2012b). Some isolated pieces are introduced to the site already knapped while some  
615 RMUs show that the main technical processes were realized on the site. However, some pieces are missing,  
616 mainly predetermined flakes and cores (e.g. RMUs Fl-12, Qtz-5). Knapping products and flake tools may  
617 therefore be mobile or curated pieces (i.e. Vaquero et al. 2012a, Vaquero et al. 2012b; Moncel et al., 2014;  
618 Spagnolo et al. 2020b; Mayor et al. 2020; Picin et al. 2020). By contrast, some RMUs show the entire  
619 reduction but not the core, indicating that a core could have been transported away from the site as a new  
620 mobile tool kit.

621  
622 There are many isolated artefacts produced in flint (**Table 6 and 7**). These pieces are all produced with  
623 Levallois technology and are mainly flakes, blades and points. There are some in quartz, quartzite and  
624 basalt, with one quartzite piece that looks like a Levallois product. The other artefacts are unretouched  
625 flakes or fragments coming from discoidal and orthogonal technologies.

626  
627 The spatial distribution of the RMUs does not show any special spatial pattern either by RMU, by type of  
628 stone or technological composition. Their density and spatial distribution correspond to the pattern  
629 observed in the spatial Kernel analysis of the lithic and faunal assemblage (**Fig. 8 and 10**). Some of them  
630 present a normal dispersion of a knapping area (e.g. RMU Fl-12, Fl-15) (Newcomer and Sieveking 1980;  
631 Böeda and Pelegrin 1985; Czesla, 1990 Vaquero et al. 2019), while others are spread over the whole  
632 occupation area (e.g. RMU Fl-13, Fl-16). A clear example is the spatial patterning of the RMU Lim-1 (unique  
633 RMU in limestone and formed only by Levallois flakes - **Table 7 and Fig. 11d**) that corresponds with the  
634 main and largest accumulation identified by the Kernel analysis as well as for the lithics than the bones.  
635 Consequently, this RMU may relate to one specific occupation event. The differences and overlap in RMU  
636 spatial patterning support the hypothesis of repeated short-term occupations. (Vaquero et al. 2012;  
637 Spagnolo et al. 2016; 2020b).

#### 638 639 **4.4.2 Lithic refits analysis**

640  
641 After the analysis of the RMU, some pieces < 1 cm long recovered from the sieving material were also  
642 taking in account for the refitting.

643 A total number of 22 refits groups comprising 49 pieces have been identified. The lithic refit rate of the  
644 whole lithic assemblage (n=2050) is 2.4% with 8.2% coming only from the identified RMU groups (n=593).  
645 Flint and quartz present the highest number of refits. Most of them are composed of two elements (82%)  
646 and with the largest comprising 4 pieces (**Table 8**).

647 The majority are knapping products, mainly flakes and flake fragments. There are only 3 cores and 1 flake-  
648 tool (**Table 9**). These products come mainly from Levallois and discoidal strategies (**Fig. 11b, 11d-f**).

649 The refits give 27 connections lines (see **Table 10**). Most of the lines correspond to knapping connections  
650 (55.5%), knapping fractures and conjoins (22.2 % each). Due to the difficulties in refitting, small retouch

651 flakes as well as the high number of isolated artefacts carried out to the site already knapped, it was  
652 difficult to identify refits related to retouch (**Table 10, Fig. 4 and Fig 10c, d**). Where refits were possible,  
653 knapping connection lines are dominant no matter the stone type. All of them following the same pattern,  
654 even if), core reduction activities were carried out *in situ* (e.g. limestone).  
655 The distances of the connection lines vary from several centimeters to almost 4 meters (**Table 11**). They are  
656 within the normal dispersion range observed by experimental archaeology for on-site knapping sequences  
657 that are normally less than 1 m in diameter and rarely exceeding 2 m (Newcomer and Sieveking 1980;  
658 Böeda and Pelegrin 1985; Czesla, 1990; Vaquero et al. 2019). Most connection lines are shorter than 1 m  
659 (n=17-63%), six refits (22.2%) are between 1 and 2 m, and only 4 (15%) between 2 and 4 m. The shortest  
660 connection lines belong mainly to the conjoins (post-depositional breakages produce by trampling). The  
661 longest connections lines are all related to knapping activities with only one refit of 3 pieces (belong to a  
662 conjoin) presenting a distance for more than 1.5 m (**Fig. 11**). Since *in situ* preservation of anatomical bone  
663 connections and broken artefacts suggests that natural processes have had minimal impact on the site,  
664 these longer connections lines suggest intentional anthropogenic movement of some pieces during daily  
665 activities,. These pieces were knapped in one area and moved to other part of the settlement and/or  
666 abandoned at the place of their last use. These pieces with intra-site mobility are all products of on-site  
667 knapping and are not distinguished by a particular raw material type.  
668 The spatial patterning of the lithic refits reveals two clear patterns. First, the refits are clearly located in the  
669 main accumulation areas identified by the Kernel analysis (**Fig. 11**). Second, there is an important number of  
670 refits that connect some of the identified clusters (e.g. A with D, E with D, B with G and one between E, F  
671 and B). Consequently, the lithic refits show a higher degree of articulation of the occupied surface than the  
672 one observed by the faunal refits (**Fig. 9**). However, we cannot confirm that these connections between  
673 areas are showing their temporal synchronicity, because (1) the unidirectionality patterns of pieces moved  
674 and (2) any recycling pattern have been observed in any of these pieces (Vaquero et al. 2015; Romagnoli  
675 and Vaquero 2019).

676  
677

## 678 **5. Discussion and conclusion**

679  
680 The results of this work demonstrate that quantitative approaches, associated with the interdisciplinary  
681 empirical processing of data, are suitable and adequate methods for describing the spatio-temporal  
682 formation of the archaeological assemblages and can be used to reconstruct human occupation patterns.  
683 We identified seven different accumulations areas, all related to subsistence activities and associated with  
684 remains related to the use of fire by-products (domestic areas *sensu* Stevenson 1991; Vaquero and Pastó  
685 2001, **Fig. 8**), although *in situ* combustion deposits and structured hearths were not identified. This is also  
686 confirmed by the results of the faunal and lithic refits and the RMU analysis (**Fig. 10 and 11**). Despite the 34  
687 m<sup>2</sup> excavated surface we know from the shape of the substratum observed in previous excavations, that the  
688 successive occupations followed the shelter ceiling and floor. The oldest occupations are farther from the  
689 shelter wall and are located on a lower limestone step.  
690 Level 4.1 of the Abri du Maras provides detailed evidence on the types of occupations under an open  
691 shelter during MIS 3. This site reveals some unusual patterns for Middle Palaeolithic short-term occupations  
692 (i.e. Sánchez-Hernández et al. 2014; Gabucio et al. 2018; Moncel et al. 2018, 2019; Bargalló et al. 2020;  
693 Cascalheira and Picin 2020; Picin et al. 2020). Previous studies have highlighted various types of  
694 Neanderthal cave and shelter occupations with a farsighted circulating model and recurrent base camps of  
695 various duration, from seasonal camps to bivouacs (Daujeard and Moncel, 2010; Daujeard et al. 2016).  
696 Instead, we have intensive *in situ* carcass processing, non-specialized dwelling activities with evidence of fire  
697 use, and no traces of carnivore activity (Hardy et al. 2013; Daujeard et al. 2019a). Furthermore, this study  
698 highlights low material displacement, more faunal refits than lithic ones, and a relatively low ratio of flake-  
699 tools. This pattern is uncommon compared to the other examples of short-term occupations both in the  
700 region and in Europe in general.

701  
702 Short-term occupations are characterized here by the introduction of large with secondary flaking *in situ*,  
703 raw material collection within 30 km of the, and behaviours organized around the exploitation of the

704 surroundings during short-term autumnal reindeer hunting episodes (can be seen in other sites *i.e.*  
705 Costamagno et al. 2006; Richards et al. 2008; Gaudzinski et al. 2009; Daujeard and Moncel 2010; Britton et  
706 al. 2011, 2012; Niven et al. 2012; Rendu et al. 2012; Daujeard et al. 2016, 2019b; Discamps and Royer 2016;  
707 Discamps and Faivre 2017; Cascalheira and Picin 2020).

708  
709 Zooarchaeological and taphonomic studies, combined with spatial analyses applied to faunal material  
710 (including bone refits), is a useful tool for identifying areas of activity (Vaquero et al. 2012a, 2012b; Rosell et  
711 al. 2012, 2019; Spagnolo et al. 2019). Faunal refitting allows us to test the time between carcass processing  
712 events. According to our analysis, we observe minor or no displacement of bone remains, with most of the  
713 refits having a distance of zero. Anatomical refits demonstrate a high fidelity of spatial distribution. Among  
714 the high number of bone refits, most are green bone fractures (Daujeard et al. 2019a). Root-etching  
715 alterations are the principal modifying agents of bone surfaces with half of the assemblage presenting more  
716 than one-third dissolved surface. However, this did not prevent the identification of numerous refits. The  
717 one dry bone fracture with a zero distance could be the consequence of sedimentary compaction without  
718 visible hiatus. Together, this shows a high preservation of the spatial integrity of the occupation level with a  
719 vertical distribution related to sediment compaction. It highlights the high probability that the level is a  
720 palimpsest of several occupations. Almost all the bones (in particular the ones involved in refits) have no  
721 traces of weathering, thus suggesting rapid burial. Moreover, we observed very few trampling marks and no  
722 carnivore disturbance. This indicated also that the rapid burial of the bone remains. Overall, this suggests  
723 that the excavated area has a high temporal resolution.

724  
725 Most of the faunal refits have a small or a zero distance. Moreover, most of the activity areas identified are  
726 not connected by bone refits, except for one green bone fracture refit involving a displacement before the  
727 bone dried and before burial. Butchery activity distributions seem to be clustered indicating different  
728 carcass processing episodes. All the activities of the butchering “chaîne opératoire” were carried out *in situ*  
729 (Vettese et al 2017; Daujeard et al 2019a). However, the absence of hearth does not allow specifying the  
730 hypothesis on the functionality of these areas (toss or drop zones, or activity areas) based on ethnographic  
731 observations (Binford 1978, Rosell et al. 2012). Clusters of bone and lithics are quite similar. We also  
732 observed some patterning relating possible butchery activities with the microaggregate lenses. Moreover,  
733 we noted a scarcity of bone remains around the microaggregate lenses.

734  
735 The implication of monospecific faunal spectra in late Neanderthal occupation contexts reflect specific  
736 behaviors which particularly raises questions regarding food meat and marrow abundance in the case of this  
737 specialized hunting strategies (Gaudzinski and Roebroeks 2000; Costamagno et al. 2006; Niven et al. 2012;  
738 Niven 2013; Castel et al. 2017). The high frequency of reindeer in level 4.1 shows that Neanderthals used  
739 the site in the autumn specifically for this task, targeting the most common species in the area (Gaudzinski  
740 and Roebroeks 2000; Costamagno et al. 2006; Niven et al. 2012; Niven 2013; Castel et al. 2017). Moreover,  
741 the selective transport of the most nutritionally valuable elements within the rock shelter shows planning  
742 and forethought (Vettese et al. 2017; Daujeard et al. 2019a). Intact metapodials with no evidence of  
743 butchery suggests a relative abundance of food and relatively short occupations of the site. This is further  
744 supported by extensive long bone breakage with little evidence of exploitation of phalanges or mandibles  
745 for marrow. The emphasis on bones with large amounts of marrow suggests a period of abundance of meat  
746 and marrow. Bone retouchers are absent indicating that bone was not reused after butchery. All this leads  
747 to evidence of several rather short occupations that are repeated over time and mostly centered on the  
748 reindeer carcass processing.

749  
750 The technological attributes observed on the RMUs and the refits confirm the preliminary results of the  
751 technological analysis of the whole lithic assemblage (Moncel et al. 2014) and emphasize several main  
752 features. First, the high degree of fragmentation of the reduction sequences and the high number of  
753 isolated artefacts brought to the site already knapped are evidence of planning ahead based on anticipated  
754 raw materla constraints and subsistence activities (Kuhn 1992, 1995). Second, the evidence of partial  
755 reduction sequences could be interpreted as a feature of repeated short-term occupations in relation to  
756 the hunting of reindeer (Turq et al. 2013; Mayor et al. 2020; Picin et al 2020). Moreover, the variability of

757 RMUs spatial distribution (see **Fig. 10, Table 7**) with some more clustered and some more scattered,  
758 reflects a series of short term occupations.  
759

760 The spatial patterning of the archaeological remains and the morphology of the shelter over time shows  
761 that the main activities areas that have been so far identified are located in the centre of the excavated  
762 area, about 4 meters from the shelter wall. The shelter substratum, with its successive steps, appears to  
763 have strongly influenced the location of occupation. The occupations are located in the best area under the  
764 roof edge to develop the subsistence activities with more light. This pattern is similar to other Middle  
765 Paleolithic sites and ethnographical data. The direct contact of the latest occupation with the limestone  
766 substratum at the foot of the shelter wall suggests that part of the sequence has been possibly eroded. The  
767 occurrence of the large limestone slabs that collapsed at some distance from the shelter wall appears to  
768 have greatly aided in the preservation of the level 4.1 occupational sequence.  
769

770

771 The good preservation of anthropogenic microfacies and scattered charcoal fragments throughout level  
772 4.1, together with the lack of evidence for *in situ* bioturbation, show that the lack of hearth structures or of  
773 distinctive firing deposits is not a bias caused by post-depositional alteration. The profusion of scattered  
774 highly fired bones and vitreous chars in an unburnt host matrix suggests that the fire-related residues have  
775 been displaced from the original activity area where they were produced and intentionally used for such as  
776 other activities, as suggested by the scattered charcoals. The excavated area may not correspond to the  
777 particular location devoted to fire maintenance and more likely represents an open well-lit area devoted to  
778 subsistence strategies since it is far from the shelter wall (Kedar et al. 2020). Wood was probably the main  
779 fuel used (see charcoals of trees collected on the site) and was probably collected from the nearby areas  
780 based on the gathering of fallen branches. The selection was based on branch sizes and condition of the  
781 wood as has been suggested for other sites (Uzquiano et al. 2012; Solé et al. 2013; Vidal-Matutano et al.  
782 2015; Allué et al. 2017; Vidal-Matutano 2017).  
783

784 The spatial distribution of the lithic refits reveals two patterns. First, the refits are clearly located to the  
785 main accumulation areas identified by the Kernel analysis (**Fig. 8**). Second, there are a significant number of  
786 refits connecting some of the identified clusters (e.g. A with D, E with D, B with G and one between E, F and  
787 B). All the faunal refits are well clustered on the accumulation area and only one connect two of them. This  
788 faunal refit with a long connection line could suggest possible food sharing between the group's members  
789 or different areas of treatment of the carcasses (Gabucio et al. 2018; Marín et al. 2019) (butchery  
790 specialized areas). By contrast, the lithic refits show a higher degree of articulation and intra-site mobility in  
791 the occupied area (n=7 refits) compared to the faunal refits (n=1 refit) (**Fig. 9 and 11**), even if the  
792 synchronicity cannot be demonstrated. This feature is also observed at other Palaeolithic sites (*i.e.* Vaquero  
793 et al. 2012a; Bargalló et al. 2016; 2020). Carcasses were exploited in the same areas and only humans and  
794 artefacts moved between the different subsistence activities areas.  
795

796 To sum up, level 4.1 of the Abri du Maras represents recurrent short-term occupations, and not a mass  
797 hunting of reindeers during one main occupation, marked by faint living floors and distinctive  
798 anthropogenic facies. Neanderthals brought materials from a collecting perimeter of 30 km and introduced  
799 some already knapped artefacts, especially during autumn for hunting reindeers and/or processing  
800 carcasses of reindeers. Some types of flint show that Neanderthal had to cross the Ardèche River to reach  
801 the shelter. Carcass processing indicates a low level of fracturing implying the recovery of meat and  
802 consumption on the spot of some marrow. Micro-wear traces and residues support that both butchering  
803 and domestic activities were performed at the site. Four pieces that refit show traces related with cutting  
804 plants and whittling wood (Hardy et al. 2013). There are not clear areas of specialized activities but there is  
805 intentional movement of some artefacts. At this juncture, it is not possible to estimate the size of the group  
806 in question but it may have been a few individuals or a family group. The absence of carnivore tooth marks  
807 on the bones abandoned on the site could be possibly explained by rapid burial, or repeated human visits to  
808 the site despite the indications of primarily autumnal occupations.  
809

810 The results of the level 4.1 of the Abri du Maras raise questions about the definition of mobile groups and

811 ephemeral occupations for Neanderthals. (Gabucio et al. 2018; Marín et al. 2019). At the nearby site of  
812 Payre, during MIS 7, we observed short-term occupations with a diversity of flint, mainly local (less than 30  
813 km), the differences being in the ratio of alluvial or colluvial flint collected (Moncel et al. 2018). Most of the  
814 types of flints Payre were similar to those of the Abri du Maras indicating that, over time, Neanderthals in  
815 the region used a similar land use strategy for flint collecting (for instance, for good quality Barremian  
816 Bedoulian flint - F14 and F34). For MIS 4-3, the Abri des Pêcheurs, located to the west in the Chassezac  
817 Valley, and the Barasses II cave (Balazuc) along the Ardèche River, the records suggest brief and recurrent  
818 occupations (bivouacs) (Moncel et al. 2008, 2018, 2019; Daujeard et al., 2019b). These sites only contain  
819 flakes and a few cores in flint with limited use of local quartz or basalt pebbles. They also have a wider  
820 diversity of flint types from alluvial deposits and colluviums from a large perimeter extending in several  
821 directions, from 10 to 30 km. This suggests that toolkits may have circulated from site to site.

822  
823 Our combined results provide new data on late Neanderthal short-term occupations regarding level 4.1 of  
824 the Abri du Maras. The use of toolkits (points, flakes, blades and some cores brought to the site), specialized  
825 seasonal hunting of reindeer, carcass processing *in situ* and repeat disposal of lightning-related materials at  
826 the same place indicate specialized, short occupations of the site by Neanderthal groups. The lack of a  
827 formal hearth may not mean lack of fire in general (contra Dibble et al. 2018) but in contrast a long-  
828 maintained knowledge of suitable fuel issued from lightning-struck wood. Indeed, distinct activity areas  
829 which vary in time and space suggest repeated occupation by one or several groups, probably centered on  
830 this specialized and seasonal reindeer hunt. Moreover, this evidence could represent shared common  
831 traditions regarding lithic, hunting and butchery practices. Comparison with Neanderthal MIS 3 sites in  
832 Europe, such as Abric Romani, Teixoneres, El Salt, El Pastor or La Quebrada, indicates a high diversity of  
833 modes of occupation and solutions for exploitation of the local territory. The picture that emerges from Abri  
834 du Maras and other MIS 3 sites in Europe shows that late Neanderthals found multiple solutions to the  
835 exploitation of local conditions across southern Europe (Delagnes and Rendu 2011; Di Modica 2011;  
836 Sánchez-Hernández et al. 2014; Vidal-Matutano et al. 2015; Villaverde et al. 2017; Mallol et al. 2019; Mayor  
837 et al. 2020; Picin et al. 2020), emphasizing their behavioural adaptability.

838

#### 860 **Authors Contributions**

861

862 M.-H.M., M.G.CH., D.V. and M-A.C. designed and conceptualized the paper, wrote the initial draft and  
863 prepared the figures, tables and supplementary information. Spatial analyses were made by M.G.CH. and

864 D.V., for the lithic and faunal remains respectively. D.V. performed the faunal refits and M.G.CH. and A.E. the  
865 lithic ones. Zooarchaeology and taphonomy analysis of large mammals was carried out by C.D and D.V.  
866 Ungulate dental micro-wear was done by F.R. Fish remains were studied by P.B. Microstratigraphic analysis  
867 was made by M.-A.C. Geology was done by S.P. Lithics were studied by M.-H.M., M.G.CH. and A.E. B.H. did  
868 the micro-wear and residues analysis on lithics. Petrographic analysis of flint was done by P.F. E.A. made the  
869 charcoal analysis. R.G. performed the databases. Excavations were conducted by M.-H.M. All the authors  
870 have interpreted and discussed the data obtained and commented on the manuscript.

**Table 7** Detailed descriptions of each RMU identified in level 4.1 by stone type, total of pieces, technical categories, number of refits and technological consideration (see also Fig. 10 and 11)

Stone type	RMU Number (n°)	Total n° pieces	Technical categories	N° of refits by RMU	General description
Quartzite	Isol-Qtzite 1	1	1 big fragment of pebble	-	Rectangular quartzite pebble fractured intentionally in the middle. Presents unifacial retouch on distal part. There are percussion and macro-traces of use on the distal edge (unknown material use).
	Isol-Qtzite 2	1	1 broken flake	-	Broken Levallois quartzite flake (proximal zone conserved) retouched in the proximal part with a simple notch. Fine brownish grain good for knapping. Flake-tool introduced into the site.
	Isol_Qtzite 3	1	1 flake	-	Levallois lengthen flake slightly <i>déjàtê</i> knapped on a fine grain quartzite. Use wear macro traces on lateral edge.
Basalt	Bas-1	5	1 core 2 fragments 3 flakes	1 (n=2)	Medium size pebble introduced in the site where is used to obtain two or three flakes and then transform in a massive tool with a thick edge ( <i>robot</i> ).

	Bas-2	1	1 fragment		Fragment of hammerstone
Limestone	Lim-1	19	13 flakes 6 fragments of flakes	2 (n=4)	Medium size flakes and fragments of flakes. The presence of cortical products and flakes from reduction sequences (even without cores) shows that the knapping strategies were realized in the site following recurrent centripetal Levallois strategies. This could be corroborated by the 2 identified knapping refits (4 pieces), one of them with the longest connection line (371 cm).
Quartz	Isol_Qtz (1 to 6)	6	3 fragments of flakes 2 flakes 1 flake-tool	-	Isolated products of different varieties of quartz that cannot be possible associate to the other RMU. All are products coming from bifacial bipolar strategies (discoïdal type)
	Qtz-1	30	1 core 1 flake-tool 7 flakes 19 fragments of flakes 2 fragmented flakes	4 (n=9)	The 30 pieces concerning all phases of the reduction sequence (cortical flakes, <i>débordant</i> elements, small fragments, tools, etc.). It seems that there are 2 different pebbles that are introduced to be knapped in the site. The tools of large formats are especially notches and denticulates. The first flakes of cortical removal of the nodule confirm the complete lithic sequences. Flakes are normally dissymmetric and with thick formats (four refits).
	Qtz-2	4	3 flakes 1 fragment of flake	-	4 isolated cortical pieces (more than 90 % of the surface) and 1 without that are shows macro-traces. Reduction sequence very fragmented. Possible introduction of one big cortical flake.
	Qtz-3	2	2 fragments of flakes	-	Both are completely cortical. Flakes of hammerstone produced by the impact?
	Qtz-4	3	3 fragments of flakes	-	There are no more pieces of this RMU, only fragments of flakes and some completely cortical.
	Qtz-5	40	2 flake-tools 10 flakes 17 fragments of flakes 11 fragmented flakes	3 (n=7)	Pebble introduced and knapped in the site, all the stages of <i>chaîne opératoire</i> were identified. The knapping products show that some left, perhaps a part of them should be transported after leaving the site as tool kit. realized. Some big flakes were transformed by retouch in sidescraper and denticulate. Presence of Siret fractures in various cases (e.g.1 refit).
	Qtz-6	5	4 fragments of flake 1 fragmented flake	-	2 cortical flakes and some small fragments of flakes. Very fragmented reduction sequence, introduction of 1 big cortical flake.
	Qtz-7	5	1 flake 1 flake-tool 3 fragments of flakes	-	2 isolated pieces, without cortex, retouched as a notch and denticulate. Some fragments of broken flakes (3). Fragmented reduction sequence and only presence of the final stages.
Flint	Isol-Fl (1 to 11)	11	8 flakes 2 fragments of flake 1 flake-tool	-	These isolated pieces belong all of them to bifacial centripetal strategies, mainly Levallois but some of them come from discoïdal ones. We should point out two typical Levallois points and one big Quina scraper. All these pieces are pieces introduced already knapped to the site (tool kit)
	Fl-1	2	2 flakes	-	2 elongated Levallois flakes introduced into the site (tool kit).
	Fl-2	12	1 core 7 flakes 2 fragmented flakes 1 fragment of flake	2 (n=4)	Complete reduction sequence: cortical flakes (refit) peeling the nodule and recurrent centripetal Levallois exploitation (refit) obtaining large flakes. The core is abandoned although it is not exhausted.
	Fl-3	6	5 flakes 1 fragmented flake	-	Advanced fragmented reduction sequence with just few flakes and small <i>débitage</i> (no refits).
	Fl-4	3	2 flakes 1 fragment of flake	-	One elongated Levallois flake and two small broken flakes. Fragmented reduction sequence that implies pieces introduced already knapped.
	Fl-5a	17	11 flakes 6 fragments of flakes 1 fragmented flake	-	Advanced and fragmented reduction sequence with no cortical elements. The knapping products are varied (configuration, <i>réaffûtage</i> , etc.) and belongs to Levallois strategies.
	Fl-5b	11	11 flakes	1 (n=4)	Reduction sequence of flakes by recurrent centripetal Levallois strategies.
	Fl-6	4	4 flakes	-	Initial phase of the reduction sequence with the presence of 4 cortical flakes. There are no refits but RMU are located in

					the same area of the site.
FI-7	5	1 flake 3 fragments of flake 1 fragmented flake	-		A set of 1 flake and 4 broken flakes (fragmented reduction sequence).
FI-8	2	2 fragmented flakes	-		1 isolated and a broken flake (no cortex). Pieces introduced into the site already knapped (tool kit).
FI-9	5	3 flakes 2 fragments of flake	1 (n=2)		Advanced reduction sequence. These knapping products belong to centripetal recurrent Levallois strategies.
FI-10	9	3 fragments of flake 3 fragmented flakes 3 flakes (1 point)	-		Set of 7 Levallois flakes introduced to the site already knapped. All come from Levallois strategies.
FI-11	6	4 flakes 1 fragment of flake 1 fragmented flake	-		Isolated pieces related with an advanced production phase. All come from Levallois strategies.
FI-12	34	1 flake-tool 14 flakes 7 fragmented flakes 12 fragments of flakes	-		Complete reduction sequence where all the technological products are represented: cortical flakes, backed elements, advanced flakes and tools, but no cores. Two possibilities (1) the core was transported after the occupation, or (2) some of the cores very patinated belongs to this RMU.
FI-13	231	129 flakes 7 flake-tools 1 core 24 fragmented flakes 70 fragments of flakes	6 (n=13)		Complete reductions sequences. It is probably that exist two or three pebbles which are knapped at the site. They were differentiated by the type of cortex and some macroscopic characteristics. They come from the same geological formation (same type of flint).
FI-14	4	2 flakes 1 fragment of flake 1 fragmented flake	-		3 semi-cortical flakes (around 25-50 %), two with macro traces of use. Reduction sequence is partial and fragmented, no cores associated.
FI-15	4	3 fragments of flake 1 flake-tool	1 (n=2)		Isolated pieces, some cortical.
FI-16a	2	1 flake 1 fragmented flake	-		Isolated cortical pieces.
FI-16b	5	1 core 1 flake 1 fragment of flake 1 fragmented flake	-		Isolated pieces of different phases of the reduction sequence, so very fragmented. They belong to Levallois strategies.
FI-16c	3	3 flakes	-		Isolated cortical pieces coming from the first phase of the reduction sequence.
FI-16d	32	2 cores 24 flakes 4 fragments of flake 2 fragmented flakes	1 (n=2)		Complete reductions sequences knapped at the site. All of them are related with different modalities of Levallois strategies.
FI-16e	32	3 cores 20 flakes 1 fragmented flake 6 fragments of flakes	-		It is probably that in some cases exist two or three pebbles which were differentiated by the type of cortex and some macroscopic characteristics. They come from the same geological formation (same type of flint). Only one refit had been found, perhaps some pieces left and where transported after leaving the site (fragmented reduction sequence).
FI-16f	30	3 cores 17 flakes 3 fragmented flakes 9 fragments of flakes	-
