8 **Abstract**

9 We present a *Pulleniatina obliquiloculata* Mg/Ca-derived thermocline water temperature
10 record (TWT) covering the last 270,000 years at the south of the Lombok Strait, one of the
11 main exits of the Indonesian Throughflow (ITF) into the Indian Ocean. The comparison with
12 TWT records from the Java-Sumatra upwelling system and the Timor Sea suggests that
13 changes in Lombok TWT reflect the balance between the wind-driven Java upwelling and the
14 ITF thermocline transport. We show that the evolution of the TWT gradient (Δ TWT) between
15 the upwelling site and the Lombok site can be used to decipher the relative strength of ITF
16 through time. The 270 ka-long, Δ TWT record shows (i) that the ITF was weaker during MIS
17 6 and MIS 2-4 compared to the late Holocene, and was enhanced during MIS8, MIS 7, MIS 5
18 and the early Holocene, and that (ii) it varied with a strong precession-related component.
19 Glacial-interglacial changes may reflect the modulation of ITF by sea-level changes through
20 the modification of ITF pathways in the Indonesian Archipelago, and/or result from changes
21 in the intensity of the Global Conveyor Belt. The strong precession contribution in the
22 relative TWT strength at our Lombok site is interpreted as revealing the importance of
23 southeast monsoon winds on ITF intensity.

24 **Key words:** Indonesian Throughflow; Java upwelling; Mg/Ca temperatures; Indian Ocean;
25 Late Pleistocene

26 **1. Introduction**

27 The Indonesian Throughflow (ITF) is a complex ocean current system connecting the
28 tropical Pacific and Indian oceans ([Gordon, 2005](#)). Every second, ~ 15 million m^3 of water is
29 transported into the Indian Ocean by the ITF. This transport mainly takes place through three
30 principal exits: the Lombok Strait, the Ombai Strait, and the Timor Sea passage ([Fig. 1](#);
31 [Sprintall et al., 2009](#)). Modern observations show that ITF transport extends from the surface
32 down to intermediate water depths with maximum transport occurring in the thermocline
33 ([Sprintall et al., 2009](#)). The change in ITF salinity, temperature and flux can influence the
34 heat and salinity distribution in the Pacific and Indian Ocean ([Hu et al., 2019](#); [Lee et al.,](#)
35 [2015](#)). ITF is also a key contributor to the global thermohaline circulation ([Gordon, 2005](#);
36 [Talley, 2013](#)). Once in the Indian Ocean, a portion of the ITF water continues its journey as
37 part of the global thermohaline circulation return branch, traveling through the tropical Indian
38 Ocean and being advected within the water masses that leak into the southern Atlantic Ocean
39 as part of the Agulhas current system ([Beal et al., 2011](#)). Thus, reconstructing past variability
40 of ITF is mandatory if one wants to fully understand the ocean's role in modulating regional
41 and global climate changes through the redistribution of ocean heat and salinity and the
42 influence of low-latitude processes on high-latitude climate changes.

43 Over the recent years, oceanographers have gained a better understanding of modern
44 ITF dynamics and hydrographic variability, and their links to low-altitude atmospheric
45 circulation at both seasonal (i.e. Australian-Indonesian monsoon) and inter-annual (i.e. El
46 Niño-Southern Oscillation, ENSO; Indian Ocean Dipole, IOD) timescales ([Sprintall et al.,](#)
47 [2009](#); [Sprintall and Révelard, 2014](#)). Much less is known, however, regarding ITF variability
48 at longer, centennial to orbital, timescales. On these long timescales, ITF variability is poorly
49 known due to the difficulty of constraining the strength of the ITF, and the paucity of good-
50 quality sedimentary records allowing the reconstruction of hydrographic properties of water
51 masses entering the Indian Ocean. There is no direct way of estimating past changes in the
52 flux of the ITF from sedimentary records. Since the ITF is a heat carrier, it was inferred that
53 past changes in its intensity have impacted the water temperature distribution along its route.
54 Thus, several studies addressed past ITF evolution through the reconstruction of paleo-
55 temperatures at surface and thermocline depths ([Fan et al., 2018](#); [Holbourn et al., 2011](#);
56 [Linsley et al., 2010](#); [Xu et al., 2008](#)). However, surface temperatures can prove difficult to
57 interpret in terms of ITF changes owing to the direct impact of radiative forcing ([Fan et al.,](#)
58 [2018](#); [Holbourn et al., 2011](#); [Linsley et al., 2010](#); [Xu et al., 2008](#)). Changes in thermocline

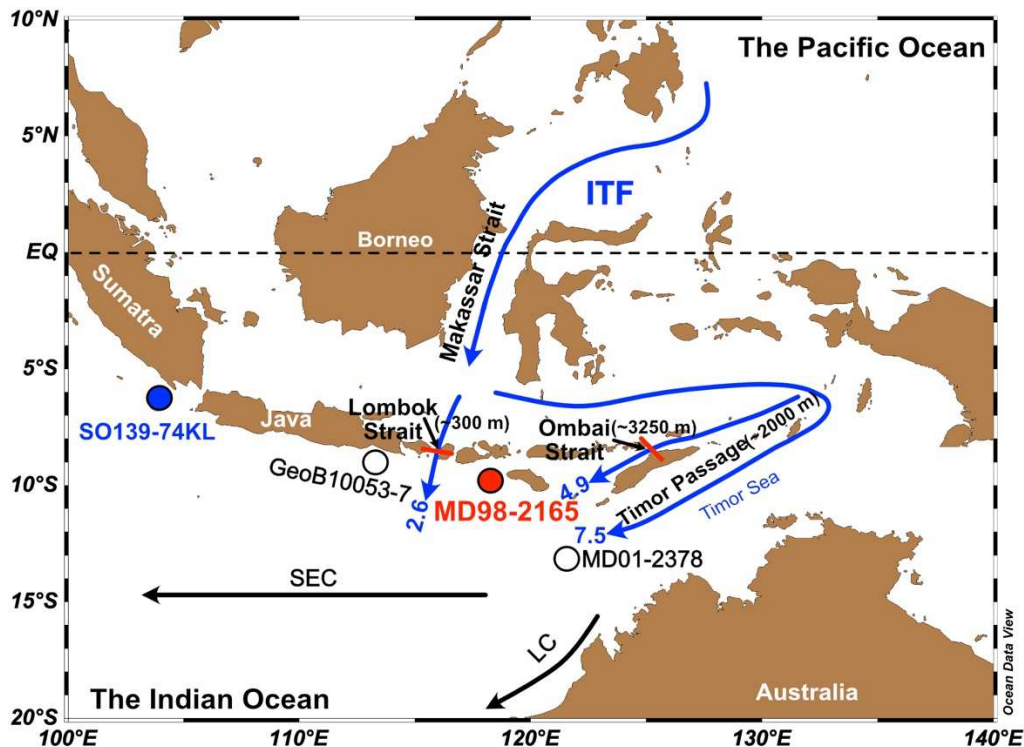

59 water temperature (TWT) gradients along the ITF pathway, on the other hand, can be
60 interpreted as reflecting chiefly past changes in ITF dynamics (Fan et al., 2018; Holbourn et
61 al., 2011). Over the last 30 ka, for instance, Fan et al. (2018) showed that the TWT gradient
62 between the north (upstream ITF) and south (downstream ITF) of Makassar Strait (Fig. 1)
63 reached maximum values during the 27-24.2 ka and 19-13.4 ka time intervals. The authors
64 interpreted these two episodes of high TWT gradient as resulting from low thermocline ITF
65 flux which could not maintain a similar TWT between upstream and downstream sites along
66 the ITF. On a longer timescale, over the last 140 ka, Holbourn et al. (2011) had previously
67 found five periods of high East-West TWT gradient in the Timor Sea during marine isotope
68 stage (MIS) 2-4, MIS5b and MIS5d. They interpreted these high TWT gradients as periods of
69 weakened thermocline ITF transport (Holbourn et al., 2011).

70 The approach based on reconstructing paleo-TWT gradient has provided very
71 important insights about past ITF variability. Yet, some potential drawbacks and puzzling
72 issues remain, which call for further studies. First of all, it is our contention that an ITF proxy
73 based on the reconstruction of paleo-TWT gradients along the main ITF track would lack
74 sensitivity during periods of high ITF fluxes. Once lateral advection is strong enough to result
75 in nearly similar TWT at two sites located apart along the ITF path, an additional increase of
76 ITF flux would not be detected in the temperature gradient. Such a lack of sensitivity may
77 possibly explain why the TWT gradient approach suggests that ITF remained strong and
78 nearly invariant most of the time over the late Quaternary (i.e. null TWT gradient) and
79 collapsed (i.e. non-null TWT gradient) only over a few cold intervals (e.g. MIS2, MIS4,
80 MIS5b and MIS5d; Holbourn et al., 2011; Fan et al., 2018).

81 Another puzzling element is the unclear relationship between ITF variability and local
82 monsoon wind forcing in the outflow region of Indian Ocean on orbital timescales. Modern
83 oceanographic observations indicate that water transport through the three main ITF exits
84 (i.e., Lombok Strait, Ombai Strait, and Timor Passage) is strongly modulated by seasonal
85 changes in monsoon wind forcing, with increased ITF transport at both surface and
86 thermocline depths during the boreal summer season, when monsoon winds blow from the
87 southeast (Sprintall et al., 2009). Based on these modern observations, we may expect that
88 some ITF modulation exists at orbital timescale, owing to the strong imprint of precession on
89 long-term SE monsoon wind dynamics (Lückge et al., 2009; Mohtadi et al., 2011a). But such
90 a link is not clearly seen in paleo-ITF records. Paleo-climatic reconstructions suggest, for
91 instance, that the strength of SE monsoon winds was at a maximum during the early

92 Holocene (~10ka), when boreal summer insolation reached a peak (Mohtadi et al., 2011a).
93 Assuming that the insolation-driven enhancement of SE monsoon winds is transferred to ITF,
94 a higher flux would be expected during the early Holocene. However, data support the
95 opposite scenario. They show a high east-west TWT gradient in the Timor Sea, which was
96 interpreted as reflecting a weakened ITF thermocline transport (Holbourn et al., 2011). This
97 observation either indicates (1) SE monsoon wind intensity and ITF transport are decoupled
98 on orbital timescale, or (2) that TWT gradients reconstructed along the Indonesian
99 Archipelago do not accurately grasp the full variability of the past ITF flux. Given the
100 complexity of oceanic circulation and vertical mixing within the Indonesian Archipelago, our
101 contention is that the lateral ITF signature on TWT gradient could have been disturbed by the
102 superimposition of local changes in temperature related to the development of seasonal
103 upwelling or downwelling cells forced by monsoon winds.

104 In the present paper, we propose to address past ITF variability through a different
105 strategy. Instead of reconstructing paleo-ITF variability based on the evolution of TWT-
106 gradient along the main path of the ITF, we propose to disentangle the respective influence of
107 upwelling and ITF on the TWT record of a site located in the SE part of the Java upwelling
108 (core MD98-2165, Fig. 1). Our strategy is based on the comparison of the TWT evolution at
109 this site with the evolution of TWT reconstructed in the nearby core SO139-74KL, located
110 south of Sumatra, further away from a main ITF exit, and strictly under the influence of the
111 Java-Sumatra upwelling (Wang et al., 2018).

112
 113 **Fig. 1.** Oceanic currents in the Indonesian Archipelago and Eastern Indian Ocean, and
 114 locations of sediment cores used in this paper: MD98-2165 (this study); SO139-74KL (Wang
 115 et al., 2018); MD01-2378 (Xu et al., 2008; Holbourn et al., 2011); and GeoB10053-7
 116 (Mohtadi et al., 2011a). ITF = Indonesian Throughflow (blue line); LC = Leeuwin Current;
 117 SEC = South Equatorial Current. The three primary ITF exits — Lombok Strait, Ombai Strait
 118 and Timor Passage — are shown, with their sill depths (in brackets). The fluxes of ITF water
 119 being transported through each of these main exits is given in Sverdrup ($1 \text{ Sv} = 10^6 \text{ m}^3 \text{ s}^{-1}$) on
 120 the map (blue numbers).

121 2. Modern oceanographic settings and past evolution of the Java upwelling

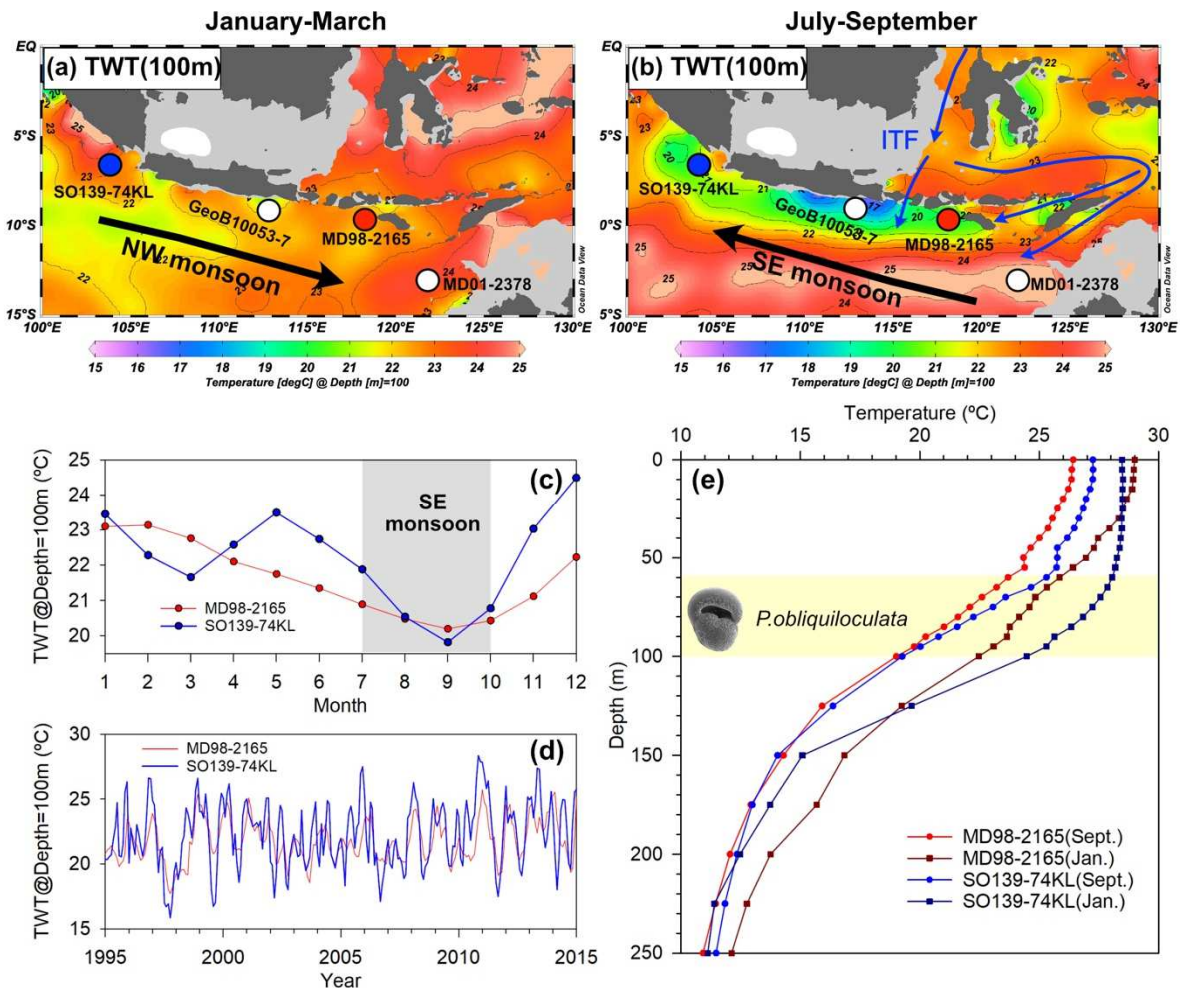

122 Core MD98-2165 is located to the southeast of Lombok strait and west of the Ombai
 123 Strait, two of the three main ITF exits in the eastern Indian Ocean (Fig. 1). The modern ITF
 124 transport is dominated by regional monsoon forcing, with maximum ITF flux occurring
 125 during the SE monsoon (boreal summer season) when the sea level is lowered by wind-
 126 driven, offshore Ekman transport along the south coast of Java (Sprintall et al., 2009). In
 127 addition to enhancing the ITF, the Ekman transport also bring to the subsurface cold waters
 128 from deeper depths, resulting in an upwelling zone characterized by cold TWT along the
 129 south coast off Java and Sumatra during the boreal summer season (Fig. 2; Susanto et al.,
 130 2001).

131 As can be seen from Fig. 2, core MD98-2165 is located to the East of the Java
 132 upwelling. Core SO139-74KL, on the other hand, is located to the west of the Java upwelling.
 133 At site SO139-74KL, further away from the main ITF exits, TWT is mainly controlled by

134 upwelling dynamics (Kuswardani and Qiao, 2014; Wang et al., 2018). In contrast, at the site
135 of MD98-2165, located in the ITF outflow region, TWT is under the combined effects of the
136 Java upwelling dynamics and the ITF transport, with upwelling being the dominant forcing of
137 seasonal TWT changes at both sites. The strong impact of the upwelling can be readily seen
138 from the seasonal maps of TWT (Fig. 2a-b) and the strong co-variance between monthly-
139 averaged TWT records from sites MD98-2165 and SO139-74KL (taking the period 1995 to
140 2015 and 100 m water depth as an example; Fig. 2c). At both sites, a characteristic low in
141 TWT takes place during the SE monsoon season (boreal summer; Fig. 2c). This low is
142 associated with the period of maximum upwelling intensity along Java and Sumatra. As can
143 be seen in Fig. 2c, the difference in TWT between the two sites is relatively small during this
144 upwelling season (less than 1 °C), and larger during the non-upwelling season (up to 2.5 °C).
145 The in-phase covariance of TWT at both sites, chiefly resulting from the upwelling dynamics,
146 can be readily seen also in the multi-annual TWT variability recorded over the same 20-year
147 period (1995 to 2005, Fig. 2d). As is shown in Fig. 2d, amplitude of temperature changes at
148 the site SO139-74KL is usually stronger than at the site MD98-2165, with higher
149 temperatures at SO139-74KL than MD98-2165 during boreal winters (non-upwelling season)
150 and colder temperatures during the boreal summers (active upwelling). The lower amplitude
151 of TWT changes at the site MD98-2165 likely results from the moderating impact of the ITF
152 advection, which tends to warm the thermocline waters during the upwelling season, but cool
153 them slightly down during the non-upwelling season, because ITF thermocline waters have a
154 lower temperature than their Indian Ocean counterparts (Gordon, 2005).

155 The underlying mechanisms that control the inter-annual ITF variability are still
156 unclear. Recent studies concluded about the highly complex nature of that variability. It is
157 thought to be associated with a combination of El-Niño Southern Oscillation (ENSO) and
158 Indian Ocean Dipole forcing (Sprintall and Révelard, 2014). Today, the inter-annual
159 evolution of TWT at MD98-2165 results from a combination of upwelling dynamics and ITF
160 variability (temperature and/or flux), with the ITF impacts being relatively small compared to
161 the upwelling influence. Previous studies have shown that strong changes in ITF occurred at
162 millennial to multi-orbital timescales (Fan et al., 2018; Holbourn et al., 2011; Zuraida et al.,
163 2009). Our main objective, in the present paper, is to study the long-term evolution TWT at
164 the exit of the Indonesian Archipelago, at the site MD98-2165, and try to disentangle the
165 potential effects of upwelling and ITF at orbital and glacial-interglacial timescales.

166 Sediment trap and core top studies indicate that the foraminiferal species *Pulleniatina*
 167 *obliquiloculata* lives in upper thermocline depth between 60 and 100 m in the Java-Sumatra
 168 upwelling region (Fig. 2e; Mohatdi et al., 2009; Mohtadi et al., 2011b). Owing to the higher
 169 flux of foraminifera during the upwelling season, shell geochemistry (e.g., $\delta^{18}\text{O}$ and Mg/Ca)
 170 of *P. obliquiloculata* tends to record the upper thermocline conditions of the upwelling
 171 season (July to October; Mohatdi et al., 2009; Mohtadi et al., 2011b). Based on *P.*
 172 *obliquiloculata* Mg/Ca-derived TWT, Wang et al. (2018) showed recently that paleo-TWT
 173 had always been chiefly controlled by upwelling variations on orbital timescale over the late
 174 Quaternary at the site SO139-74KL. In this study, we used the same approach (i.e., Mg/Ca
 175 ratio measured on the thermocline dwelling species *P. obliquiloculata*) to reconstruct past
 176 TWT variations at site MD98-2165.

177
 178 **Fig. 2. Modern oceanographic settings in the studied area.** (a) and (b) show the water
 179 temperature distribution at a depth of 100 m (maximum ITF transport depth, Sprintall et al.,
 180 2009) averaged over the January to March season ((a) NW monsoon season) and over the
 181 July to September season ((b) SE monsoon season). Datasets are from WOA13 (Locarnini et
 182 al., 2013). The locations of sediment core MD98-2165 (red dot), SO139-74KL (blue dot),
 183 MD01-2378 (white dot) and GeoB10053-7 (white dot) are also shown. Black arrows in (a)
 184 and (b) indicate the prevailing seasonal wind direction; blue arrow in (b) represents the ITF.

185 (c) Monthly evolution of TWT (100 m of water depth) averaged over the latest 20 years
186 (1995-2015) available in Simple Ocean Data Assimilation (SODA) database (Carton and
187 Giese, 2008) at sites MD98-2165 and SO139-74KL. The grey shaded area indicates the SE
188 monsoon season. (d) Evolution of monthly thermocline water temperature (100 m of water
189 depth) over the period 1995 to 2015 at sites MD98-2165 (red line) and SO139-74KL (blue
190 line) from the same SODA database. (e) Depth profiles of temperature during different
191 seasons at sites MD98-2165 and SO139-74KL. Horizontal yellow area indicates the habitat
192 depth range of *P. obliquiloculata* in the Java-Sumatra upwelling region.

193 3. Material and methods

194 3.1 Sediment core MD98-2165 and age model

195 Sediment core MD98-2165 (9.65S, 118.34E) was retrieved at a water depth of 2100
196 m to the southeast of the Lombok Strait and southwest of the Ombai Strait (Fig. 1). The core
197 was obtained during the Images IV cruise of the French R/V *Marion Dufresne*. It is 42.3 m
198 long, the upper 34.5 m are studied in this paper. Previous analyses on this core include 20
199 accelerator mass spectrometry (AMS) ^{14}C dates at several depth intervals between 0 and 800
200 cm (Waelbroeck et al., 2006), and high-resolution oxygen isotope records from both
201 planktonic (*Globigerinoides ruber*) and benthic (*Cibicides wuellerstorfi* and *Hoeglundina*
202 *elegans*) foraminifera along the whole core (Levi, 2003; Levi et al., 2007; Waelbroeck et al.,
203 2006). These data were used to construct the age model and oxygen isotope stratigraphy.

204 An initial age model had been constructed by using absolute radiocarbon ages and
205 benthic $\delta^{18}\text{O}$ foraminiferal stratigraphy (Levi, 2003; Levi et al., 2007; Waelbroeck et al.,
206 2006). In this initial age model, calendar ages were computed using MARINE98 calibration
207 curve (Waelbroeck et al., 2006). Here, we updated the radiocarbon calendar ages by using the
208 latest MARINE20 calibration curve (Heaton et al., 2020). We set the local marine reservoir
209 age (ΔR) to -117 ± 70 years based on a modern measurement in the Java-Sumatra upwelling
210 region (Southon et al., 2002). In between dated control-points, the conversion of depths to
211 ^{14}C -derived calendar ages was made using the Bayesian statistical methodology of Bacon
212 (Blaauw et al., 2011). For this upper core section (down to 774 cm), the absolute age
213 uncertainties (2σ) are generally less than 0.5 ka.

214 For the lower part of the core (774 – 3889 cm), we establish a new depth-age model
215 by aligning the benthic $\delta^{18}\text{O}$ record of MD98-2165 to global benthic $\delta^{18}\text{O}$ stack. We used the
216 LR04 stack (Lisiecki and Raymo, 2005) for the interval 270-150 ka, and the revised LS16
217 stack (Lisiecki and Stern, 2016) for the interval 150-0 ka. We used the HMM-Match
218 MATLAB code (Lin et al., 2014) to automatically align benthic $\delta^{18}\text{O}$ record of MD98-2165
219 to the global benthic stack. This HMM-Match MATLAB code provides 95% confidence for

220 $\delta^{18}\text{O}$ alignment by using a hidden Markov model probabilistic algorithm (Lin et al., 2014). It
 221 is worth to note that these age uncertainties only take into account alignment uncertainties
 222 and not including the age uncertainties of $\delta^{18}\text{O}$ stacks used as targets. As can be seen in Fig.
 223 3b, the alignment age uncertainties are generally lower than 2 ka in the interval of 300 – 60
 224 ka due to the high similarity between our benthic $\delta^{18}\text{O}$ and the global stacks. However, in the
 225 interval 60 – 25 ka the alignment age uncertainties increase dramatically and reach a
 226 maximum of ~ 6 ka. This is mainly due to the target and the MD98-2165 $\delta^{18}\text{O}$ records
 227 showing more differences, with many more details and variability in the benthic $\delta^{18}\text{O}$ record
 228 of MD98-2165. Over this interval, MD98-2165 benthic $\delta^{18}\text{O}$ shows five peaks, whereas there
 229 are only four in the global stack (Fig 3 a). The depth-age model for this interval was thus
 230 simply obtained by assuming a constant sedimentation rate between 60 ka (1252 cm, the last
 231 control-point for which there is no ambiguity in the correction with the $\delta^{18}\text{O}$ stack) and 25.3
 232 ka (774 cm, the oldest ^{14}C date). This modification clearly increases the visual fit between
 233 the benthic $\delta^{18}\text{O}$ of MD98-2165 and the global stack (Fig. 3 c).

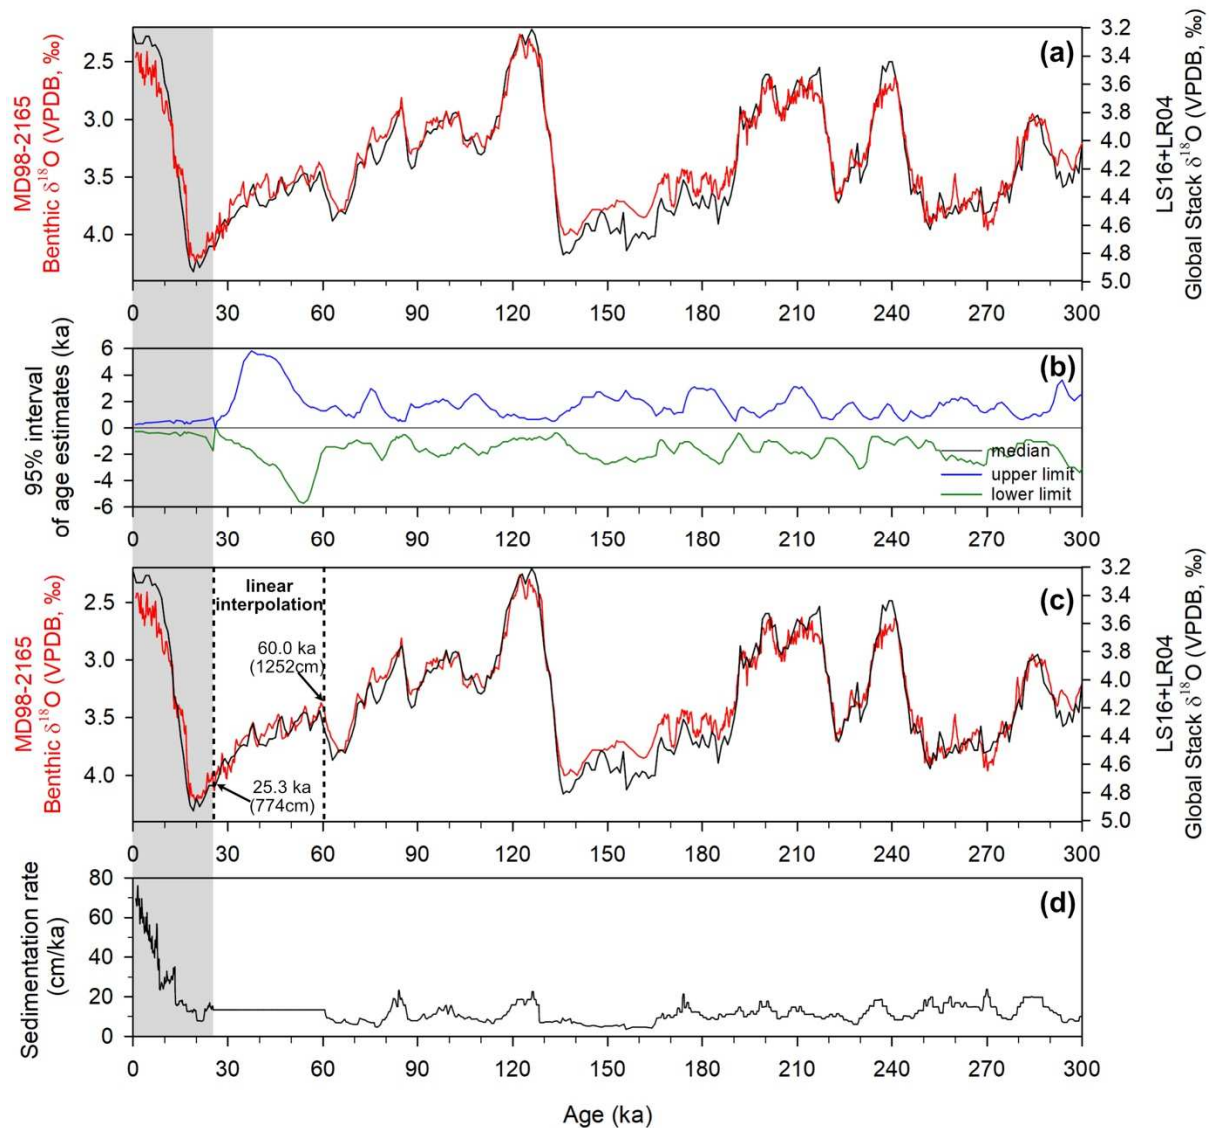

234 Based on the depth-age model, the average sedimentation rate is ~ 13 cm/ka (Fig. 3 d).
 235 From 300 to 20 ka — the interval over which the age model is mainly based on $\delta^{18}\text{O}$
 236 alignment — the sedimentation remains relatively constant around 10 cm/ka. From 20 to
 237 present, the estimated mean sedimentation rate increases dramatically from ~10 cm/ka to ~70
 238 cm/ka. Part of that increase is likely associated with the elastic rebound of the coring cable
 239 and the resulting over-sampling of upper sediments during the early phase of coring
 240 (Szeremeta et al., 2004). Oversampling during giant coring was not properly corrected during
 241 the early IMAGES cruises.

242 **Table 1.** AMS ^{14}C dates and corresponding calendar ages of core MD98-2165

Composite depth (cm)	^{14}C age $\pm 1\sigma$ (years BP)	Calendar age (years BP)	95% (2 σ) confidence interval (years BP)
55	1150 \pm 40	653	381 - 907
135	2210 \pm 40	1772	1498 - 2084
213	3210 \pm 40	3012	2744 - 3312
260	3910 \pm 90	3851	3513 - 4228
320	4740 \pm 110	4949	4548 - 5352
460	7500 \pm 110	7941	7577 - 8388
560	10340 \pm 120	11531	11050 - 12069
600	11430 \pm 130	12880	12526 - 13245
620	12100 \pm 130	13638	13289 - 14222
640	13040 \pm 150	14856	14257 - 15395

656	13590 ± 140	15734	15296 - 16215
664	14050 ± 120	16251	15951 - 16565
674	14360 ± 140	16896	16490 - 17359

245 **Fig. 3.** Age model of MD98-2165. (a) Comparison between MD98-2165 benthic $\delta^{18}\text{O}$ and the
 246 global stack. The chronology in the 0 – 25ka interval is based on radiocarbon ages (gray bar
 247 interval), while in the 25 – 300 ka interval it is based on $\delta^{18}\text{O}$ alignment. (b) The 95%
 248 confidence band around the median; calculated through a Bacon approach in the 0 – 25 ka
 249 interval (gray bar interval); and estimated in the HMM-Match alignment over the 25 – 300 ka
 250 interval. (c) Comparison between MD98-2165 benthic $\delta^{18}\text{O}$ and the global stacks. 0 – 25 ka

251 based on radiocarbon ages (gray bar interval); 25 – 60 ka based on linear interpolation
252 between 25 ka (774 cm) and 60 ka (1252 cm); 60 – 300 ka based on $\delta^{18}\text{O}$ alignment. (d)
253 Sedimentation rates. Gray bar indicate interval which age model is established by absolute
254 radiocarbon ages.

255 **3.2 Mg/Ca measurements**

256 For measuring *P. obliquiloculata* Mg/Ca ratio, core MD98-2165 was sampled at 4-12
257 cm interval in the 110-3450 cm depth interval, corresponding to 1.5 – 270 ka. Samples were
258 dried and weighted. Samples were then washed over a 63 μm sieve. Residuals were dried on
259 a sheet of filter paper. About 30 tests of *P. obliquiloculata* were picked from the 250-355 μm
260 size fraction. Foraminiferal tests were gently crushed between two glass plates under a
261 binocular. Crushed tests were then transferred to acid-cleaned 500 μl centrifuge tubes for
262 further cleaning. Samples were cleaned following the method described in (Barker et al.,
263 2003). After cleaning, each sample was dissolved within 0.075M HNO_3 and then centrifuged
264 for removing undissolved particulate impurities. The supernatant solution was transferred to a
265 new acid-cleaned 500 μl centrifuge tube. Mg/Ca ratio were measured using an inductively
266 coupled plasma mass spectrometry (ICP-MS, Analytik Jena PlasmaQuant MS Elite), and as
267 well as for Al/Ca, Mn/Ca and Fe/Ca for examining the cleaning efficiency on clay
268 contamination and post-depositional Mn-rich oxide coatings. Aliquots of samples were first
269 analyzed for Ca concentrations and the remaining solutions were diluted to reach a Ca
270 concentration around 100 ppm for all the samples in order to minimize possible matrix
271 effects. For the calibration of Mg/Ca analyses, we used a series of six standard solutions with
272 Ca concentration around 100 ppm and Mg/Ca ratios covering the range of values commonly
273 observed in foraminiferal calcite: Standard 1 = 0.64 mmol/mol, Standard 2 = 1.66 mmol/mol,
274 Standard 3 = 2.63 mmol/mol, Standard 4 = 3.69 mmol/mol, Standard 5 = 5.23 mmol/mol,
275 Standard 6 = 7.72 mmol/mol. Standard 3 being used as our drift-correction solution was
276 analyzed every 3 samples for monitoring the instrument variability and correcting samples
277 after the analysis. The long-term reproducibility of Mg/Ca measurements obtained by
278 replicating analyses Standard 4 solution is $\pm 1.4\%$ (1σ). This estimation is based on 144
279 analyses performed during 24 working sessions over a one-year period. No relationship was
280 observed between Mg/Ca and Mn/Ca, Fe/Ca or Al/Ca variations. Thus, no Mg/Ca data was
281 rejected from our dataset.

282 **3.3 Conversion of Mg/Ca ratios to temperatures and consistency of datasets**

283 Mg/Ca-based TWT were compared between different sediment cores in this study. As
284 shown in Table 2, the Mg/Ca from the different studies were measured from slightly different

285 foraminifera shell sizes and by using different cleaning methods. Xu et al. (2010)
 286 demonstrated that for *P. obliquiloculata* species the specimens picked from the 250-315 μm
 287 and $>315 \mu\text{m}$ size fractions do not exhibit significant Mg/Ca differences. However, the use of
 288 different cleaning methods for Mg/Ca analysis, specifically with or without a reductive step
 289 designed to remove oxide coating, leads to different Mg/Ca-based temperature estimates
 290 (Barker et al., 2003; Pang et al., 2020; Rosenthal et al., 2004). It has been shown that the
 291 reductive cleaning step can decrease the Mg/Ca ratios by a few percent compared to values
 292 obtained after a non-reductive cleaning.

293 We performed a detailed study of cleaning effects on Mg/Ca temperatures obtained
 294 on core MD98-2165 samples. Our results show that applying a reductive step decreases the
 295 Mg/Ca ratio of *P. obliquiloculata* by 4% compared to the non-reductive cleaning method
 296 (Pang et al., 2020). In order to minimize the cleaning method bias when comparing our
 297 Mg/Ca-TWT with those from other studies which used a reductive step in their cleaning
 298 strategy, the reductively cleaned Mg/Ca datasets (listed in Table 2) were corrected by +4%.
 299 Such cleaning-offset correction does not alter the relative temperature variations along each
 300 core.

301 The Mg/Ca ratio measured by this study and those from other studies (listed in Table
 302 2) were converted to temperatures by using the same calibration equation developed by
 303 (Anand et al., 2003): $\text{Mg/Ca} = 0.328 \exp(0.09 \cdot T)$ for *P. obliquiloculata*. When using this
 304 calibration, the +4% correction for the reductively cleaned Mg/Ca datasets leads to a +0.45°C
 305 shift in temperature. The total uncertainty in Mg/Ca-TWT reconstruction for core MD98-
 306 2165 (this study) was estimated by propagating the uncertainties introduced by Mg/Ca
 307 measurements and Mg/Ca temperature calibration. This total uncertainty is on average about
 308 $\pm 1^\circ\text{C}$ (1σ).

309 **Table 2. Sediment cores used in this study.**

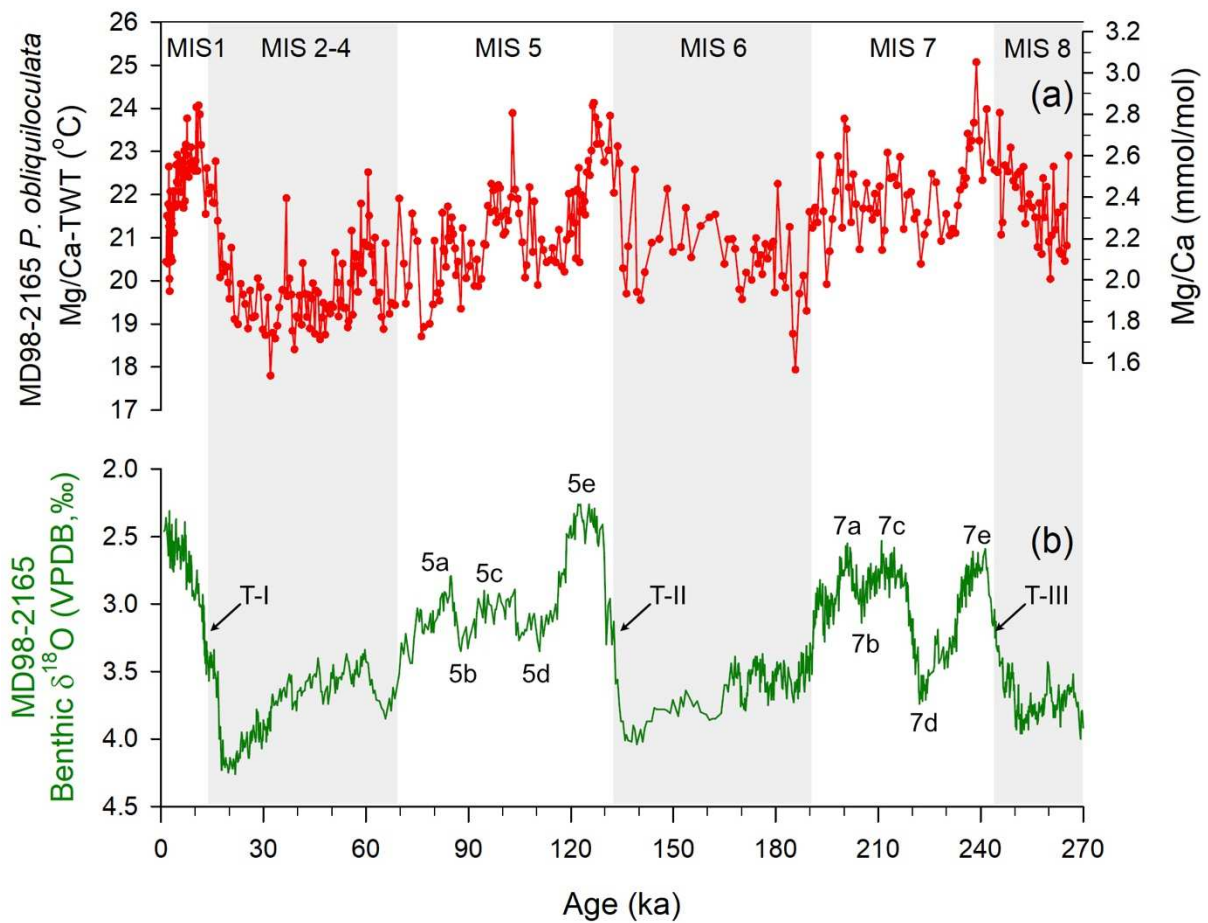

Core ID	Lat./Long. (water depth)	Species (size)	Cleaning*	Reference
MD98-2165	9.65 S, 118.34 E (2100m)	<i>P. obliquiloculata</i> (250-350 μm)	NRC	This study
SO139-74KL	6.54 S, 103.83 E (1690m)	<i>P. obliquiloculata</i> (350-450 μm)	RC	Wang et al., 2018
MD01-2378	13.08 S, 121.79 E (1783m)	<i>P. obliquiloculata</i> (250-315 μm)	RC	Xu et al., 2008

310 *NRC :non-reductively cleaning method; RC : reductively cleaning method.

311 4. Results

312 The *P. obliquiloculata* Mg/Ca and the estimated TWT from MD98-2165 are shown

313 versus age in Fig. 4. Mg/Ca ratio of *P.obliquiloculata* vary between 1.6 and 3.1 mmol/mol,
314 corresponding to TWT ranging between 17.8 ± 0.9 and 25.1 ± 1.2 °C. The core top TWT (at
315 ~1.5ka) is ~ 20.4 °C, which is identical, within the reconstructed TWT uncertainty, to modern
316 mean temperature of ~ 20.6°C during the SE monsoon season at the water depth of 100 m.
317 TWT variations show some similarities compared to the benthic $\delta^{18}\text{O}$ records at the glacial-
318 interglacial timescale, such as a long-term cooling trend from MIS5e to MIS2 and rapid, high
319 amplitude warmings during the benthic $\delta^{18}\text{O}$ terminations. The amplitude of glacial-
320 interglacial TWT changes is $\sim 3.3 \pm 1.5$ °C for Termination-III (T-III, transition MIS8/MIS7),
321 4.6 ± 1.5 °C for T-II and 5 ± 1.5 °C for T-I. Although they show some similarities at the glacial-
322 interglacial timescale, TWT are not always warmer during interglacial than glacial periods.
323 For example, during the Holocene, TWT decreases by up to 4°C towards present (from ~
324 23.8°C at ~11 ka to ~19.8 °C at ~2.5 ka), which leads to the TWT in late MIS 1 being similar
325 and even colder than some of the TWT reconstructed for glacial periods. This pattern is also
326 observed in MIS 7 and MIS 5. These results suggest that TWT changes at site MD98-2165 do
327 not strictly follow the global climate variations embedded in the $\delta^{18}\text{O}$ record, but contain a
328 strong regional/local imprint.

329

330 **Fig. 4.** Paleoclimate records of core MD98-2165. (a) *P. obliquiloculata* Mg/Ca-derived TWT.
 331 (b) Benthic $\delta^{18}O$ record of MD98-2165 as a stratigraphic reference (Levi, 2003; Waelbroeck
 332 et al., 2006). MIS stands for Marine Isotope Stage. Sub-stages of MIS5 (5a-5e) and MIS7
 333 (7a-7e) are also marked. T-I, T-II and T-III mark the glacial terminations.

334 5. Discussion

335 5.1 Disentangling the impacts of vertical mixing (upwelling) and lateral advection (ITF) 336 on the TWT of site MD98-2165, South of Lombok

337 As aforementioned, the site of core MD98-2165 is under the influence of two of the
 338 three main ITF exits in the Indian Ocean. Seasonal TWT variations at this site are linked to
 339 the dynamics of the wind-driven Java upwelling (Fig. 2; Susanto et al., 2001), with the ITF
 340 likely acting as a moderator, smoothing out the amplitude of TWT changes compared to
 341 TWT changes at the site of core SO139-74KL, within the core of Java-Sumatra upwelling.
 342 The ITF probably also explains part of the interannual TWT variability at site of MD98-2165,
 343 in particular through the combined influence of ENSO and IOD changes (Sprintall and
 344 Révelard, 2014; Susanto et al., 2001).

345 Marine sediment records have shown that, on the long, millennial to orbital timescales,
346 the SE monsoon winds have always been a permanent feature of atmospheric circulation in
347 this region (Lückge et al., 2009; Mohtadi et al., 2011a; Steinke et al., 2014). Furthermore, the
348 detailed study of core SO139-74KL concluded that TWT changes at this site have been
349 always controlled by the upwelling dynamics under the influence of SE monsoon wind
350 intensity (Wang et al., 2018). These observations suggest that seasonal variability at the site
351 of our core MD98-2165 has most likely been always under the influence of the upwelling
352 dynamics. And the long-term variability at the site of MD98-2165 should show a
353 combination of upwelling and ITF impacts.

354 In order to disentangle upwelling and ITF components, we compare in Fig. 5 the last
355 25 ka evolution of TWT at our site with that of TWT from core SO139-74KL located in the
356 west of Java upwelling and away from the ITF outflow region (Wang et al., 2018) and from
357 core MD01-2378 located in the center of the Timor Sea main exit, away from the upwelling
358 system (Holbourn et al., 2011; Xu et al., 2008). These two sites represent end-members for
359 TWT variability near our site: with and without the influence of the upwelling system.
360 Concentrating on the last 25 ka makes it possible (i) to achieve a comparison over an interval
361 with robust ¹⁴C-based age models, and (ii) to focus on a key time period spanning from the
362 last glacial maximum to the later Holocene, and characterized by a peak in boreal summer
363 insolation at ~10 ka. In Fig. 5 we also display a proxy of upwelling intensity (% *Globigerina*
364 *bulloides*), obtained from core GeoB10053-7, located in the heart of the Java upwelling (Fig
365 1 and 2; Mohtadi et al., 2011a).

366 As shown in Fig. 5, from 25 to about 16 ka, TWT of MD98-2165 were similar to
367 TWT of SO139-74KL, but colder than TWT from MD01-2378, located outside the upwelling
368 zone. This indicates that the upwelling dominated the TWT of MD98-2165 while the ITF
369 exerted only a weak influence. This observation is in rather good agreement with the study of
370 Fan et al. (2018), which suggested a weakened ITF during 27- 24.2 and 19-13.4 ka. By
371 contrast, from ~16 to 4 ka, the TWT of MD98-2165 were much warmer than TWT of
372 SO139-74KL and comparable to TWT of MD01-2378. Over this period, higher percentages
373 of *G. bulloides* in core GeoB10053-7 indicate that the upwelling along Java was much
374 stronger than today, suggesting enhanced local SE monsoon winds (Mohtadi et al., 2011a).
375 This stronger SE monsoon wind signal is clearly imprinted in the TWT record of core
376 SO139-74KL through the responsible change of upwelling intensity at this site to the SE
377 winds, which shows its minimal values during the early Holocene, coeval with the peak

378 in %*G. bulloides* (Fig. 5). However, our data indicate that in this context of enhanced SE
379 monsoon winds, the TWT record at site MD98-2165 varied opposite to that of SO139-74KL,
380 showing maximum temperature values at ~10ka, about ~ 6°C higher than the TWT at site
381 SO139-74KL, and close to MD01-2378 values. This suggests that, contrary to what we
382 observe at site SO139-74KL, enhanced wind-driven Ekman offshore transport did not result
383 in decreased TWT at site MD98-2165. This indicates that TWT during the early Holocene
384 was dominated by an enhanced, lateral ITF transport of warm water rather than by the
385 upwelling of cold water. The TWT of MD98-2165 during the early Holocene was nearly 4°C
386 higher than during the glacial time (taken at ~ 20 ka for reference) and the later Holocene (at
387 ~1.5ka). From 4 ka towards the present, TWT from core MD98-2165 tend to become
388 progressively similar to those from the upwelling site SO139-74KL, varying along with the
389 boreal summer insolation. This implies that the influence of ITF at the site of core MD98-
390 2165 gradually weakened towards the present.

391 Our observations suggest that, during the early Holocene peak in boreal summer
392 insolation, when SE monsoon winds and upwelling intensified, the ITF thermocline water
393 was warmer and its flux was stronger. The increase of ITF thermocline water temperature can
394 be readily deduced from the co-evolution of TWT at the site of MD01-2378 and MD98-2165,
395 which show positive correlation with boreal summer insolation. This temperature evolution
396 likely results from the fact that ITF waters chiefly originate from the North Pacific Ocean
397 where temperatures are controlled by boreal summer insolation (Bolliet et al., 2011; Dang et
398 al., 2012). The stronger ITF flux during the early Holocene is suggested by the evolution of
399 MD98-2165 temperatures, which increased while the upwelling intensity increased, clearly
400 indicating that ITF became dominant, overwhelming the influence of the upwelling and
401 driving thermocline temperatures from MD98-2165 closer to those from the Timor Sea site
402 MD01-2378.

403 As aforementioned, modern observations tie the dynamics of the Java-Sumatra
404 upwelling and seasonal ITF changes to summer insolation forcing, through the SE wind
405 dynamics. Our observations suggest that such a control is also acting at orbital timescales,
406 with changes in summer boreal insolation not only driving the upwelling dynamics (Wang et
407 al., 2018), but also strongly modifying the thermocline ITF temperature and flux.
408 Interestingly, at this orbital timescale, the ITF signal becomes dominant over the upwelling
409 activity in controlling TWT of MD98-2165, whereas modern data indicate that, at seasonal
410 timescale, the TWT variability is clearly dominated by upwelling variability (Fig. 2).

411 In Fig. 5c, we managed to synthesize the above observations by computing a record
412 that takes into account the relative TWT changes at our three reference sites. The proxy,
413 named %TimorTh (Timor Thermocline %), is designed to quantitatively address the degree
414 of similarity between TWT at MD98-2165 with respect to (i) the upwelling site SO139-74KL
415 and (ii) the non-upwelling site MD01-2378. After the three records were interpolated to the
416 same constant time interval (1 ka), we computed at each age increment the TWT difference
417 between SO139-74KL and MD98-2165 ($TWT_{MD98-2165} - TWT_{SO139-74KL}$), and normalized
418 them with respect to the TWT difference between the Timor sea TWT (ITF end member) and
419 the SO139-74KL TWT (upwelling reference; $TWT_{MD01-2378} - TWT_{SO139-74KL}$). The ratio is
420 expressed as a percentage:

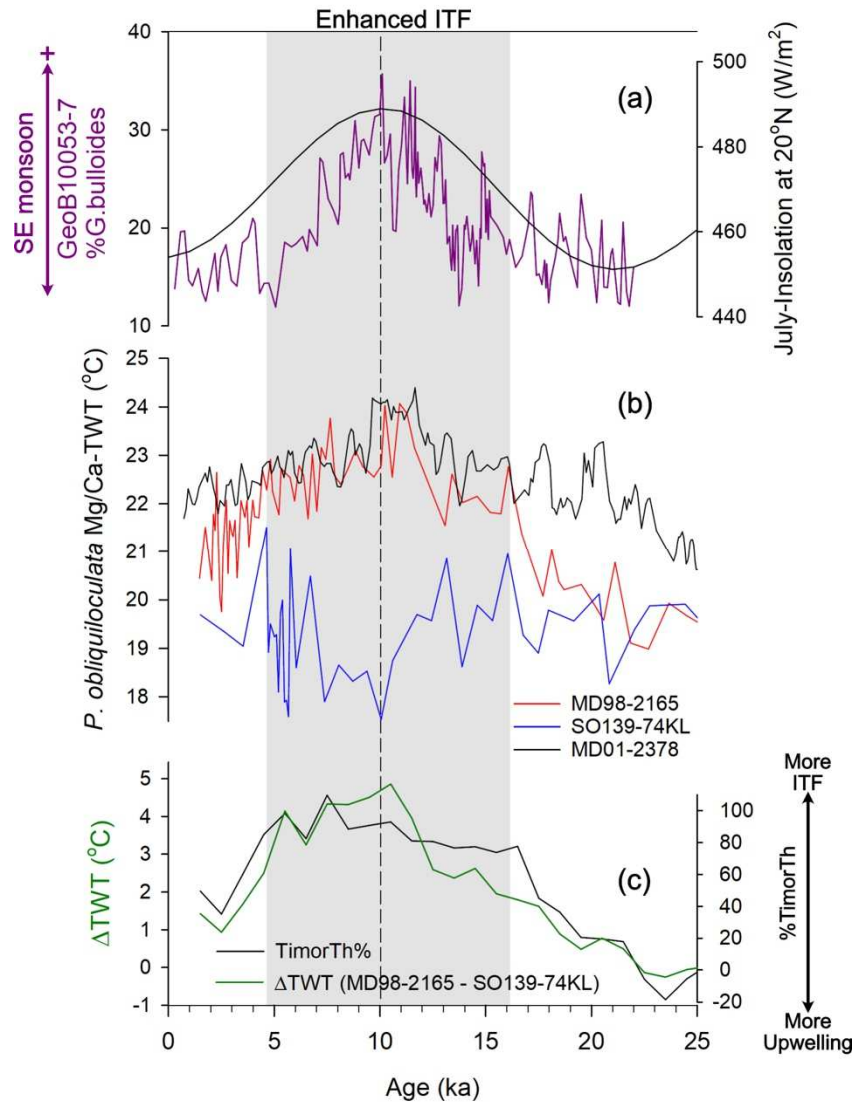

$$421 \quad \%TimorTh_{MD98-2165} = (TWT_{MD98-2165} - TWT_{SO139-74KL}) / (TWT_{MD01-2378} - TWT_{SO139-74KL}) * 100.$$

422 When %TimorTh is close to 1 (i.e. TWT at our site is similar to that of MD01-2378), the
423 influence of ITF is maximal, whereas when it is close to 0 (i.e. TWT at our site is similar to
424 that of SO139-74KL), it is the upwelling that chiefly controls the thermocline temperature in
425 the vicinity of Site MD98-2165. Age models for all the three TWT records over the last 25 ka
426 are based on ^{14}C dates, the age model uncertainties (2σ) are less than 0.5 ka for each core
427 (MD98-2165: Table 1 and Fig. 3; SO139-74KL: Lückge et al., 2009; MD01-2378: Xu et al.,
428 2008). As we aim at using mainly the %TimorTh proxy to show the dynamic influence of
429 ITF and upwelling at site MD98-2165 at orbital timescales, the relatively small age model
430 uncertainties are not able to affect our conclusions.

431 As can be seen in Fig. 5c, the %TimorTh proxy clearly shows the orbital-driven
432 signal embedded in the ITF variability. However, the proxy also emphasizes somehow a
433 step-like evolution since the Last Glacial Maximum, with a rapid evolution from 23 to 16 ka
434 followed by a more progressive change, almost a plateau, in the early Holocene (Fig. 5c).
435 This plateau exists because TWT at site MD98-2165 and MD01-2378 become nearly similar
436 in the interval younger than 16 ka. But, as can be readily seen from the Fig. 5b, the two
437 temperature records continue to evolve, the temperature increasing at both sites to reach their
438 maximum value at ~ 10 ka. Thus, the near plateau we observe in the %TimorTh profile above
439 ~ 16 ka represents a “saturation” of the proxy. When the ITF flux increases, bringing the
440 TWT of site MD98-2165 closer to those at site of MD01-2378, there exists a threshold above
441 which any further increase in the ITF flux remains unseen because TWT at both sites are
442 already similar. In the introduction of this paper, we suggested the existence of such a
443 sensitivity problem for proxies based on the TWT difference between two sites located along

444 the main ITF path. This type of limitation is what we clearly observe, here, in the %TimorTh
445 proxy during termination I and the early Holocene.

446 The fact that TWT changes at orbital-scale are clearly different and somewhat anti-
447 correlated at site MD98-2165 and at site SO139-74KL, suggests an alternative way of
448 expressing the relative contribution of ITF: by considering simply the TWT gradient between
449 the two sites ($\Delta\text{TWT} = \text{TWT}_{\text{MD98-2165}} - \text{TWT}_{\text{SO139-74KL}}$). As can be seen (Fig. 5c) both
450 approaches clearly emphasize the orbital-related imprint in the ITF variability. However, the
451 approach based on the simple difference in TWT (ΔTWT) results in a smoother and more
452 gradual evolution over the studied 25-0 ka interval and does respect the full evolution of
453 TWT profiles, which peak at about ~ 10 ka. A higher-resolution study devoted to the 25-0 ka
454 interval will be necessary to dig further into similarities/differences between the two
455 approaches and resolve the sub-orbital variability. In the present paper, we focus only on the
456 long-term ITF dynamics by using the relative evolution of TWT at sites of MD98-2165 and
457 SO139-74KL. Although potential drawbacks may exist in the ΔTWT approach, the rather
458 good coherence between the ΔTWT and %TimorTh profiles suggest that the main source of
459 variability is indeed associated with ITF changes. Another additional advantage of the ΔTWT
460 approach is that by dealing only with two cores one also reduces the age-model uncertainties.

461

462 **Fig. 5. Evolution of paleoceanographic records over the past 25ka.** (a) Relative
 463 contribution (%) of *G. bulloides* in the foraminiferal assemblages of core GeoB10053-7 (dark
 464 purple line), a proxy of upwelling activity (large % of *G.bulloides* correspond to enhanced SE
 465 monsoon, and vice versa (Mohtadi et al., 2011a); And July insolation (black curve) at 20 °N
 466 (Laskar et al., 2004). (b) *P. obliquiloculata*-derived TWT of MD98-2165 (red line, this study),
 467 SO139-74KL (blue line, Wang et al., 2018) and MD01-2378 (black line, Xu et al., 2008). (c)
 468 Estimation of relative contribution of ITF and upwelling on TWT at site MD98-2165
 469 (%TWT, black curve; see text for details), and difference between TWT at sites MD98-2165
 470 and SO139-74KL (ΔTWT, dark green curve; see text for details).

471 **5.2 Evolution of the ITF relative strength in response to precession-paced insolation**
 472 **forcing and sea level changes during the last 270 ka**

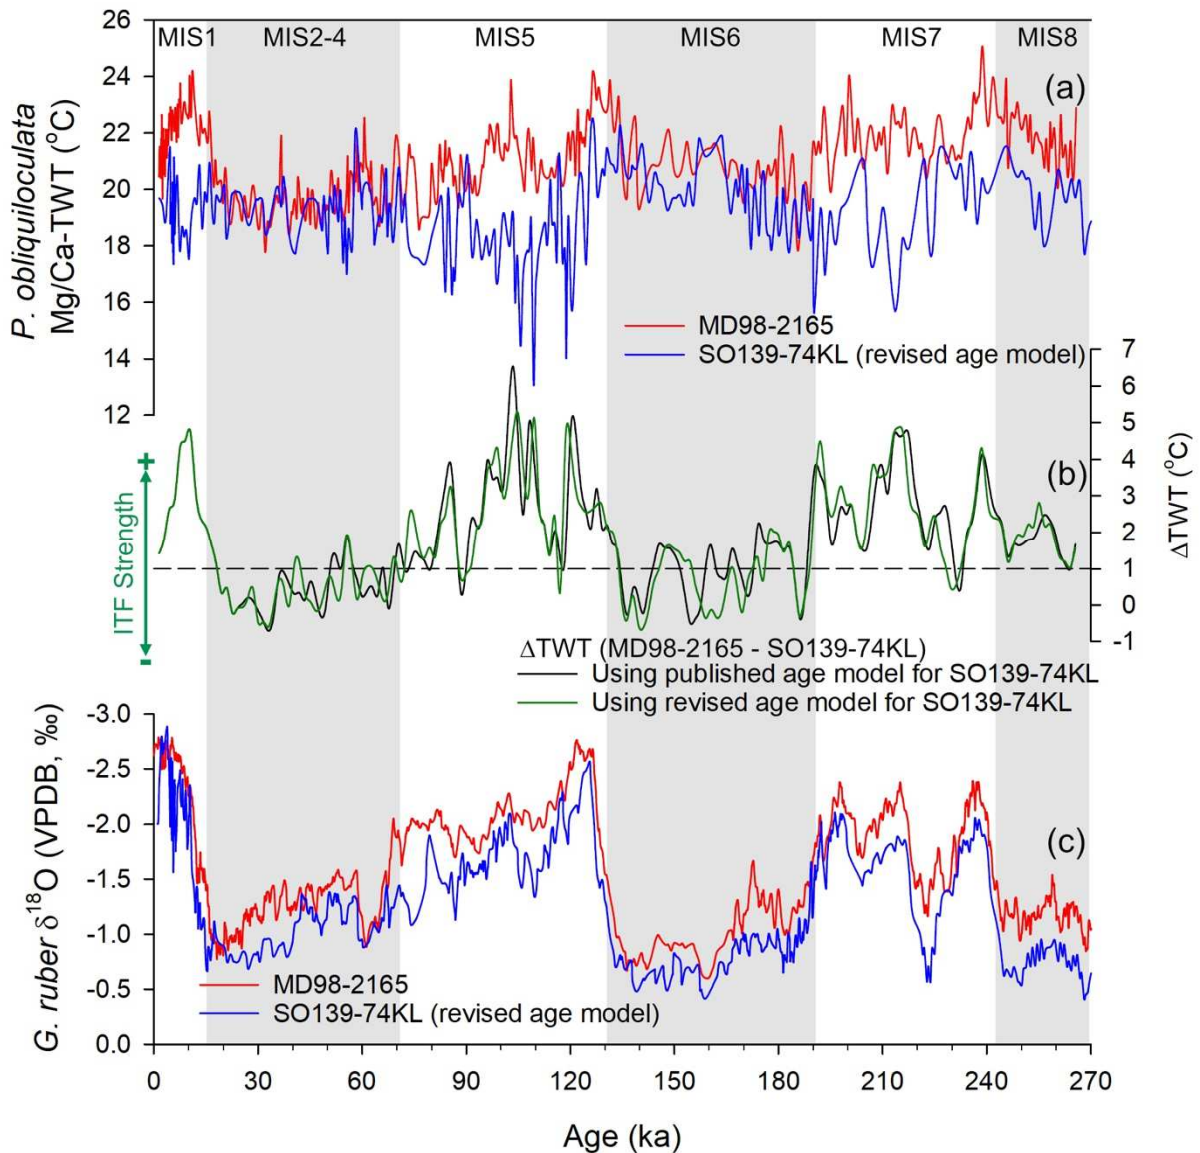

473 As was already seen above for the 25-0 ka interval, the TWT record of MD98-2165
 474 shows remarkable differences compared to the TWT record from core SO139-74KL (Fig. 6a).
 475 During MIS 7, MIS 5 and MIS1, TWT at site of core MD98-2165 were generally higher than
 476 at the site of core SO139-74KL. By contrast, the difference in TWT between these two core

477 sites were relatively small during MIS 6 and MIS 2-4 and, to a lesser degree, during MIS 8.
478 Inside these glacial and interglacial intervals, the difference in TWT between the two sites
479 also varies and suggests a strong orbital component.

480 We constructed a Δ TWT record over the full 270 ka interval. The TWT record from
481 MD98-2165 has an average resolution of ~ 0.6 ka and cover the time period between ~ 1.5
482 and ~ 266 ka, whereas the TWT record from SO139-74KL has an average resolution of ~ 1.1
483 ka and cover the time period between ~ 1.5 ka and ~ 290 ka (Wang et al., 2018). After
484 applying a three-point moving average, we interpolated linearly the TWT records of both
485 cores to a constant 1.5 ka step from 1.5 ka to 265.5 ka. In order to estimate the impact of
486 potential age model bias on the reconstructed Δ TWT profile during the periods without AMS
487 ^{14}C dates, we used, both, the published age model for core SO139-74KL (Lückge et al.,
488 2009), and a revised age model developed in this study by tuning the planktonic $\delta^{18}\text{O}$ record
489 from SO139-74KL to the planktonic $\delta^{18}\text{O}$ record from core MD98-2165 (both obtained from
490 *G. ruber*). The resulting Δ TWT records are shown in Fig. 6b. As can be readily seen, the two
491 alternate age models only result in small differences between the Δ TWT profiles and,
492 therefore, the same conclusions would be reached using either record as long as major
493 changes in the Δ TWT evolution are concerned. In the rest of the manuscript, we used the
494 Δ TWT record obtained with the revised age model of SO139-74KL.

495 In the top Holocene (i.e. 1.5 ka), the difference in TWT between the two sites is $\sim 1^\circ\text{C}$.
496 In order to facilitate the comparison with the upper Holocene situation, a reference line has
497 been drawn at 1°C all along the Δ TWT profiles in Fig. 6b. As can be readily seen, the Δ TWT
498 during cold stages MIS 6 and MIS 2-4 were generally lower than this upper Holocene $\sim 1^\circ\text{C}$
499 reference value, whereas Δ TWT during the warmer stages MIS 7, MIS 5 and the Holocene
500 were higher, Δ TWT reaching up to $\sim 6^\circ\text{C}$. The MIS 8 is a peculiar cold stage characterized
501 by a relatively strong Δ TWT, greater than 1°C . The MIS 7d and MIS 5b sub-stages show low
502 Δ TWT, very close to or even smaller than 1°C (Fig. 6b). Moreover, the Δ TWT record shows
503 clearly cyclic variations inside glacial and especially interglacial stages. For example, large
504 Δ TWT peak values repeatedly occur in warm substages of MIS 7 (a, c and e), MIS 5 (a, c and
505 e) and as well as in the early Holocene (~ 10 ka). As already mentioned for the 25-0 ka
506 interval, the decoupled and somewhat anti-phased TWT variability between MD98-2165 and
507 SO139-74KL on orbital and glacial-interglacial timescales contrasts with the strong seasonal
508 co-variance of TWT at the two sites, which is observed today (Figure 2). Based on the
509 detailed observations made in the 25-0 ka interval, we conclude that ITF intensity was likely

510 stronger than for the upper Holocene during warm stages and sub-stages, and weaker during
 511 colder stages and sub-stages. This is in line with major conclusions reached by [Holbourn et al.](#)
 512 ([2011](#)) for ITF variability in MIS 5 and the MIS 4-2. Interestingly, our data suggest that the
 513 ITF intensity was apparently stronger during MIS 8 than for the late Holocene, whereas ITF
 514 intensity may have been similar to the late Holocene during MIS 7d and MIS 5b

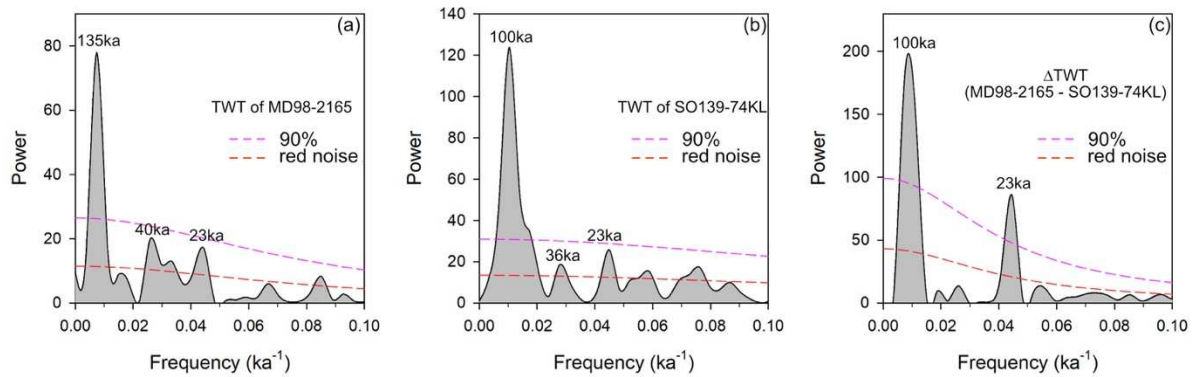

515

516 **Fig. 6. Comparison of *P. obliquiloculata* Mg/Ca-derived TWT between core MD98-2165**
 517 **and SO139-74KL.** (a) TWT of MD98-2165 (red line, this study), TWT of SO139-74KL
 518 (blue line, [Wang et al., 2018](#), on revised age model, see the text). (b) Δ TWT = TWT(MD98-
 519 2165)-TWT(SO139-74KL); Δ TWT in dark green line is calculated by using our revised age
 520 model for core SO139-74KL (see text for detail), Δ TWT in black line is calculated by using
 521 published age model for core SO139-74KL ([Lückge et al., 2009](#)); black dashed line is 1°C of
 522 Δ TWT served as a reference. (c) *G. ruber* $\delta^{18}\text{O}$ (after 3-point moving average) of MD98-
 523 2165 (red line, [Levi, 2003](#)) and SO139-74KL (blue line, [Wang et al., 2018](#), on revised age

524 model).

525 We conducted spectral analyses in order to extract the quasi-cyclic variability
526 observed in the TWT records from core MD98-2165 and SO139-74KL and in the Δ TWT
527 profile. Spectral analysis reveals the presence of all the main orbital-like components (namely
528 eccentricity, obliquity and precession) above the theoretical red noise spectrum (Fig. 7a-b). It
529 suggests the strong role of the \sim 100 ka cycle, clearly above the 90% confidence level. This
530 long-term contributor has a period of \sim 135 ka in core MD98-2165 and \sim 100 ka in SO139-
531 74KL. The incoherency in the periodicity likely results from the relatively short length of the
532 records. With only \sim 270 ka, the core MD98-2165 record covers just two such \sim 135 ka
533 cycles, clearly suggesting a potential bias in the spectral analysis results. Although slightly
534 longer, the 290 ka-long TWT record of core SO139-74KL, does not provide either a good set
535 of data for deciphering the potential “eccentricity” component. Actually, a more thorough
536 examination of this \sim 100 ka cycle through band-pass filtering reveals that, in core SO139-
537 74KL, it is strongly associated to the almost linear trend in TWT seen between 170 and 70 ka.
538 Thus, it does not correspond to the usual glacial-interglacial \sim 100 ka oscillation, which is
539 seen for instance in planktonic foraminiferal $\delta^{18}\text{O}$ record (Fig. 6).

540 Interestingly, the obliquity component (\sim 40 ka) is seen in the TWT record from core
541 MD98-2165 where it is even stronger than the 23-ka component (Fig. 7a), and it corresponds
542 only to a small \sim 36 ka peak in the TWT record from SO139-74KL, just above the red noise
543 spectrum level (Fig. 7b). The 23 ka cycle associated to precession is clearly seen in both
544 records, although it is below the 90% confidence level. The power spectrum of Δ TWT
545 reveals clearly 100-ka and 23-ka components (Fig. 7c), with the 23-ka component being
546 clearly enhanced in the Δ TWT. The fact that no obliquity component is seen in the Δ TWT
547 profile indicates that this signal is co-variant to a large extent in both TWT records and
548 cancels out when subtracting one TWT record from another.

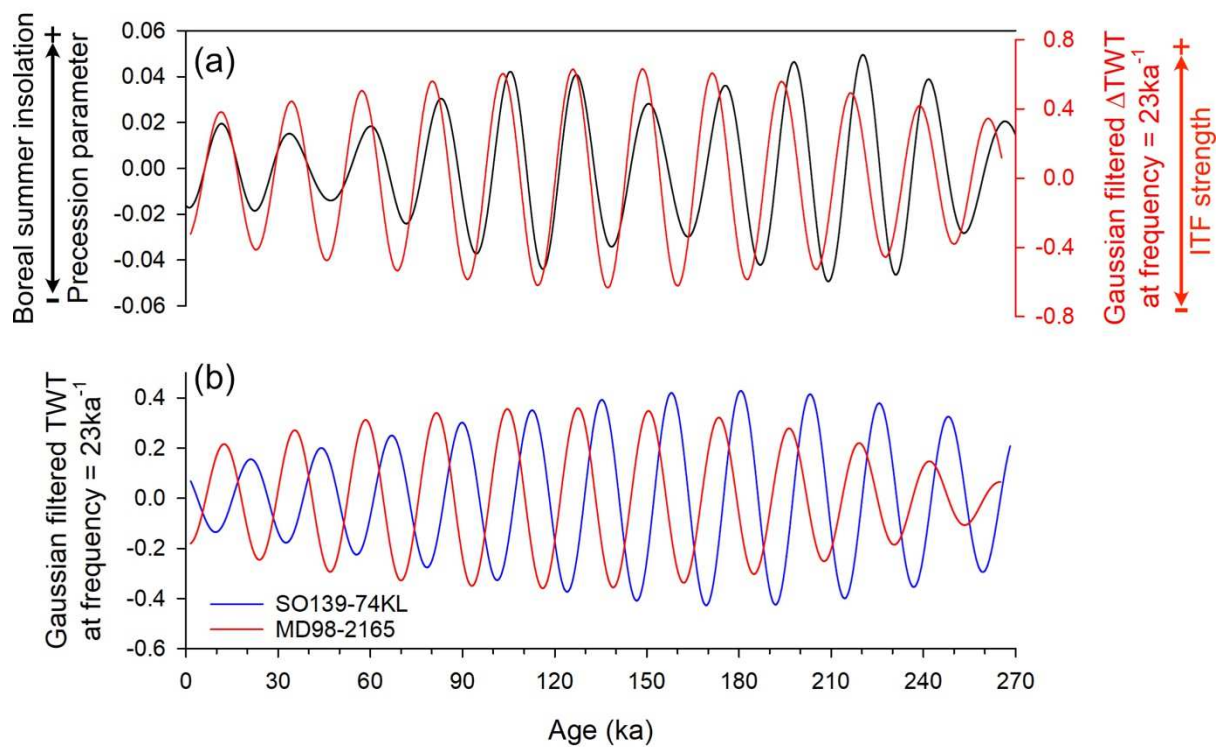

549

550 **Fig. 7.** Spectral analysis of TWT records from core MD98-2165 (a), SO139-74KL (b), and
 551 Δ TWT (c). Spectral analysis is conducted by using the REDFIT module from Past3 software
 552 (Hammer et al., 2001). The settings for the analysis are: Window = Welch, Oversample = 1
 553 and Segments = 1; the red and pink dashed line indicate red-noise and 90% false-alarm level,
 554 respectively.

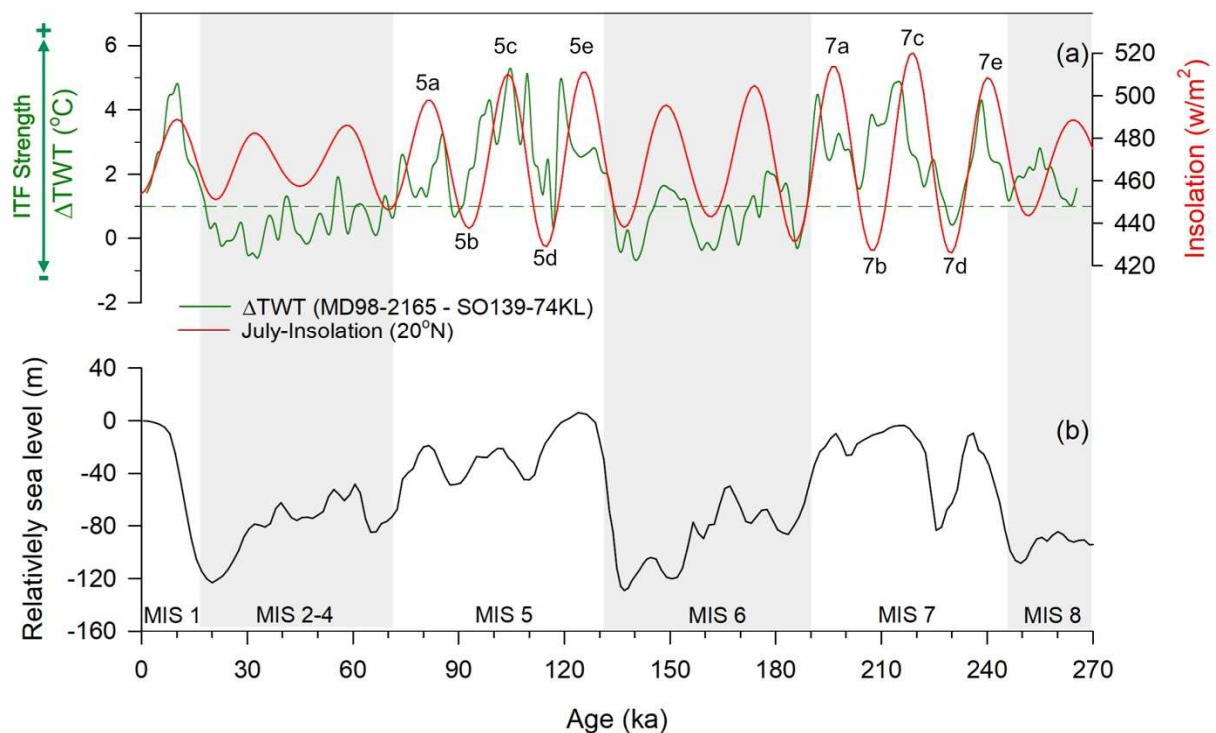

555

As expected, the 23-ka component from Δ TWT shows a strong resemblance with the
 556 precession signal (Fig. 8a). The enhanced precession-like component in Δ TWT compared to
 557 the two initial TWT records comes from the nearly anti-phased evolution of TWT at the 23-
 558 ka precession scale in core MD98-2165 and SO139-74KL (Fig. 8b), with increasing
 559 (decreasing) boreal summer insolation inducing decreased (increased) TWT at the site of
 560 SO139-74KL and increased (decreased) TWT at the site of MD98-2165. This result is in
 561 agreement with previous observations made over the last 25 ka interval (see above), which
 562 showed that when SE monsoon winds increased with increasing boreal summer insolation,
 563 they brought more cold water into the thermocline at site SO139-74KL by boosting the
 564 upwelling, but resulted in more warm water being carried at site MD98-2165 through
 565 enhanced ITF (and vice-versa). The persistent correlation between the Δ TWT with the boreal
 566 summer insolation over the last 270 ka (Fig. 9a) clearly indicates that the same mechanisms
 567 that we described over the last 25ka interval acted over the last 270 ka, resulting in the strong
 568 23-ka precession component. It is our contention, therefore, that changes of ITF intensity flux
 569 and temperatures have been strongly influenced by precession-paced low-latitude insolation
 570 changes over the last 270 ka.

571

572 **Fig. 8.** Comparison of filtered proxy records with the precession parameter. (a) Comparison
 573 of precession parameter (black line) with the gaussian filtered ΔTWT at frequency = 23 ka^{-1}
 574 (red line). (b) Comparison of gaussian filtered TWT at frequency = 23 ka^{-1} between MD98-
 575 2165 (red line) and SO139-74KL (blue line). Gaussian filtering is conducted by using the
 576 software AnalySeries2.0 (Paillard et al., 1996), the filtering frequency center at 0.044 ± 0.003
 577 ka^{-1} for all the TWT and ΔTWT records.

578

579 **Fig. 9.** Comparison of ΔTWT with boreal summer insolation and relative evolution of sea
 580 level. (a) The dark green curve is $\Delta TWT = TWT (MD98-2165) - TWT (SO139-74KL)$; the
 581 red curve is July insolation at $20^{\circ}N$ (Laskar et al., 2004); substages of MIS 5 (5a to 5e) and
 582 MIS 7 (7a to 7c) are also marked. (b) reconstructed evolution of sea level changes
 583 (Waelbroeck et al., 2002).

584 The glacial-interglacial variability in ΔTWT can be seen through two different effects:
 585 (i) the average values are lower in MIS 6 and MIS 4-2, and (ii) the amplitude of ΔTWT
 586 variations are also reduced during these cold stages (Fig. 9a). This suggests that ITF was
 587 weakened and with a lower range of variability during glacial periods. As the Indonesian
 588 Archipelago is an area characterized by numerous islands and shallow sills, this glacial-
 589 interglacial variability of ITF may be associated to some extent with glacio-eustatic sea level
 590 variations. The lowered sea level, by exposing shallow shelves in the Indonesian archipelago,
 591 could have modified the land-sea thermal gradient and regional albedo, thus potentially
 592 influencing the ITF by modulating the SE monsoon strength in addition to orbital forcing
 593 (DiNezio et al., 2018). However, such scenario is undermined by the fact that no ~ 100 -ka,
 594 glacial-interglacial component was found in the paleo-records of SE monsoon winds (Lückge
 595 et al., 2009; Wang et al., 2018). As an alternate hypothesis, the up to 120 m of sea level drop
 596 during glacial stages may have had an impact on the ITF flux by shallowing the ITF
 597 pathways especially at the Lombok Strait where the sill is only ~ 300 m depth at present (Fig.

598 1). It is likely that shallowed pathways reduced the thermocline ITF flux, and reduced both
599 the influence and variability of ITF on the TWT of site MD98-2165. However, this scenario
600 fails to explain the peculiar case of MIS 8, which despite being a glacial stage shows a
601 stronger Δ TWT (and thus, presumably, a stronger ITF flux) than during the late Holocene.

602 As none of these two scenarios can convincingly explain the general decrease of ITF
603 strength during glacial periods, another possibility would be that glacial-interglacial changes
604 of ITF are not controlled through regional sea-level effects but result from changes in the
605 thermohaline circulation and the global dynamics affecting the strength of surface and sub-
606 surface return branches of the Great Conveyor Belt. ITF eventually exits the Indian Ocean to
607 the Atlantic Ocean around the southern tip of Africa through the Agulhas leakage. The ITF
608 and the Agulhas leakage are thus the beginning and ending parts of the upper branch of the
609 Great Conveyor Belt in the Indian Ocean, respectively. Studies show that the Agulhas
610 leakage was largely reduced during glacial intervals, due to the northward migration of the
611 Southern Ocean subtropical front (Beal et al., 2011; Peeters et al., 2004). The reduction of
612 both the thermocline ITF and the Agulhas leakage during glacial periods, may indicate that
613 both mechanisms are simply the expression of a general weakening of the Great Conveyor
614 Belt return branch. However, whether there is indeed a causal relationship changes in the ITF
615 and Agulhas leakage is out of the scope of this study. Further studies are needed to confirm
616 the ITF variability at this glacial-interglacial timescale and explore the potential implications
617 and mechanisms.

618 **6. Conclusions**

619 In this study, we presented a 270-ka long *P. obliquiloculata* Mg/Ca-derived TWT
620 record from core MD98-2165, located in the east of Java-Sumatra upwelling zone and in the
621 main ITF outflow region. Over the last 25 ka, we showed that the TWT record of MD98-
622 2165 oscillates between the pure, upwelling-driven TWT values from core SO139-74KL,
623 located in the west of Java-Sumatra upwelling, and a TWT record from the Timor Sea
624 (MD01-2378), away from the upwelling influence. The TWT gradient (Δ TWT) between the
625 upwelling site and our site can be used to decipher the relative strength of ITF through time.
626 The 270 ka-long, Δ TWT record indicates (i) that the ITF was weaker during MIS 6 and MIS
627 2-4 compared to the late Holocene, and was enhanced during MIS8, MIS 7, MIS 5 and the
628 early Holocene, and that (ii) it varied with a strong precession-related component. We
629 conclude that this precession component results from the direct link between ITF strength and

630 SE monsoon wind intensity, driven by boreal summer insolation. Today, the ITF is strongest
631 during the SE monsoon season and our results suggest therefore that this seasonal pattern is
632 also what could explain the ITF variability at the orbital timescale. On glacial-interglacial
633 timescale, sea level changes may exert an effect on the TWT changes at site MD98-2165 by
634 shallowing the ITF pathways although it fails to explain all the observations. An alternative
635 explanation rests upon past changes in the intensity of the Great Conveyor Belt, which may
636 have driven the glacial-interglacial ITF change. Further studies are needed to disentangle
637 underlying mechanisms driving the glacial-interglacial ITF changes.
