Abstract

The Fourier transform microwave spectrum of isopropenyl acetate ($\text{CH}_3\text{-COO-C}(\text{CH}_3)=\text{CH}_2$) has been measured under molecular beam conditions. The experimental data as well as quantum chemical calculations have shown that this molecule exists as only one conformer of C_1 symmetry, in which the vinyl group is tilted by an angle of approximately 70° against the plane containing the ester group. Due to internal rotation of the acetyl methyl group, we found large A-E splittings of all lines (from a few MHz up to 1 GHz or more). We also were able to resolve the splitting due to the internal rotation of the second isopropenyl methyl group. The A species lines split into doublets and the E species lines into triplets. These splittings vary from 10 kHz up to 1 MHz, much smaller than the splittings due to the acetyl methyl group. By analyzing the spectrum with the program Xiam, a torsional barriers of $135.3498(38) \text{ cm}^{-1}$ and $711.7(73) \text{ cm}^{-1}$ for the acetyl methyl group and the isopropenyl methyl group were observed, respectively. All lines in the spectrum were also fitted with the program Erham to a standard deviation of only 2.3 kHz.

Keywords: Microwave spectroscopy, Isopropenyl acetate, Internal rotation

Introduction

From our studies on allyl acetate [1], $\text{CH}_3\text{-COO-CH}_2\text{-CH=CH}_2$, we learned that the vinyl group was not located within the plane formed by the ester group, but tilted by an angle of 129° against it. This induced us to investigate isopropenyl acetate, which is an isomer of allyl acetate. To the best of our knowledge no microwave studies have been carried out on this system before. We were interested to find out whether also in this case the isopropenyl group is tilted against the ester group.

Our interest in large amplitude motions also motivated us for this work. To our knowledge only very few acetate esters have been investigated. The first measured acetate ester was methyl acetate [2]. In this case, the barrier to internal rotation of the acetyl methyl group is $99.559(83) \text{ cm}^{-1}$. In our own studies on ethyl acetate [3] and allyl acetate [1], we observed a barrier of $101.606(23) \text{ cm}^{-1}$ and $98.093(12) \text{ cm}^{-1}$, respectively. Therefore we expected also in the case of isopropenyl acetate a rather low hindering barrier on the order of 100 cm^{-1} .

When Hirota studied the microwave spectrum of propene [4] he found a barrier to methyl rotation of $698.4(5) \text{ cm}^{-1}$. Since the situation in the isopropenyl group is similar, we expected also to be able to resolve the splittings due to the isopropenyl methyl group.

Experimental

Isopropenyl acetate was purchased from Merck Schuchardt OHG, Hohenbrunn, Germany. A gas mixture containing 1% isopropenyl acetate in a carrier gas at a total pressure of 100 to 200 kPa was used throughout. In most cases helium was chosen because the rotational temperature of the molecular beam is not as low as with argon or neon and therefore also higher J levels can still be observed. All spectra were recorded using a molecular beam Fourier transform microwave (MB-FTMW) spectrometer in the frequency range 4 to 26.5 GHz [5,6]. This spectrometer can be used in a high resolution mode as well as in a scan mode. In the scan mode a number of overlapping spectra are recorded in the high resolution mode. Since the direction of microwave propagation

and gas pulse are co-axial [7], in the high resolution mode all lines are split into doublets due to the Doppler effect. The line width was in the range from 10 to 25 kHz, the line positions can be determined with an accuracy of 1 kHz for strong lines and 5 kHz for weaker lines.

A typical spectrum of the A and E species is shown in Fig. 1 and Fig. 2, respectively.

<< Fig. 1 approximately here >>

<< Fig. 2 approximately here >>

We found that some triplets, as the one in Fig. 2, show a narrow additional splitting on the order of 20 kHz. Under the influence of inhomogeneous magnetic fields these splittings vanished. We therefore attributed it to proton spin-spin or spin-rotation coupling as will be discussed below.

Spectral Analysis

1. Symmetry labels

According to our *ab initio* calculations (see below) the point group of the isopropenyl acetate molecule is C_1 , i.e. it has no symmetry plane. There are two internal rotors, the acetyl methyl group with a rather low hindering barrier and the isopropenyl methyl group with a high barrier. The molecular symmetry group is isomorphic to the direct product group [8] $C_3^{(1)} \otimes C_3^{(2)}$. Both C_3 symmetry groups involved have three one-dimensional symmetry species A, E_a , E_b . We will label the rotorsional wave functions by AA, $AE=AE_a+AE_b$, $EA=E_aA+E_bA$, $EE=E_aE_a+E_bE_b$, and $EE^*=E_aE_b+E_bE_a$. In a species $\Gamma_1\Gamma_2$ the acetyl methyl group will be represented by Γ_1 and the isopropenyl methyl group by Γ_2 . Due to the low barrier of the acetyl methyl group all spectral lines show wide splittings into an A and an E component. The A component is split under the influence of the isopropenyl methyl group into a narrow AA, AE doublet, the E species splits into a narrow EA, EE, EE^* triplet.

2. Ab initio calculations

In order to have reasonable rotational constants for spectral assignment we carried out a structure optimization at MP2/6-311++G** level using the Gaussian03 package [9]. This level of theory had been used for similar molecules before and usually yielded rotational constants which were quite close (approximately 1%) to the experimental ones. A better agreement cannot be expected, because the calculated rotational constants refer to the equilibrium internuclear distances whereas the experimental constants are usually effective constants averaged by the zero point vibration. Besides the rotational constants also the angles $\angle(i,g)$, $g=a,b,c$ between the internal rotor axes and the inertial axes were calculated from the *ab initio* geometry, since they can directly be compared to our experimental data. The rotational constants and the angles are given in Tab. 1, the optimized geometry is shown in Fig. 3, the cartesian coordinates are available as supplementary material (Tab. S5).

<< Fig. 3 approximately here >>

In this work we were only interested in the *trans* conformer of the ester. *Cis* esters are known to be much higher in energy and are therefore usually not observed under molecular beam conditions.

In contrast to our initial assumption the optimized structure had no symmetry plane and the isopropenyl group was tilted out of the plane of the ester group. Therefore we decided to calculate a potential curve where the dihedral angle $\varphi = \angle(C_5, O_7, C_8, C_9)$ (for atom numbers see Fig. 3) was varied while all other geometry parameters were allowed to relax. The result is shown in Fig. 4. The curve has been parametrized by a Fourier expansion given in Tab. 2. The potential energy minima at $\varphi \approx \pm 70^\circ$ represent a pair of enantiomers. The same result is obtained by global structure optimization. Two C_s geometries at 0° and $\pm 180^\circ$ represent maxima in the potential curve and can be definitely excluded as stable conformers.

<< Fig. 4 approximately here >>

We also calculated the potential functions of the internal rotation of the isopropenyl methyl group and the acetyl methyl group in a similar manner. Again, the potential curves were parametrized by Fourier expansions. The Fourier coefficients are summarized in Tab. 2. Usually, the potential is given by the Fourier expansion

$$V(\alpha) = \frac{V_3}{2} (1 - \cos 3\alpha) + \frac{V_6}{2} (1 - \cos 6\alpha) + \dots$$

It should be noted that the V_n potential ($n=3,6,\dots$) is given by $V_n = 2 |a_n|$. For the isopropenyl methyl group we found a V_3 barrier of 656.2 cm^{-1} with a V_6 contribution below 2%. The acetyl methyl group yielded a V_3 barrier of 120.5 cm^{-1} . Here a significant V_6 term of 24.7 cm^{-1} was found, which is 20% of V_3 . As a consequence, the potential curve is a distorted cosine function with broadened minima and narrow maxima.

3. Spectral assignment

We started our experimental studies with a broadband scan recorded in the frequency range 9.3 to 14.5 GHz. Within this range, a total of 120 multiplets were found. All lines were remeasured in the high resolution mode. Almost all lines appeared as AA, AE doublets or as EA, EE, EE* triplets. In a first step we tried to fit the AA components separately with a rigid rotor program. It should be mentioned that *b*- and *c*-type transitions were quite strong whereas *a*-type lines turned

out to be very weak and could not be observed in the scan at all. After the AA components had been assigned, a complete spectrum with all torsional components was predicted using the Xiam [10] code. In a first approach we assumed the barrier of the acetyl methyl group to be approximately 100 cm^{-1} as found in methyl acetate [2], ethyl acetate [3], or allyl acetate [1], but no agreement with the observed spectrum was found. Then we successively increased the barrier up to 135 cm^{-1} , where finally the observed and calculated spectra roughly matched. We fitted 50 transitions with 247 torsional components using the Xiam code. Since the A-E splitting caused by the acetyl methyl group is very large, whereas the splittings within the AA-AE doublets and the EA-EE-EE* triplets are rather small, we only fitted the *absolute line positions* of the AA and the EA lines. For the other species we fitted the AA-AE, EA-EE, and EA-EE* *splittings* referred to AA and EA, respectively. The *narrow splittings*, which contain the information of the *high barrier* could be fitted almost within the experimental uncertainty. On the other hand, the large splittings, determined by the low barrier, could be reproduced only within 10 to 350 kHz, which is on the same order of magnitude as the small splitting. Therefore, fitting all absolute positions of all lines would not allow to determine the high barrier. The resulting molecular parameters are given in Tab.1. A list of all fitted lines is available as supplementary material (Tab. S1 and S2). The standard deviation of the fit is 75.5 kHz. This is much larger than our experimental uncertainty which is estimated to be approximately 2 kHz. This discrepancy is due to the limitations of the Xiam code. In order to check for a correct assignment we fitted the same data set also with the Erham code [11] and found a standard deviation of 2.3 kHz which is very close to experimental accuracy. The parameters fitted with Erham are also given in Tab. 1. A list of all fitted lines is given in the supplementary data (Tab. S3 and S4). The agreement between the rotational and centrifugal distortion constants, and also the angles between the internal rotor axes and the inertial axes obtained with Xiam and Erham is quite good. Unfortunately, the Erham code does not provide information on the potential barrier V_3 but only on more effective tunneling parameters.

Results and Discussion

Our studies revealed some interesting aspects of the isopropenyl acetate molecule which are different from our initial ideas. In contrast to our assumption, but in agreement with our *ab initio* calculations, isopropenyl acetate has no mirror plane. This has been confirmed by the observation of *c*-type AA species transitions. Moreover, more than 95% of all measured transitions could be assigned. Therefore it must be assumed, that only one conformer exists under molecular beam conditions. This is consistent with our attempts to find other conformers by *ab initio* calculations, where also only one conformer (as a pair of two enantiomers) was found.

The barrier to internal rotation of the acetyl methyl group was found to be approximately 135 cm^{-1} , which is surprisingly high if compared to other acetates like methyl acetate [2], ethyl acetate [3], and allyl acetate [1], where the barrier is always on the order of 100 cm^{-1} . However, it should be mentioned that in the case of vinyl acetate [12] a barrier of $155.1(1)\text{ cm}^{-1}$ was found, which is still higher than the barrier found in isopropenyl acetate. Obviously, in both cases there is some delocalization of π -electrons extends from the vinyl double bond to the ester group, which increases the potential barrier. In the case of allyl acetate the vinyl group is not involved in delocalization and the barrier remains near 100 cm^{-1} . However, we will continue our work on esters to study this feature in detail.

For the isopropenyl methyl group we found a barrier of $711.7(73)\text{ cm}^{-1}$. This is somewhat smaller than we expected at the beginning of our studies. However, it is in reasonable agreement with the barrier of $698.4(5)\text{ cm}^{-1}$ reported by Hirota for propene [4], where the local environment of the methyl group is similar.

Finally, it should be mentioned that besides the splittings due to internal rotation additional very narrow splittings were observed. These splittings changed their appearance or they disappeared when the measurements were carried out in the presence of an inhomogeneous magnetic field ranging from one to five times the strength of the earth's magnetic field. Therefore we concluded that these extra splittings arise from proton spin-rotation and spin-spin coupling. It is surprising that the lines are influenced by those low external magnetic fields since it is often believed that in closed-shell molecules Zeeman effects due to the earth's magnetic field cannot be observed at all.

ACKNOWLEDGMENTS

We thank the Center for Computing and Communication of the RWTH Aachen University for free computer time and the Land Nordrhein-Westfalen for funds. Furthermore, we thank R. Missong for her contributions within her bachelor thesis, J. Broda and C. Willems for the contributions within a student research project. Finally we would like to thank P. Groner for making his Erham code available to the spectroscopic community.
