47

48 **ABSTRACT**

49 Our study aims to reconstruct the palaeogeography of the northern part of the Lesser Antilles in
50 order to analyse whether emerged areas might have existed during the Cenozoic, favouring
51 terrestrial faunal dispersals between South America and the Greater Antilles along the present-day
52 Lesser Antilles arc. The stratigraphy and depositional environments of the islands of Anguilla, St
53 Martin, Tintamarre, St Barthélemy, Barbuda and Antigua are reviewed in association with
54 multichannel reflection seismic data acquired offshore since the 80's in the Saba, Anguilla and
55 Antigua Banks and in the Kalinago Basin, including the most recent academic and industrial surveys.
56 Seven seismic megasequences and seven regional unconformities are defined, and calibrated from
57 deep wells on the Saba Bank and various dredges performed during marine cruises since the 70's in
58 the vicinity of the islands. Onshore and offshore correlations allow us to depict an updated and
59 detailed sedimentary organisation of the northern part of the Lesser Antilles from the late Eocene to
60 the late Pleistocene. Paleogeographic reconstructions reveal sequences of uplift and emergence
61 across hundredwide areas during the late Eocene, the late Oligocene, the early middle-Miocene and
62 the latest Miocene-earliest Pliocene, interspersed by drowning episodes. The ~200 km-long and ~20
63 km-wide Kalinago Basin opened as an intra-arc basin during the late Eocene - early Oligocene. These
64 periods of emergence may have favoured the existence of episodic mega-islands and transient

65 terrestrial connections between the Greater Antilles, the Lesser Antilles and the northern part of the
66 Aves Ridge (Saba Bank). During the Pleistocene, archipelagos and mega-islands formed repeatedly
67 during glacial maximum episodes.

68

69 **1. INTRODUCTION**

70

71 The Caribbean, including the Greater and Lesser Antilles located at the northeastern edge
72 of the Caribbean Plate, are regarded as one of the most important centres of insular
73 biodiversity (Myers al., 2000; Mittermeier et al., 2011). Despite decades of studies, the
74 phylogenetic origins and historical biogeography of this astonishing biodiversity remain,
75 however, controversial (e.g., Hedges et al., 1992; MacPhee and Iturralde-Vinent, 1995, 2005;
76 Iturralde-Vinent and MacPhee, 1999; Myers et al., 2000; Hedges, 2001, 2006; Ali, 2012). In
77 an island setting, either over-water transports (natural rafts of matted vegetation) or land
78 connections provide possible routes for dispersal of terrestrial organisms and their
79 colonization of these remote Caribbean islands. If over-water dispersals by rafting are
80 sweepstake dispersals (and as such hardly predictable), the possibility of over-land (via land-
81 bridges) dispersals relies on the regional tectono-magmatic evolution of the Lesser Antilles
82 subduction zone.

83 Biogeographic models for Antillean terrestrial organisms derive from limited
84 palaeontological and phylogenetic inferences (either based on the morphology or on
85 genes/proteins of living and recently extinct species) (Hedges, 1996; Woods et al., 2001;
86 Graham, 2003; Roca et al., 2004; MacPhee, 2005; Fabre et al., 2014; Brace et al., 2015, 2016;
87 Courcelle et al., 2019; Delsuc et al., 2019; Presslee et al., 2019; Marivaux et al., 2020). They
88 also derive from still controversial paleogeographic models of the Caribbean Plate evolution
89 (e.g., Stephan et al., 1990; Iturralde-Vinent and MacPhee, 1999; Pindell and Kennan, 2009)
90 and global reconstructions (Blakey, <https://deeptimemaps.com/>; Scotese; 2016). The main

91 discussed model for explaining the arrival of many terrestrial organisms of South American
92 origin on the Caribbean islands relate to a possible 2 Myrs- long period of subaerial exposure
93 of the Aves Ridge (Fig. 1) at the Eocene-Oligocene transition. Following this model, the ridge
94 momentarily constituted a land-bridge (named GAARlandia, for land of **G**reater **A**ntilles–
95 **A**ves **R**idge) between northern South America and the Greater Antilles (e.g., MacPhee and
96 Iturralde-Vinent, 1995; Iturralde-Vinent and MacPhee, 1999; MacPhee, 2005; Iturralde-
97 Vinent, 2006)).

98 Contrary to the Aves Ridge, the potential contribution of the Lesser Antilles in early
99 dispersals of South American faunas and flora has never been considered. This is paradoxical
100 because the archipelago is located closer to the subduction deformation front and has
101 experienced uplift and drowning events likely favouring land-organism dispersals and
102 subsequent insular evolution. This is particularly obvious in the Guadeloupe archipelago
103 where repeated uplifts, leading to subaerial exposures, and subsequent drownings have been
104 evidenced (Cornée et al., 2012; Münch et al., 2013, 2014; De Min et al., 2014). Further north,
105 it has been proposed that the Pleistocene rodent *Amblyrhiza*, an endemic giant chinchilloid
106 caviomorph from Anguilla, St Martin and St Barthélemy islands, could be closely related to
107 early Oligocene chinchilloids from Puerto Rico (Velez-Juarbe et al., 2014; Marivaux et al.,
108 2020), thereby extending the evolutionary history of this rodent group back to 30 Ma, and
109 revealing its widespread distribution between the Greater Antilles and the northern Lesser
110 Antilles through time.

111 In this work, we study the palaeogeographic evolution of the northeastern part of the
112 Lesser Antilles during the Cenozoic, as it may have constituted an episodic emerged area
113 between the Aves Ridge to the southwest and the Greater Antilles to the North: the GrANoLA
114 land -Greater Antilles- Northern Lesser Antilles land (Philippon et al., 2020a). Previous
115 bathymetric reconstructions and offshore-onshore geological investigations have suggested

116 that the Kalinago intra-arc rift basin (Figs. 1, 2) may have undergone substantial vertical
117 motion (e.g., Bouysse et al., 1985a; Mann et al., 1995; Feuillet et al., 2011) and 15%
118 extension (Legendre et al., 2018). In the whole Eastern Caribbean (Aves Ridge, Greater and
119 Lesser Antilles), accurate constraints on the chronology, duration and spatial extent of land
120 emergence and drowning during the Cenozoic are, however, strongly missing to reconstruct
121 the regional paleogeographic evolution. This lack of information prevents the effective testing
122 of biogeographic models deriving from gene-based and morpho-anatomical phylogenies and
123 associated divergence time estimates. In this work, we refine the sedimentology and
124 stratigraphy of the deposits over an area extending from the Saba Bank to the Antigua Bank
125 encompassing the Kalinago Basin (Figs. 1, 2), and use these analyses to reconstruct the
126 vertical motions that occurred in this key area of the Northern Lesser Antilles. The study is
127 based on new onshore palaeoenvironmental, biostratigraphic, and structural data, combined
128 and correlated with new offshore-dredged samples and seismostratigraphic interpretation of
129 seismic reflection data from the ANTITHESIS (Marcaillou and Klingelhoefer, 2013; 2016)
130 and GARANTI cruises (Lebrun and Lallemand, 2017), which allow us to reconstruct the
131 palaeogeographic evolution of the region.

132

133 **2. TECTONO-MAGMATIC EVOLUTION OF THE NE CARIBBEAN SINCE** 134 **THE CRETACEOUS**

135

136 The westward subduction of the Proto-Caribbean/Atlantic Ocean lithosphere beneath the
137 Caribbean Plate initiated from Cuba southward during the Cretaceous. The Great Arc of the
138 Caribbean (GAC) is the magmatic expression of this subduction. Magmatic arc samples from
139 the southern Aves Ridge and Leeward Antilles offshore Venezuela indicate that subduction
140 occurred there since the middle-late Cretaceous (Coniacian; Neill et al., 2011) or after

141 Santonian (Hastie et al., 2021). During the Paleocene and the early Eocene, the motion of the
142 North American Plate relative to the Caribbean plate changed from north-eastward to
143 eastward (Pindell and Kennan, 2009; Boschman et al., 2014). At the same time, the collision
144 of the Bahamas Bank margin with the Caribbean Plate sutured the subduction along its
145 northern part (accreting Cuba to the North American plate) whereas a new E-W trending
146 transform plate boundary formed along the proto-Cayman Trough that started opening (e.g.,
147 Pindell and Kennan, 2009; Boschman et al., 2014). Subsequently, the Greater Antilles
148 underwent sinistral shearing and were dismembered along the new transform plate boundary
149 (Fig. 1). The present-day trench curvature of the northern Lesser Antilles subduction zone and
150 along strike variation of the convergence obliquity most likely results from this Eocene
151 reorganisation of the plate boundary and subsequent left lateral motion of the Bahamas Bank /
152 Cuba margin relative to the Caribbean Plate interior (Boschman et al., 2014; Philippon and
153 Corti, 2016; Philippon et al., 2020b). Today, the Greater and Lesser Antilles margins are
154 separated by an elongated, fault-bounded basin, the Anegada Trough (e.g., Jany et al., 1990;
155 Laurencin et al., 2017 and references therein; Fig. 1). Based on dredged samples and seismic
156 reflection profiles, the opening of the Anegada Trough is supposed to have occurred during
157 the middle or the late Miocene (Jany et al., 1990), and its activity has probably been
158 negligible since 2 Ma (Chaytor and ten Brink, 2015; Calais et al., 2016). Our study area lies
159 south of this major tectonic structure separating the Greater from the Lesser Antilles (Fig. 1).

160 Three phases of arc magmatism are recognized along the Antillean subduction zone, with
161 lateral variation with time:

162 (i) arc magmatism was first established during the Late Cretaceous-Paleocene along the
163 Aves Ridge (Fig. 1) as part of the GAC (ages of arc magmatic rocks range between 88 Ma
164 and 59 Ma; Fox et al., 1971; Bouysse et al., 1985a; Neill et al., 2011).

165 (ii) The GAC then migrated eastward (*i.e.*, trenchward) probably during the middle
166 Eocene, as evidenced by the occurrence of Lutetian lavas in the Grenadines Islands
167 (Westercamp et al., 1985). This Eocene arc is present beneath the southern Lesser Antilles
168 islands, and, from Martinique northward, Eocene to earliest Miocene remnants of this arc are
169 exposed and dated in the forearc domain (Westercamp, 1988; Bouysse and Westercamp,
170 1990; Legendre et al., 2018) (Fig. 1). Along the northern Lesser Antilles, this arc is exposed
171 and dated based on radiometric data in Antigua (middle Eocene to earliest Miocene; Nagle et
172 al., 1976; Briden et al., 1979; Mascle and Westercamp, 1983; Weiss, 1994), St Barthélemy
173 (middle Eocene to latest Oligocene; Legendre et al., 2018), and St Martin (late Eocene to
174 early Oligocene; Nagle et al., 1976; Briden et al., 1979). Late Paleogene volcanoclastic arc (or
175 backarc) rocks have also been found in deformed zones of the Virgins Islands, Puerto-Rico
176 and Anguilla (Briden et al., 1979; Andréieff et al., 1988; Jolly et al., 1998; Rankin, 2002),
177 thereby suggesting that the remnant arc extended across the incipient Anegada Trough at this
178 time. These rocks, nevertheless, have never been related neither to those of the Aves Ridge
179 nor to those of the Grenada Basin.

180 (iii) The modern arc (inner arc of Mc Cann and Sykes, 1984) is formed 50 km west of the late
181 Paleogene-early Neogene remnant one (outer arc of Mc Cann and Sykes, 1984). From
182 Guadeloupe northward, volcanism occurred since the early Pliocene (e.g., Samper et al.,
183 2007; Favier et al., 2019; Carey et al., 2020). The northernmost island of the arc is Saba
184 where volcanism occurred during the Late Pleistocene (Defant et al., 2001). Offshore north of
185 Saba, Pliocene volcanic and volcanoclastic rocks have been dredged from the Luymes Bank
186 (cruise ARCANTE 1) and the Noroît Seamount (cruise ARCANTE 3, 118) (Figs. 1 and 2)
187 (Bouysse et al., 1981; 1985b).

188

189 **3. GEOLOGICAL SETTING OF THE NE CARIBBEAN ISLANDS**

190

191 ***3.1. Anguilla Bank***

192 Three main islands emerge from the large, shallow water Anguilla Bank: from north to
193 south Anguilla, St Martin (including the islet of Tintamarre) and St Barthélemy (Fig. 2).
194 Neogene deposits are exposed on these three islands (Christman 1953; Andréieff et al., 1987;
195 1988; older references therein).

196 St Martin consists of 2000 to 3000 m-thick Eocene volcanoclastic turbidites intruded
197 by late Eocene-early Oligocene granodiorites (28.4-31.3 Ma; Nagle et al., 1976; Briden et al.,
198 1979). In the southwestern part of the island, late Oligocene magmatic rocks may also occur
199 but remain undated (Andréieff et al., 1988, 1989). On the southwestern and eastern margins of
200 the island, Neogene carbonates deposited unconformably on Paleogene rocks, which were
201 tilted along a NE-SW fault bounding the northwestern coast of the island. Drilled cores from
202 the southwestern deposits recovered up-to-250 m of Neogene carbonates along the margin of
203 the island (Terres Basses; Dagain et al., 1989). On the islet of Tintamarre, the basal part of the
204 Neogene deposits remains unknown. According to Andréieff et al. (1988), the deposits at St
205 Martin and Tintamarre constitute two main formations with unknown relationships: 1) > 70
206 m- thick sedimentary rocks which were deposited during the late Burdigalian in a reefal
207 depositional setting; 2) 80 m- thick distal forereef sedimentary rocks which were deposited
208 between the late Serravallian and the Messinian in St Martin only.

209 In the island of Anguilla, the oldest sedimentary deposits consist of late Paleocene to
210 Eocene volcanoclastic turbidites tilted to the south-east (Andréieff et al., 1988). These
211 turbidites are unconformably overlaid by a 100 m- thick biostromal coral reef deposit
212 considered to be either early Miocene or middle Miocene (Andréieff et al., 1988; Budd et al.,
213 2005). Shallow water carbonates are poorly known from other islets of the Anguilla Bank,

214 Sombrero (Pliocene) and Dog Islands (late Burdigalian-early Langhian; Bouysse et al., 1985a;
215 Andréieff et al., 1987).

216 During the cruises ARCANTE, dredged samples have been collected on flanks of the
217 Anguilla Bank (Bouysse and Guennoc, 1983; Bouysse et al., 1985a) (Fig. 2). On the
218 southwestern margin of the Anguilla Bank, dredges 46V and 47V yielded Pleistocene to
219 Holocene carbonate sediments. On the northern margin, dredge 121D provided Pliocene-?
220 Pleistocene tuff limestones, Serravallian marls, and late Eocene magmatic rocks (36.5 to 33
221 Ma interval, whole rock K-Ar ages; Bouysse et al., 1985a). Finally, to the east of the Bank,
222 dredges E402 and ST31 yielded uppermost Cretaceous radiolarian-bearing limestones and
223 Pleistocene clays, respectively.

224

225 **3.2. *Kalinago Basin***

226 The Kalinago Basin is a NW-SE trending, 100 km- long intra-arc rift separating the
227 Anguilla Bank from the recent active volcanic arc (Bouysse et al., 1985a; Jany et al., 1990)
228 (Fig. 2). The basin is bounded by syn- to post- Neogene faults and possibly comprise
229 deformed, Cretaceous to Oligocene or Miocene rocks overlain by poorly deformed, 2.000 m-
230 thick Neogene to Pleistocene deposits (Jany, 1989; Jany et al., 1990; Church and Allison,
231 2004). At the northern margin of the basin on slopes of the Aguillita Spur, dredge RV-
232 Eastward 1390 (Fig. 2) yielded clays and marls that were deposited between the Pliocene and
233 the Pleistocene (Jany, 1989). In the southern part of the basin, southeast of Montserrat (Fig.
234 2), the Integrated Ocean Drilling Program (IODP) Leg 340 (out of Fig. 2) drilled 181 m of
235 late Pleistocene volcanoclastic deposits (Coussens et al., 2012).

236

237 **3.3. *Saba Bank***

238 The shallow water Saba Bank (Figs. 1 and 2) has been intensively explored for oil
239 prospecting (Warner, 1990; Larue and Warner, 1991; Daly, 1995; Church and Allison, 2004;
240 Matchette-Downes, 2007). On the basis of seismic investigations and wells SBD1 (total depth
241 of 2977 m; Marathon Group) and SBD2 (total depth of 4231 m; Fina Group), the bank
242 comprises from bottom to top: 1) a deformed Cretaceous to Paleocene sedimentary basement
243 topped by an unconformity; 2) a subaerial, at least 120 m- thick, porphyritic andesitic
244 sequence dated at 34.4 ± 3.7 Ma and 37.3 ± 1.4 Ma (whole rock K-Ar); 3) a *ca* 900 to 1000
245 m- thick “turbidite” unit dated from the early late Eocene to the early Oligocene based on
246 planktonic foraminifera and calcareous nannofossils; this unit correlates with late Eocene
247 reefs developed on palaeostructural highs; 4) a *ca* 1500 m- thick volcanoclastic “fluvio-
248 deltaic” unit, which were deposited between the early late Oligocene and the early Miocene
249 based on calcareous nannofossils and benthic foraminifera, and 5) an “upper carbonate unit”,
250 which was deposited between the middle Miocene and the early Pliocene based on planktonic
251 foraminifera, and which indicates a shallowing-upward trend (Church and Allison, 2004).

252 North of the Saba Bank, a Pliocene (*ca* 4 Ma) volcanic activity has been evidenced on
253 the Luymes Bank and the Noroît Seamount and may correspond to the northeastern
254 termination of the active volcanic Lesser Antilles Arc (Bouysse et al., 1985a; b). Along with
255 volcanic rocks and clasts, Pliocene-Pleistocene pelagic limestones were mainly recovered and
256 coral reefs and red-algal limestones were also dredged. Finally, one dredge (119D) south of
257 the Noroît Seamount yielded some porphyritic andesite fragments dated at 66.5 ± 1.5 Ma
258 (whole rock K-Ar; Bouysse et al., 1985a), corresponding, like in the Saba Bank and St Croix
259 Island, to the Maastrichtian-Danian GAC basement (Speed et al., 1979) (Fig. 2).

260

261 **3.4. Antigua Bank**

262 The Antigua island comprises three main lithostratigraphic units with an estimated
263 total thickness of 2.500 m. These units are tilted northeastward on the footwall of the normal
264 faults forming the NE side of the Kalinago Basin (e.g., Martin Kayes, 1969; Frost and Weiss,
265 1979; Mascle and Westercamp, 1983; Multer et al., 1986; Weiss, 1994; Donovan et al., 2014;
266 Robinson et al., 2017): 1) the Basal Volcanic Complex (1500 m- thick), poorly constrained as
267 either middle Eocene or Oligocene (39.7-23 Ma; *in* Briden et al., 1979); 2) the Central Plain
268 Group (500 m- thick), composed of volcanoclastic deposits with freshwater and marine
269 limestones, supposed to have been deposited during the Oligocene (Mascle and Westercamp,
270 1983; Robinson et al., 2017); 3) the late Oligocene Antigua Formation, composed of shallow
271 water limestones evolving eastward into deep marine limestones.

272 The Barbuda island consists of four shallow water carbonate formations (Fm.)
273 separated by subaerial erosional surfaces (Brasier and Mather, 1975), from bottom to top: the
274 Highland Fm. (bank edge facies, 40 m- thick at least), Beazer Fm. (fringing reefs, 5 m- thick;
275 Pleistocene), Codrington Fm. (fringing and barrier reefs, 5 m- thick; late Pleistocene) and
276 Palmetto Fm. (eolian dunes, reef, lagoon, and beach deposits, 10 m- thick; Holocene). The
277 age of the Highland Fm. is still debated: Oligocene (Reed, 1921), middle Miocene (Brasier
278 and Mather, 1975), early Pliocene (Brasier and Donahue, 1985; Watters et al., 1991) or
279 Pleistocene (Russell and Mc Intire, 1966; Land et al., 1967; Martin Kaye, 1969).

280 Four dredges performed during the ARCANTE cruises provided reliable information
281 (Andréieff et al, 1980; Bouysse and Guennoc, 1983) (Fig. 2). On the western margin of the
282 Antigua Bank (also eastern margin of the Kalinago rift), dredge 71D yielded Pliocene to
283 Pleistocene bioclastic limestones from an outer reef depositional setting. On the eastern side
284 of the bank, dredge 79D, collected between 1,800 and 2,000 m depths, yielded late Oligocene
285 carbonates from outer-ramp setting and early Miocene pelagic micritic limestones. Above, at

286 480 m depth, dredge 80D yielded late Miocene marls and Pliocene pelagic carbonate deposits.
287 On top the of the bank, at 30 m depth, dredge 78V yielded recent reefal limestones.

288

289 **4. METHODS AND DATA**

290

291 ***4.1. Rock-samples analyses***

292 New field investigations were conducted in 2015, 2017 and 2020 onshore in Anguilla,
293 St Martin and Tintamarre islands with respectively 7, 7 and 6 logged and sampled sections
294 (Appendices C, D, E). For biostratigraphic analyses, 18 samples were collected in Anguilla,
295 17 in St Martin and 24 in Tintamarre. Combined with field-investigations and
296 sedimentological information, the biostratigraphic analyses allow a correlation between the
297 sections and provide a revised lithostratigraphic sketch of the onshore Neogene deposits of the
298 Anguilla Bank. This onshore sampling was completed by seven offshore carbonate samples
299 collected from three rock-dredge hauls carried out during the GARANTI cruise (Fig. 2):
300 Dredge DR GA-04-01 was collected on the northern steepest flank of the Martinita Seamount;
301 Dredge DR GA-04-02 was collected on the southern flank of this Martinita Seamount
302 ; and Dredge GA-03-01 was collected on the Southeastern Spur (Appendix I). For the island
303 of St Barthélemy, we use the recently published results of Cornée et al. (2020) (Appendix G).
304 In Barbuda, we logged and sampled the Highland Fm. (Appendix F) in 2006; 19 samples were
305 collected. In Antigua, 10 samples were chosen for thin sections in order to refine the age of
306 the Antigua Fm. (Appendix G).

307 Across the whole studied area, a total of 125 polished thin sections were obtained from
308 each carbonate rock-type sample in order to analyse their microfacies and fossil content. The
309 identified microfacies were attributed to a depositional environment following the
310 classification of Wright and Burchette (1996), supplemented by the larger benthic

311 foraminiferal content (BouDagher-Fadel, 2008) (e.g., Appendix B). In addition, 18 soft rock
312 samples were washed over a 65 μm screen and the residues were analysed for foraminiferal
313 biostratigraphy. Finally, standard smear-slides were also prepared for 14 of these soft rock
314 samples for calcareous nannofossil analyses (Appendix A). Our biostratigraphical analyses
315 are based on a complete inventory of larger benthic foraminifera, planktonic foraminifera and
316 calcareous nannofossil taxa found in the thin sections and standard smear-slides. We used the
317 zonal schemes and bio-events calibrations of BouDagher-Fadel (2013, 2015, 2018) for
318 planktonic and larger benthic foraminifera, and those of Backman et al. (2012) for calcareous
319 nannofossils, which have been calibrated against the time scale of Gradstein et al. (2012).

320 Finally, we used the $\text{Ar}^{40}/\text{Ar}^{39}$ method to date a large boulder (50 cm) of a fresh
321 porphyritic andesite reworked in submarine lahar deposits overlain by Neogene limestones in
322 the southwestern part of St Martin Island (details are given in Appendix K).

323

324 *4.2. Seismic reflection profiles*

325 We analyzed eight new profiles from the GARANTI cruise that occurred in 2017 on
326 board *L'Atalante* R/V (Lebrun and Lallemand, 2017), together with a set of multichannel
327 reflection seismic lines recorded during cruises ANTITHESIS 1 (2013) and 3 (2017)
328 (Marcaillou and Klingelhoefer, 2013; 2016) (Fig. 2). Acquisition parameters for the selected
329 MCS lines include a 3.902 inche^3 airgun array source and a 720 channels-6.25m trace spacing
330 streamer ensuring a 120-fold coverage. Quality control and binning of the MCS data were
331 performed on board using QCSispeed® and SolidQC® (Ifremer), and processing was
332 performed using GEOVATION® (CGG). Processing sequence includes band-pass (2–7–60–
333 80 Hz) and FK filtering, Spherical divergence and amplitude (gain) correction, predictive
334 deconvolution, three steps velocity analysis and Normal Move-Out (NMO) correction,
335 external mutes, internal mutes and further multiple attenuation by 2D-Surface-Related

336 Multiple Elimination and Radon domain filtering, velocity stack and constant velocity
337 (1500m/s) FK migration.

338 Our data set also includes petroleum seismic data acquired in 2D in the 80's over the
339 Saba Bank and an industrial database on the Saba Bank (Fina 1980; Aladdin 1988). These
340 seismic data, described in Church and Allison (2004), show a lower resolution as compared to
341 those of the GARANTI and ANTITHESIS lines. They allow us, however, to extend our
342 interpretation to a zone that is nowadays closed to seismic investigations. We also benefited
343 from other seismic lines from the "Comité d'Etude Pétrolière et Marine" (CEPM) under the
344 supervision of the "Institut Français du Pétrole et des Énergies Nouvelles" (IFPEN) acquired
345 in the 70's during the Antilles IV cruise (e.g., Bouysse et al., 1985a; b; Bouysse and Mascle,
346 1994). The seismic stratigraphy of the Saba Bank petroleum surveys was calibrated by using
347 two exploration wells (SBD1 and SBD2; Church and Allison, 2004). The CPEM lines in the
348 vicinity of the Antigua Bank were calibrated using offshore-onshore correlations (Legendre,
349 2018), wells IODP 340 (Coussens et al., 2012) and dredges ARCANTE 1 (Andréieff et al.,
350 1980).

351 Seismic facies and units are determined following the classical criteria of Mitchum and
352 Vail (1977) and Roksandic (1978).

353

354 **5. RESULTS**

355

356 **5.1. Onshore**

357 *5.1.1. Anguilla*

358 Seven sections of Anguilla (Appendix C) yielded stratigraphically significant taxa of
359 larger benthic foraminifera (Appendix B) and calcareous nannofossils (Appendix A). Based
360 on the identified taxa, we were able to date each of the logged and sampled sections (Fig. 3).

361 Above Paleogene turbiditic beds tilted to the SE (Crocus Bay section; Andréieff et al., 1988)
362 (Fig. 4A), we found 60 m- thick coral boundstones organized into coral banks and low-relief
363 domes where platy and massive colonies dominate (Fig. 4, B, C, E, F). Associated with the
364 boundstones, we found some bioclastic packstones with abundant corals, larger benthic
365 foraminifera (miogypsinids, amphisteginids, miliolids, and soritids, e.g., *Archaias*), echinoids,
366 red algae, mollusks (pectinids and oysters), and frequent *Teredo* in life position (Fig. 4D). Ten
367 genera and eighteen species of hermatypic corals occur in this platform, among which the
368 *Porites* genus is dominant, the next most abundant being *Montastraea* and *Stylophora* (Budd
369 et al., 1995). Our biostratigraphic analyses indicate that the succession encompasses the
370 Aquitanian to Tortonian-Messinian interval (N4-N18, 23-5.33 Ma) and, except the local
371 occurrence of hardgrounds, no clear evidence of hiatuses has been found in the field. Beds are
372 vertically stacked but low-angle cross-bedded units were found prograding southeastward
373 along the southern coast (e.g., localities ANG3, 9 and 10) and in the northeastern part of the
374 island (ANG 6) (Appendix C).

375 The Neogene deposits of Anguilla likely correspond to those of an isolated shallow
376 reefal, protected inner platform (Fig. 3), as already suggested by Budd et al. (2005) based on
377 the study of some coral build-ups. This platform contains units with prograding beds towards
378 the SE, indicating that it was opening towards a deeper marine setting.

379

380 5.1.2. *St Martin*

381 Above tilted Paleogene volcanoclastic rocks, the succession of the southwestern part of
382 the island comprises, from bottom to top (Fig. 5; localities in Appendix D):

383 1. **10 to 18 m- thick coral reef boundstones and associated bioclastic packstones**
384 (Fig. 6A to C). In the Sabannah area, 4 m- high patch reefs with branching colonies are
385 exposed. Larger benthic foraminifera are mainly represented by miogypsinids and

386 amphisteginids. Planktonic foraminifera (globigerinids) and calcareous nannofossils are also
387 present. At Mullet Bay, we found cross-bedded packstones with red algae and foraminifera
388 and some coral beds. The benthic foraminiferal assemblages are dominated by amphisteginids
389 and *Asterigerina*. Elsewhere, in the Juliana Bay and Kool Hill sections, well bedded bioclastic
390 limestones and coral banks are exposed. Foraminifera are dominated by *Archaias*,
391 *Praerhapydionina*, *Cyclorbiculina*, *Miosorites*, *Androsinopsis* and *Miarchaias*, associated
392 with small miliolids and textulariids. At Kool Hill, karstic cavities infilled by red silty clays
393 and associated with a paleosol level indicate a temporary emersion (Fig. 7C). Our
394 biostratigraphical analyses indicate that the lower part of these deposits correlates with
395 planktonic foraminiferal Zone N5 (latest Aquitanian-early Burdigalian, 21-18 Ma) and the
396 upper part with Zones N6-N8a (late Burdigalian, ~18-15.97 Ma) (Appendix D). The late
397 Burdigalian deposits of the Juliana Airport road section (Fig. 7A) are affected by
398 synsedimentary normal faults (Fig. 7A, B) associated with a local subaerial erosion surface
399 with karstic gullies. Karstic microcaves were found only below this surface, which confirms
400 the existence of a temporary emersion (Fig. 7C-E).

401 2. **31 m- thick bioturbated wackestone with intercalations of packstone and**
402 **breccias.** The wackestones yielded planktonic and benthic foraminifera as well as red algae.
403 The packstones contain red algae, foraminifera, echinoids and green algae, with some beds
404 organized into hummocky cross-stratification. Some patch reefs with several coral genera
405 locally occur (Fig. 6D). The breccias consist of angular cm- sized debris of coral reef and
406 bioclastic deposits. Planktonic foraminifera indicate that the lowermost part of this
407 sedimentary unit was deposited during the late Serravallian-Tortonian, between 12.8 Ma and
408 8.2 Ma. Above, foraminiferal assemblages point to Zones N14 to N19 (Tortonian to possibly
409 Zanclean, 11.6-3.8 Ma). The foraminifera in the uppermost part of the section point to Zone
410 N19 and were deposited during the Zanclean, between 5.33 Ma and 3.8 Ma. The perireefal

411 blocks of the breccias originated from two different sources: some developed laterally to
412 patch reefs (Fig. 6D); others were eroded from the underlying late Burdigalian coral complex.
413 Langhian to lower Serravallian deposits were not identified in St Martin, which could then
414 indicate a depositional hiatus.

415 3. **1 to 3 m- thick cross-bedded packstone with red algae and foraminifera**, resting
416 on a subaerial erosive surface (Fig. 6E). The foraminifera found in these deposits point to
417 Zone N19 (Zanclean, 5.33-3.8 Ma).

418 In the southwestern part of St Martin, the Aquitanian-Burdigalian deposits comprise
419 different depositional settings (Fig. 5). To the West (Terres Basses), we found high-angle
420 dipping coral rubble beds overlain by low-angle dipping coral build-ups. This area is
421 interpreted as the outer slope of a coral system, probably set up on the flanks of a late
422 Oligocene subaerial volcano. In the Sabannah area, the occurrence of m- high patch reefs with
423 branching colonies, planktonic and benthic foraminifera, is interpreted as a reef to foreef zone
424 in an open sea (BouDagher-Fadel, 2008; Montaggioni and Braithwaite, 2009). At Mullet Bay,
425 packstones with red algae and benthic foraminifera (amphisteginids and *Asterigerina*) and
426 some coral beds and crossbedding occur, indicating inner-ramp, reefal deposits. In the Juliana
427 Bay and Kool Hill sections, coral banks and benthic foraminiferal assemblages are indicative
428 of a quiet lagoonal depositional environment (Andréieff et al., 1988; Tucker and Wright,
429 1990; BouDagher-Fadel, 2008). To the east of St Martin, the data of Andréieff et al. (1987;
430 1988) indicate the presence of coral reefs at Pinel Islet and on islets east of Phillipsburg. As a
431 result, St Martin was an island during the early Miocene, bordered by coral reef formations
432 with lagoons to the southeast and fringing reefs to the northeast. Langhian deposits were not
433 found, suggesting a possible middle Miocene emersion. Deposition of the upper Serravallian–
434 Tortonian sediments of St Martin (Cupecoy) first occurred in a mid-outer-ramp environment
435 above the Burdigalian reefal deposits indicated by abundant pelagic microfossils. These

436 deposits change upward into mid to inner ramp settings with coral patch-reefs, and associated
437 reefal breccias during the Messinian and the early Zanclean. Zanclean erosional surfaces
438 affect the deposits, indicating a shallowing upward trend ending with an emergence. In this
439 area, the occurrence of reworked breccias from Burdigalian reefal deposits testifies
440 for indicates the permanence of emerged areas.

441

442 5.1.3. Tintamarre

443 At Tintamarre, the deposits are dominated by clayey limestones that yielded abundant
444 macrofauna and larger benthic foraminifera dominated by *Lepidocyclina*, *Miolepidocyclina*,
445 *Miogypsina* and *Amphistegina* associated with planktonic foraminifera. On the basis of six
446 outcrops (Appendix E), the succession comprises, from bottom to top (Fig. 8):

447 1. **13 m- thick packstones** with bivalves (oysters, *Amusium*, *Chlamys*), echinoids
448 (*Clypeaster* and scutellids), larger benthic foraminifera, and some coral debris. The
449 microfossils from the upper part of this unit correlate with the early part of Zone N8 (late
450 Burdigalian);

451 2. **11 m- thick matrix-supported lower megabreccia** with reefal to perireefal clasts
452 (Appendix D; Fig. 9A). Clasts are cm to m- sized with blocks reaching 3 m wide, embedded
453 into a lime wackestone matrix displaying slump structures and forereef-derived bioclasts
454 (*Clypeaster*, larger benthic foraminifera, red algae, and molluscs). Reworked blocks do not
455 display emersion features;

456 4. **0 to 4 m- thick brown clays with gypsum crystals**. This facies, found only in the
457 TINT 10 locality on the northern coast of the island laterally pinches on top of the
458 megabreccia (Appendix D). The three previously described units are yellow to orange in the
459 field, locally brown;

460 5. **33 m- thick wackestone with packstone and breccia interbeddings.** Wackestones
461 mostly yielded bivalves (*Amusium* and other pectinids), echinoids (*Clypeaster*, scutellids), and
462 benthic foraminifera. Packstones are unsorted, mm- to cm- grain-sized, debris-flows with
463 well-preserved pieces of corals, red algae and molluscs. A hummocky cross-stratification is
464 locally found into the packstones. The breccia is composed of cm- grain-sized reworked reefal
465 to perireefal limestones. The succession is tilted to the SE below an erosional surface
466 (Appendix E). The lower 19 m of the lithological succession is green and contains
467 microfossils pointing to Zones N6-N8 (late Burdigalian, 18-15.97 Ma); the upper 14 m is
468 white and microfossils point to Zones N8-N11 (Langhian, 15.9-13.6 Ma).

469 6. **Up to 11 m- thick calcareous upper megabreccia** (Fig. 10). This megabreccia rests
470 unconformably on an erosional surface that transects previously tilted deposits (Appendix E).
471 It is composed of dm- to m- sized transported blocks of coral reef and associated bioclastic
472 deposits and rafted red algae and coral limestone beds reaching several tens of meters long
473 and up to 5 m- thick (Appendix E; Fig. 9A, B). The blocks are embedded into a white to pink
474 wackestone matrix. The megabreccia is crosscut by shear zones and displays numerous soft
475 sediment structures, slump, recumbent folds, isoclinal folds and balls and pillows (Fig. 9C;
476 Appendix E). Shear zones and slumps are indicative of a transport direction to the S-SE. The
477 reefal and red algal-coral rafted beds and clasts yielded benthic foraminiferal assemblages of
478 Zones N5-N8a (latest Aquitanian-Burdigalian; e.g., samples CSM 42, 70 and 71; Appendix
479 E). The matrix yielded planktonic foraminifera further indicating Zone N8b (early Langhian,
480 15.4-15 Ma). Consequently, the upper megabreccia deposited during the early Langhian and
481 comprises reworked Burdigalian limestones.

482 In Tintamarre, Burdigalian to lower Langhian deposits are dominated by clayey
483 limestones that provided shallow-water fauna and debris flow interbeddings with transported
484 corals. Two megabreccias with rafted beds and slumps also occur. The depositional setting is

485 interpreted as an open sea, muddy forereef slope testified by abundant and well-preserved
486 coral fragments (Fig. 8). During the late Burdigalian, however, lagoon conditions temporarily
487 existed with the deposition of gypsum clays above the lower megabreccia. This indicates that
488 the forereef slope depositional setting temporarily turned to shallower conditions then. The
489 upper megabreccia comprises Burdigalian debris and rafts, which were emplaced in a muddy
490 forereef environment during the early Langhian (15.4-15 Ma) (Appendix E; Fig. 9). This
491 megabreccia unconformably lies upon southeastward tilted and eroded early Langhian beds.
492 The blocks of the upper megabreccia do not display any emergence or tectonic features. This
493 indicates that both their destabilization and transportation have occurred under submarine
494 conditions, as classically seen in submarine active tectonic settings where large scale mass
495 wasting is reported (e.g., Hine et al., 1992; Zachariasse et al., 2008; Dailey et al., 2019). The
496 upper megabreccia was transported towards the ESE to SE, indicating that it originated from
497 the WNW to NW in the submerged part of the Burdigalian reefal platform of Anguilla. One
498 way to explain this arrangement is to consider that normal faults trending NE-SW and
499 deeping NW occurred at that time between Anguilla and St Martin, this type of fault having
500 been identified in the southwestern part of St Martin (Legendre, 2018).

501

502 5.1.4. *Barbuda*

503 The Highland Fm. comprises a 30 m- thick carbonate succession. The lower part of
504 the formation does not crop out. From bottom to top we identified (Appendix F):

- 505 1. **4.5 m- thick grainstones with isolated massive, coral colonies.** Corals are dominated
506 by *Montastraea* and *Porites*. The sediments yielded benthic foraminifera (*Miarchaias*, and
507 *Amphistegina*) pointing to the late Miocene;
- 508 2. **9 m- thick red algal and larger benthic foraminifera-rich wackestones to**
509 **packstones;**

510 3. **3.5 m- thick wackestones with some isolated coral colonies** and benthic and
511 planktonic foraminifera (*Neogloboquadrina acostaensis*, *Sphaeroidinellopsis subdehiscens*,
512 and *Globorotalia margaritae*) indicative of a Zanclean age;

513 4. **12.5 m- thick red algal wackestones to packstones with benthic and planktonic**
514 **foraminifera.** The uppermost part of the succession is severely weathered. Planktonic
515 foraminifera indicate that the lower and upper parts of the unit was deposited during the
516 Zanclean and between the Zanclean and Piacenzan, respectively.

517 In Barbuda, benthic foraminifera are dominated by amphisteginids. Mud and planktonic
518 foraminifera occur throughout the section. Corals are documented as isolated, and consist of
519 massive colonies in life position. Consequently, the depositional environment is interpreted as
520 an open-sea, shallow water reefal to foreereef muddy carbonate platform or ramp deposited in
521 low-energy conditions. These results are in agreement with those of Brasier and Donahue
522 (1985), who estimated a palaeobathymetry of *ca* 40-50 m. The middle part of the section is
523 dominated by planktonic foraminifera facies devoid of corals, indicating a deeper
524 environment of deposition than the lower and upper parts of the section. This suggests that the
525 succession has recorded a regressive-transgressive cycle (Appendix F). During the late
526 Miocene-Zanclean interval (samples BAR 1 to 9; Appendix F), the depositional environment
527 changes from reefal inner-ramp (*ca* 10-20 m palaeodepth) to outer-ramp (*ca* 40-50 m
528 paleodepth). The maximum palaeodepth is reached between samples BAR 9 and 13 and
529 occurred during the Zanclean, when wackestones with abundant planktonic foraminifera were
530 deposited. Above, outer-ramp environment changes into mid-ramp during the Zanclean-
531 Piacenzan (?), thereby indicating a moderate regressive trend.

532 5.1.5. Antigua

533 The lowest marine limestone beds of the Antigua Fm. yielded Rupelian foraminifera
534 (*Eulepidina undosa*, *Lepidocyclina* (L.) *urnagunensis*) (Appendix G), while the limestones

535 above them contained Chattian foraminifera (*Lepidocyclina (Lepidocyclina) yurnagunensis*,
536 *L. (Nephrolepidina) braziliana*, *Heterostegina israelskyi*, and *Neorotalia* sp.) (e.g., Pares
537 cross-section; Appendix G.). Consequently, the Antigua Fm. is likely to have been deposited
538 between the Rupelian and the Chattian.

539 In Antigua, the Central Plain Group was deposited into lakes and coastal lagoons, as
540 previously documented (e.g., Martin-Kayes, 1959; Frost and Weiss, 1979; Donovan et al.,
541 2014). Above, the Antigua Fm. was deposited along a low-angle northeastward dipping
542 carbonate ramp, with inner-ramp, reefal environments in the southwest changing
543 northeastwardly into a mid-ramp depositional setting characterized by abundant planktonic
544 foraminifera. These results are in agreement with the regional sedimentary organisation
545 proposed by Martin-Kaye (1969).

546

547 **5.2. Offshore**

548 The profiles GA 11, GA 15, ANT019-24, CPEM 302, CPEM 509 and CPEM 510 are
549 used to compare onshore data with offshore ones because: 1) GA 15 intersects the seismic
550 profile C2 of the Saba Bank petroleum prospect, which was calibrated using wells SBD1 and
551 SBD2 (Matchette-Downes, 2007); 2) GA 11 allows following seismic sequences to the north
552 across the Kalinago Basin; 3) ANT019-24 allows investigating the northwestern margin of the
553 Anguilla Bank; 4) CPEM 302 provides information about the southern part of the Anguilla
554 Bank and allows correlations with the southern part of the Kalinago Basin; and 5) CPEM 509
555 and CPEM 510 illustrate the seismic stratigraphy of the Antigua Bank. In addition, the
556 northern ends of lines GA 08 and GA 09 are only 5 km away from the island of St Martin
557 (Appendix J), 213A was performed on the Anguilla Bank south of St Barthélemy (Appendix
558 J), and 509-510 are located in the vicinity of the island of Antigua, allowing onshore-offshore
559 correlations.

560

561 *5.2.1. Seismic sequences*

562 We identified seven seismic megasequences bounded by regional prominent
563 unconformities and their correlative conformities (Vail et al., 1977; van Wagoner et al., 1988;
564 Cattuneanu, 2006) over the whole investigated area (MS1 to MS7). The most complete
565 succession is best exemplified south of the Saba Bank, along crossing lines GA 15 (ENE-
566 WSW; Fig.10A) and Saba Bank C2 (NW-SE; Fig. 10B). The C2 line was reinterpreted and a
567 seismic pattern partly similar to that of Church and Allison (2004) was found, thereby
568 allowing chronostratigraphic assignments to the megasequences. From bottom to top they are:
569 - **Megasequence 1 (MS1)**: it comprises poorly-defined, chaotic reflectors, locally overlaid by
570 low to very low frequency, discontinuous reflectors. Transparent facies also occur. The top of
571 the sequence is an erosional unconformity termed SB1 usually underlined by a strong
572 amplitude reflection. In wells SBD1 and SBD2, MS1 is overlaid by a subaerial andesitic lava
573 flow that occurred during the late Eocene (38.1-35.9 Ma interval; Church and Allison, 1984).
574 MS1 is found on the GARANTI and ANTITHESIS lines (Figs. 10 to 12; Appendix J) and on
575 the CPEM lines, especially in the southern part of the Kalinago Basin (Fig. 13).

576 No accurate information about MS1 is available yet. Nevertheless, reworked
577 Cretaceous and Paleocene microfossils have been found in the overlying megasequence MS3,
578 suggesting that MS1 is partly made of sedimentary rocks of these ages.

579 - **Megasequence 2 (MS2)**: it comprises seismic units displaying inverted half-graben
580 structures with faint and subparallel to fan-shaped reflectors (Fig. 10A and B). In some cases,
581 it is organized into fan-shaped reflectors draping underlying topographic highs and thickening
582 downward (Fig. 11A; 12). The half-grabens are visible on NE-SW profiles (fig. 10B) and not
583 on NW-SE profiles (Fig.10A), suggesting that their orientation is overall NW-SE. MS2 has
584 not been reached by the drillings. The top of MS2 is the irregular, erosional, newly defined

585 surface SB2 found extended below the late Eocene subaerial andesite drilled in the Saba Bank
586 (Church and Allison, 1984). MS2 has not been recognized in the southern part of the Kalinago
587 Basin (Fig. 13). MS2 probably consists of sedimentary deposits lying unconformably on MS1
588 (Figs. 10A, 11A). It underwent a late mid-Eocene compression leading to inversion of half
589 grabens (Philippon et al., 2020a).

590 - **Megasequence 3 (MS3)**: it comprises up to 2.5 second two-way travel-time (stwt)- thick
591 deposits. MS3 is characterized by discontinuous to continuous reflectors of low amplitude,
592 medium to high frequency, always sub-parallel and well stratified, locally prograding (Fig.
593 10). MS3 onlaps above SB2 and seals the compressive deformations in MS2. It is marked by
594 an abrupt change in seismic facies that evolves from continuous well-bedded reflectors, low-
595 angle truncations in MS2 to onlaps in MS3. The top of the sequence is covered by an
596 unconformity hereafter named SB3. MS3 was not identified in the southern part of the
597 Kalinago Basin (Fig. 13).

598 In the northern part of the Kalinago Basin, MS3 displays regular, mid-amplitude and
599 parallel reflectors (Fig. 10) that progressively pinch against spurs (Fig. 10A, 11A). On lines
600 GA-08 and 09, MS3 displays prograding beds on the southern margin of the Anguilla Bank, a
601 pattern that is also found on lines ANT 19 and 24 (Fig. 11B; Appendix J). These prograding
602 beds are related to downslope detritus originating from the topographic highs. Along the
603 flanks of the spurs, the beds of MS3 are organised into fans mimicking the shape of the relief
604 and down-lapping above unconformity SB2, controlled by NW-SE trending syn-sedimentary
605 faults (Figs. 11A and 13; Appendix J). On the Walichi Flat, south-southwestward prograding
606 beds develop above the basement (Fig. 12B). Offshore in the Antigua Bank and the southern
607 part of the Kalinago Basin, MS3 is missing (Fig. 14). Onshore, continental deposits are
608 recorded (Central Plain Group of Antigua). These observations indicate that the Kalinago
609 Basin was not extending in this area (Fig. 13). Consequently, MS3 has been deposited into

610 sub-basins separated by topographic highs. As no recent fault was evidenced on the margins
611 of the Kalinago Basin, the difference of elevation between the top of the Anguilla Bank and
612 the MS3 deposits of the Kalinago Basin varies between 1,000 to 1,500 m, broadly reflecting
613 the palaeobathymetry of the deep parts of the basin. Such a difference in elevation is also
614 found in the southeastern part of the Saba Bank (Fig. 10).

615 In summary, MS3 unconformably resting upon the erosional surface SB2 is characterised
616 by high relief changes with topographic highs (Walichi Flat, Saba Bank, and spurs) and
617 newly-formed depocentres controlled by synsedimentary normal faults (northern Kalinago
618 Basin).

619 - **Megasequence 4 (MS4)**: it comprises up to 2.5 stwtt- thick gently-dipping reflectors, locally
620 organized into low angle inclined prograding units (Figs. 10 to 12). Onlaps are present against
621 paleoreliefs (Appendix J). The sequence ends with an erosional surface termed SB4 that
622 truncates the underlying reflectors. Locally, low angle reflectors of the overlying
623 megasequence onlap onto SB4. Opposite to MS3, MS4 occurs regionally, from the Kalinago
624 Basin in the NW (Figs. 11, 12) to the Antigua Bank in the SE (Fig. 13).

625 Northeast of Saba Bank, deposition of MS4 is controlled by synsedimentary faults in
626 the NW-SE direction. (Fig. 11A). Southeast of the Saba Bank, MS4 displays parallel bedding
627 (Fig. 10) or fans (Fig. 11A), above the unconformity SB3. In the vicinity of the submarine
628 spurs (Anguillita, Southeastern seamounts) and highs (Saba Bank, Anguilla Bank, and
629 Walichi Flat), SB3 is erosional with toplaps in the underlying MS3 and onlaps in the
630 overlying MS4 (Figs, 10, 11, 13; Appendix J). In the southern part of the Kalinago Basin and
631 Antigua Bank, MS4 directly overlies MS1. Consequently, MS4 is deposited on a topographic
632 surface SB3 which is erosional, except in the deepest parts of the depressions. SB3 exhibits an
633 erosive character over *ca* 500 m vertical drop at maximum, and consequently sedimentation in
634 troughs occurred at several hundred meters depth.

635 - **Megasequence 5 (MS5)**: it reaches 1 stwtt- thick and comprises medium to strong
636 amplitude, medium frequency, parallel continuous reflectors. The sequence shows an
637 aggrading pattern and retrogrades on older reliefs. The top of MS5 is characterised by an
638 unconformity termed SB5. SB5 is either erosional (Fig. 10A, northern part) or bedding is sub-
639 parallel with low-angle onlaps above (Fig. 10B, Saba Bank). MS5 is found from the Kalinago
640 Basin in the NW (Fig. 11, 12) to the Antigua Bank in the SE (Fig. 13).

641 In the Kalinago Basin, South of the Saba Bank, Walichi Flat and Antigua Bank, MS5
642 is organised into parallel reflectors mostly parallel to MS4 reflectors. Onlaps are found in the
643 vicinity of submarine highs, above SB4. The latter displays clear erosional features on the
644 spurs, on the margin of the Anguilla Bank, on the Walichi Flat and on the uppermost part of
645 the Saba Bank (Figs. 10, 11, 12). Consequently, SB4 is interpreted as a subaerial structure
646 developed on submarine highs, that is confirmed by the analysis of the dredged GA 03 rock-
647 samples collected on the southeastern spur (Fig. 2; Appendix I; see below). Erosion is found
648 over a few hundred meters depths at maximum, suggesting that deposition of MS5 occurred at
649 several hundred-metres depth in basin areas.

650 - **Megasequence 6 (MS6)**: it reaches 0.5 stwtt- thick and comprises medium- to strong-
651 amplitude, medium-frequency, continuous and parallel reflectors and prograding reflectors.
652 On the Saba Bank, reflectors are parallel and strongly reflective (Figs. 10, 11), like on the
653 Anguilla Bank and the Antigua Bank (Fig. 13). In the southern part of the Kalinago Basin,
654 MS5 is locally overlain by an erosional surface termed SB6.

655 - **Megasequence 7 (MS7)**: it is distinguishable in the southern part of the Kalinago Basin and
656 Antigua Bank on CPEM seismic lines (Figs. 2, 13). It comprises medium- to strong-
657 amplitude, medium-frequency, continuous and parallel reflectors which locally display fan
658 shaped structures. In the northern part of the investigated area, SB6 is parallel to reflectors

659 and both MS6 and MS7 are often indistinguishable. Consequently, they are grouped into a
660 MS6+MS7 megasequence (Fig. 10).

661 In most of the investigated area, deposits of MS6 and MS7 conformably cap those of
662 MS5. Erosional features are found in the vicinity of spurs (Anquillita and Martinita
663 seamounts) and on Walichi Flat where SB5 displays truncations of the underlying MS5 (Fig.
664 11). Discrete onlaps of fan-shaped reflectors of MS7 above SB6 are found in the southern part
665 of the Kalinago Basin, partly related to the synsedimentary activity of recent normal faults
666 (Fig. 13).

667

668 5.2.2. *GARANTI dredged samples*

669 Dredged samples have been collected on the flanks of seamounts in the northwestern part
670 of the Kalinago Basin and are localized on seismic profiles to allow calibrating the seismic
671 stratigraphy (Fig. 2): DR GA-04-01 and DR GA-04-02 are located on the seismic profile
672 GA11 and DR GA-03-01 on GA13.

673 Dredge DR GA-04-01 (Fig. 11), in MS6, yielded bioclastic wackestones to packstones
674 with red algae and benthic foraminifera. Larger benthic foraminiferal assemblages in these
675 samples correlate with the planktonic foraminiferal zones N14-N18, thus indicating a late
676 Miocene age of deposition (Appendix I).

677 Dredge DR GA-04-02 (Fig. 11), in MS6, yielded wackestones and packstones with
678 planktonic foraminifera. One sample points to Zones N18-N19 (latest Messinian-Zanclean,
679 5.8-3.8 Ma), when another points to Zone N19 (Zanclean, 5.33-3.6 Ma). The wackestones
680 with planktonic foraminifera are bored and borings are infilled with likely modern muds
681 containing planktonic foraminifera of Zones N22-N23 (Calabrian-Holocene).

682 Dredge GA-03-01 in MS5 yielded packstones with red algae and foraminifera pointing to
683 Zones N12b-N20a (Serravallian-Zanclean). The packstones have suffered from

684 microsparitization and are crosscut by opened fractures infilled with wackestones enriched in
685 planktonic foraminifera and reworked microsparitized red algal packstones (Appendix I). The
686 foraminifera found within the wackestones infillings point to Zone N19 (Zanclean).

687

688 **6. DISCUSSION**

689

690 ***6.1. Age model***

691 *6.1.1. Onshore*

692 In the Anguilla Bank, the synthetic lithostratigraphical succession of each island can be
693 reconstructed and correlated based on our new biostratigraphic data and field investigations
694 (Fig. 14). In the three islands of the Anguilla Bank, the age of the lower part of the Neogene
695 reefal deposits ranges between the (late?) Aquitanian and the Burdigalian. This age is
696 consistent with i) our new radiometric data at *ca* 25-24 Ma (latest Oligocene) of the andesitic
697 boulder from submarine lahar deposits found below the carbonate platform in St Martin
698 (Appendix K) and ii) that of a subaerial lava flow found in St Barthélemy in a similar setting
699 (Legendre et al., 2018; Cornée et al., 2020) (Appendices G and H). Middle Miocene
700 (Langhian-Serravallian) deposits occur in Anguilla and Tintamarre, but they are missing in St
701 Martin where an erosional unconformity is strongly suspected to have occurred between the
702 Burdigalian and the uppermost Serravallian-Tortonian deposits. However, outcrop conditions
703 did not allow direct observation of this surface. Late Miocene (Tortonian-Messinian)
704 sediments were found in St Martin and Anguilla. In Tintamarre, they may have deposited, but
705 were probably removed by erosion. Zanclean deposits have been identified in St Martin where
706 they are transected by erosional surfaces.

707 In the Antigua Bank and Barbuda, the Highland Fm. encompasses the late Miocene-
708 Piacenzan interval at youngest (Appendix F). Neither unconformity nor major facies change

709 were found between the upper Miocene deposits (samples BAR 1 to BAR 7) and the
710 overlying Zanclean ones. Consequently, a latest Miocene age is considered here (Messinian)
711 for the lower part of the Highland Fm. In Antigua, sediments of the Central Plain Group
712 deposited during the Rupelian (because they are located below the Antigua Fm.), and those of
713 the Antigua Fm. deposited between the Rupelian and the Chattian (Appendix G).

714

715 *6.1.2. Offshore-onshore correlations*

716 Age calibration of offshore sequences and unconformities takes into account the
717 calibration of line C2 with Saba Bank wells, correlations through seismic sequences and
718 unconformities, and dredges data from the GARANTI and other cruises (Fig. 2). These
719 combined data allow calibrating the seismic stratigraphy, correlating onshore and offshore
720 sequences and concur to constrain a late Eocene-Pleistocene age range for the deposits of the
721 Anguilla Bank, Antigua Bank, and Kalinago Basin (Fig. 15).

722 • **MS1:** it correlates with the acoustic basement overlain by a subaerial andesitic
723 complex or MS2. The only chronostratigraphic data available indicate ages ranging between
724 38.7 Ma and 30.8 Ma (Priabonian–Rupelian) in the Saba Bank wells (Church and Allison,
725 2004; Matchette-Downs, 2007). The wells did not reach nor MS1 neither MS2 but yielded
726 reworked Cretaceous and Paleocene microfossils in the sequences overlying the subaerial
727 andesitic complex. Following Jany et al. (1990) and Church and Allison (2004), MS1 is
728 considered to have been deposited between the Late Cretaceous and the middle Eocene.

729 • **MS2:** this locally folded unit (Philippon et al., 2020a) (Fig. 10A) was previously
730 included into the acoustic basement of Church and Allison (2004). It is located between the
731 basement and the Priabonian-Rupelian andesites of wells SBD1 and SBD2, and the overlying
732 megasequence MS3 dating from the late Eocene-early Oligocene. On land at St Barthélemy,
733 compressive structures affecting middle Eocene carbonate deposits (Cornée et al., 2020) have

734 been estimated to have occurred during the late middle-Eocene (Philippon et al., 2020a).
735 Consequently, MS2 and SB2 are assigned to the early middle-Eocene.

736 • **MS3:** it corresponds to the “Lower Carbonate Unit” and the “Channel Turbidite Unit”
737 of Church and Allison (2004) identified on the re-interpreted profile C2 (Fig. 10B). Based on
738 foraminiferal data, the “Lower Carbonate Unit” points to the late Eocene in well SBD1. Based
739 on calcareous nannofossils, the “Channel Turbidite Unit” has been dated to the late Eocene-
740 early Oligocene interval in well SBD2 (Church and Allison, 2004). Consequently, MS3 has
741 an age ranging from the late Eocene to the early Oligocene.

742 • **MS4:** it corresponds to the “Fluvial Deltaic Unit” of Church and Allison (2004) on
743 profile C2 (Fig. 11). This unit yielded microfossils ranging in age from the late Oligocene to
744 the early Miocene (Church and Allison, 2004). On profile GA 08, MS4 can be traced to 5 km
745 off St Martin (Fig. 2; Appendix J). There, MS4 displays progradations and chaotic reflectors.
746 Onshore in St Martin, the margin of the early Miocene carbonate platform is marked by
747 forereef slope deposits which exhibit high dip. (Fig. 6A-B). Moreover, an Oligocene subaerial
748 unconformity was also found in St Martin (Andréïeff et al., 1988; this work) and St
749 Barthélemy (Cornée et al., 2020), between late Eocene and early Miocene deposits. In the
750 Antigua Bank, MS4 partly correlates with the Rupelian-Chattian Oligocene Antigua Fm.
751 Consequently, MS4 deposited during the late Oligocene-early Miocene interval, and the
752 underlying unconformity SB3 is Oligocene.

753 • **MS5:** it corresponds to the lower part of the Upper Carbonate Unit. Foraminifera and
754 calcareous nannofossils indicate that its lower part is not younger than the early Serravallian
755 and its upper part Zanclean at youngest (Church and Allison, 2004). The basal unconformity
756 SB4 is assigned to the middle Miocene and can be traced up to the margin of the Anguilla
757 Bank (lines CPEM 302, GA 08, GA 09; Appendix J). Onshore in St Martin and Tintamarre,
758 this middle Miocene (Langhian) unconformity also occurs, and is overlaid by late Serravallian

759 to Zanclean deposits (Fig. 14). In V-shaped basins eastward in the forearc, Boucard et al.
760 (2021) also described a regional erosional unconformity UB2 between early and middle
761 Miocene sedimentary units. Consequently, MS5 is assigned to the middle-late Miocene and
762 the underlying SB4 unconformity was possibly emplaced during the Langhian.

763 • **MS6:** it corresponds to the upper part of the “Upper Carbonate Unit” of Church and
764 Allison (2004). In the Saba Bank wells, this sequence provided bioclastic coral-dominated
765 deposits covering a red-algal dominated platform. MS6 rests on the erosional unconformity
766 SB5, which corresponds to the base of the reefal deposits still remaining undated. The haul-
767 dredges carried out during the cruise GARANTI on the Martinita and Southeastern seamounts
768 within MS5 and MS6 (Figs. 2 and 11), yielded upper Miocene and lower Pliocene limestones
769 (DR GA 03-01, 04-01, and 04-02; Appendix I). Because microsparitization is found in the
770 upper Miocene limestones, which are also affected by open fractures infilled with Zanclean
771 deposits, we conclude that the Martinita and Southeastern seamounts emerged during the
772 latest Miocene at oldest, and that they subsequently started drowning during the Zanclean.
773 This emersion could relate to SB5. Moreover, the lower Pliocene limestones at site DR-04-02
774 exhibit borings that may indicate that the seamounts were very near sea level or emergent
775 during the Piacenzan-Gelasian interval and were drowned by the Calabrian. These borings
776 could relate to SB6 unconformity. In St Martin, erosional unconformities are found in lower
777 Zanclean deposits (Fig. 6E). In the Guadeloupe Archipelago (*ca* 250 km further south), there
778 is a shallow water carbonate platform that was deposited above a major, latest Miocene to
779 early Pliocene, erosional unconformity (Cornée et al., 2012; Münch et al., 2014; De Min et
780 al., 2015). Red algae-rich deposits dominate in its lower part (Zanclean-Gelasian), and
781 gradually change upwards to coral-dominated deposits (Gelasian-Calabrian). This succession
782 is similar to MS6 in Saba Bank wells. In the Antigua Bank, MS6 was also partly correlated
783 with the Zanclean-Calabrian deposits recovered from the IODP leg 340 (Legendre, 2018).

784 Consequently, the underlying SB5 unconformity is confidently assigned to the latest
785 Miocene-early Pliocene, and MS6 to the early Pleistocene.

786 • **MS7**: it mainly occurs in the southern part of the Kalinago Basin where it is thick
787 enough to be identified on seismic profiles. The wells recovered from IODP 340 indicate a
788 Calabrian (1 Ma) to Holocene age (Coussens et al., 2012). In the northern part of the Kalinago
789 area, MS7 remains thin and was grouped with MS6.

790 In summary, offshore and onshore data allow us to date the Cenozoic deposits in the
791 northern Lesser Antilles, assigning ages to the regional unconformities and estimating the
792 duration of their corresponding hiatuses (Fig. 15): SB1 was emplaced during the Paleocene to
793 middle Eocene ; SB2 during the late Eocene; SB3 during the Oligocene; SB4 during the
794 middle Miocene (Langhian); SB5 during the latest Miocene-early Pliocene; and SB6 during
795 the early Pleistocene.

796

797 ***6.2. Palaeogeographical evolution***

798 Using our dataset that combines onshore and offshore investigations and correlations,
799 we are able to propose novel palaeogeographical maps of the Northern Lesser Antilles (Fig.
800 16). Sequence boundaries on seismic lines were considered subaerial when regional erosional
801 features were observed, with the following criteria: clearly-identified toplaps and onlaps
802 below and above the unconformities, respectively.

803 During the Eocene, the Anegada Passage did not exist (Jany et al., 1990; Mauffret and
804 Jany, 1990). The upper Eocene SB2 unconformity, following an upper Eocene compression
805 (Philippon et al., 2020a), is regionally erosive. MS2 is only preserved as relict patches in the
806 northern part of the Kalinago Basin, Saba Bank and Anguilla Bank, suggesting that SB2 is the
807 expression of a general emersion. The emerged area was extended from the Saba Bank to the
808 Antigua Bank, for at least 300 km, and was connected to Puerto Rico (GraNoLa landmass of

809 Philippon et al., 2020a). In the Anguilla Bank, late Eocene sedimentation resumed after SB2,
810 linked to volcanic activity in St Barthélemy.

811 During the latest Eocene-early Oligocene (MS3) (*ca* 38-28 Ma), to the north of the
812 studied area, a major extensional episode occurred along NW-SE trending faults. The
813 Kalinago Basin opened and the sea invaded the depressions despite the sea level drop of about
814 a hundred meters that occurred at the Eocene-Oligocene transition (Miller et al., 2020). The
815 Saba, Anguilla and Antigua banks and the Walichi Flat remained all above sea level in the
816 footwall of normal faults. At that time, volcanism was active in Antigua, St Martin and St
817 Barthélemy islands, and in Saba Bank (Fig. 16B).

818 During the late Oligocene (SB3) (28-23 Ma), the rifting propagated southward and the
819 Kalinago Basin deepened. Its eastern and western shoulders were uplifted and became
820 emergent in the Saba Bank and from Antigua to the Walichi Flat (Fig. 16C). Onshore, this
821 emergence is clearly recorded: in St Martin, subaerial upper Oligocene volcanism is now
822 proven and Aquitanian reefs developed onto tilted and eroded Eocene sediments (Andréieff et
823 al., 1988; this study); in St Barthélemy, an erosional surface crosscutting the upper Eocene
824 deposits is capped by upper Oligocene subaerial lavas (Cornée et al., 2020); in Antigua, the
825 Rupelian Central Plain Fm. was deposited in an inland paleoenvironmental setting, then the
826 sea invaded the island during the Rupelian and the Chattian.

827 During the latest Oligocene-early Miocene (MS4) (24-16 Ma), only small islands
828 remained above sea-level, despite hundred meters sea level drops, indicating a significant and
829 general subsidence (Fig. 16D). The now drowned but previously emerged area extending
830 from Antigua to Anguilla was then capped by reefal carbonate deposits delineated by steep
831 slopes and their associated deposits. Elsewhere, basin sediments were deposited. Some
832 tectonic activity is recorded in the Anguilla Bank with mass wasting and synsedimentary
833 normal faults in St Martin (Legendre, 2018; this study). A subaerial volcanic activity is

834 evidenced in St Barthélemy and Antigua. Offshore, MS4 infilled depressions or fringes spurs,
835 indicating regional subsidence. Fault activity is recorded only to the north of the study area,
836 on the southern margin of the Walichi flat, in the Kalinago Basin. In the forearc to the east of
837 the Anguilla Bank, steep NE-SW trending fault controlled basins opening (V- shaped basins,
838 Boucart et al. (2021)) (Fig. 1B) (St Barthélemy and Antigua valleys). NW-SE and their
839 conjugated NE-SW trending normal faults were sealed by MS5 (Fig. 10A). In St Martin, the
840 upper Oligocene pluton and its country rock are tilted along NE-SW trending faults
841 (Legendre, 2018). In Anguilla, the Eocene beds were tilted to the SE and capped by a sub-
842 horizontal Miocene carbonate platform, suggesting that the tilt was also controlled by this set
843 of NE-SW trending faults. Consequently, moderate fault activity is found only in the northern
844 part of the investigated area, at the vicinity of the Anegada Trough, which probably started to
845 open.

846 At St Martin in the Juliana airport section (Appendix D), E-W trending synsedimentary
847 normal faults affected the upper Burdigalian lagoonal deposits. These faults display dip-slip
848 kinematics indicating a NNE-SSW extension (Fig. 7) (Legendre, 2018; Noury et al., 2018).
849 Such an orientation is consistent with the Kalinago rift trend. Local uplifts have been recorded
850 during this tectonic episode, at Juliana and Kool Hill, with the occurrence of karstic features
851 (Appendix D). In Tintamarre, the lower megabreccia also was deposited during the late
852 Burdigalian (Fig. 9; Appendix E), and it was likely coeval with the deposition of lagoonal
853 sediments indicative of a temporary uplift (Fig. 14). Consequently, the emplacement of the
854 lower megabreccia is most related to observed strain affecting the Juliana section, both
855 indicating moderate N-S to NNE-SSW extension (*i.e.* parallel to the trench extension) in this
856 area between 18 Ma and 16 Ma.

857 During the early Langhian (SB4) (15.4-15 Ma), the sea level rose by 80 m (Miocene
858 climatic optimum; Miller et al., 2020; Westerhold et al., 2020). Large islands, however,

859 emerged and shallow banks were deposited. This indicates that another significant uplift event
860 occurred, which was most probably controlled by NE-SW faults that tend to be parallel to the
861 Anegada Trough (Fig. 16E). Antigua, southern Anguilla and Saba Banks became emergent
862 whilst the northern Anguilla Bank remained under shallow waters. Elsewhere, basin
863 sediments have been deposited. East of Anguilla Bank, the spurs separating the V- shaped
864 paleovalleys emerged during the early-middle Miocene and underwent erosion (Boucard et
865 al., 2021). Volcanic activity is not recorded onshore neither offshore.

866 Between the middle Miocene and the early Pliocene (MS5) (*ca* 15-4 Ma), a new
867 regional drowning occurred and only small islands were emergent (St Barthélemy and St
868 Martin) (Fig. 16F). From Anguilla to Antigua, shallow water reefal platforms have formed
869 whilst basin deposits occurred elsewhere and the V- shaped basin did not operate anymore
870 (Boucard et al., 2021). On the southern margin of the Anguilla Bank, MS5 locally display
871 chaotic reflectors that could indicate slope deposits (Fig. 13B).

872 During the latest Messinian-early Zanclean (SB5) (*ca* 6-4 Ma), the sea level rose by 20
873 m (Miller et al., 2020) but new islands appeared, indicating a regional uplift (Fig. 16G). These
874 new islands, fringed by shallow-water carbonate deposits, emerged from Anguilla to Antigua
875 and shallow-water reefal deposits were emplaced on the Saba Bank. The volcanic islands of
876 the present-day volcanic arc began to emerge by the Pliocene in northwest St Eustatius and
877 southeast St Kitts (e.g., MacDonald et al., 2000). Elsewhere, basin deposits are observed.

878 During the Zanclean-Calabrian (MS6) (4-1 Ma), glacio-eustatic sea level variations
879 could reach 90 m (Miller et al., 2020). The present-day physiography of the northern Lesser
880 Antilles was mostly acquired (Fig. 16H). A regional drowning has however occurred, of
881 greater amplitude than sea level variations, since only small islands remained emerged (St
882 Martin, St Barthélemy, Anguilla, and Antigua). Eastward in the forearc, a drastic subsidence
883 occurred and is likely to be related to margin basal and frontal subduction erosion, which

884 probably accounts for the retreat of the volcanic arc westward (Boucard et al., 2021).
885 Contemporaneously, the volcanic islands of the recent arc emerged, extending from
886 Montserrat to Saba. Discrete synsedimentary faulting is recorded in the southern part of the
887 Kalinago Basin. On the Antigua, Anguilla and Saba Banks, reefal and red algal platforms
888 were emplaced.

889 During the middle and late Pleistocene, several glaciations occurred, coinciding with
890 recurrent up-to-*ca* 120 m- drops in global sea level (e.g., during Marine Isotopic Stages 16a,
891 12a, 10a, 6a, and 2 [at 0.63, 0.44, 0.34, 0.14, and 0.03 Ma, respectively]; Railsback et al.,
892 2015; Miller et al., 2020; Westerhold et al., 2020) (Fig. 16I). Evidence of emersion has been
893 found in carbonate submarines banks, such as Saba Bank, where giant sinkholes, several
894 hundred meters deep, have been recently revealed (van Duyl and Meesters, 2018). These
895 drops had direct consequences on the emerged areas and relationships between the northern
896 Lesser Antilles islands.

897

898 ***6.3. Geodynamic settings since the late Eocene***

899 The strain pattern observed in this study reflects the accommodation of trench bending
900 that followed a plate boundary rearrangement at the northeastern corner of the Caribbean
901 Plate, which originated both from collision between the Bahamas Bank and Greater Arc of the
902 Caribbean with along its northern boundary and a major change in plate kinematics
903 (Boschman et al., 2014; Legendre et al., 2018; Philippon et al., 2020a, b; Boucard et al.,
904 2021). Our palaeogeographical reconstructions (Fig. 16) allow, for the first time, to evidence
905 regional scale vertical motions affecting the whole northern Lesser Antilles. Indeed, we show
906 the emergence of hundreds km- long landmasses along the trench in the arc area and
907 subsequent regional drownings of these lands at the scale of tens Myrs.

908 Following the E-W compression that occurred during the late-middle Eocene
909 (Philippon et al., 2020a), which led to large emerged areas in the northern Lesser Antilles, the
910 tectonic regime changed drastically. Since then, the palaeogeography has been controlled by
911 regional extensional setting leading to alternating episodes of uplift and subsidence. Vertical
912 motions are controlled by two sets of normal faults trending NE-SW and NW-SE,
913 respectively. The Kalinago Basin opened during the late Eocene-early Oligocene and
914 propagated from north to south, between ~34 and ~28 Ma, in intra-arc rift position (MS3).
915 First, this opening was controlled by NW-SE trending normal faults, *i.e.* parallel-to-the-
916 trench. Later on, NW-SE and NE-SW trending regional normal faults affected the northern
917 Lesser Antilles realm (MS3 and MS4) (Jany et al., 1990; Legendre et al., 2018; Boucard et al.,
918 2021; this work). Consistently, NE-SW-trending faults fractured the inner forearc generating
919 deep V-shapes valleys separated by shallow crustal spurs (Boucard et al., 2021). This regional
920 extension in the upper plate possibly resulted from the Bahamas Bank collision and westward
921 drifting, the consecutive margin convex bending and crustal blocks rotations (Mann et al.,
922 2005; Philippon et al., 2020b). This extension might also be consistent with a transient trench
923 rollback (over a short time lapse) during the early stages of extension. Soon after SB3 (late
924 Oligocene erosional surface), the zone of maximum subsidence switched eastward to the
925 forearc, on the eastern margin of the Kalinago Basin where the V-shaped deep basins and
926 Spurs opened during the late Oligocene-early Miocene (Boucard et al., 2021). Volcanism
927 remained active from Antigua to St Barthélemy, and ceased at *ca* 24 Ma in St Barthélemy and
928 St Martin.

929 Between SB4 and SB5 (middle Miocene-early Pliocene) the deformation regime
930 changed. The tectonic activity along the NE-SW faults, which bound the V-shaped basins, has
931 progressively ceased and deep NW-SE faults resulted from an extensive deformation normal
932 to the margin. A significant subsidence affected the forearc and the Kalinago basin. The

933 volcanic arc migrated westward into the arc interior. The margin has likely undergone a long-
934 term frontal erosion compared to the accretionary Central and Southern Lesser Antilles. This
935 frontal erosion, trench landward migration associated with margin extension, fracturing,
936 drastic subsidence and volcanic arc landward retreat testify for enhanced basal erosion of the
937 upper plate (Boucard et al., 2021).

938

939 ***6.4. Faunal dispersals***

940 Our results indicate that prominent uplift events occurred during the late Bartonian-
941 early Priabonian, the Chattian, the Langhian and the early Zanclean in the northern Lesser
942 Antilles. During these intervals, hundred kilometers- long and wide emerged islands extended
943 from Antigua to the Anguilla and Saba Banks (Fig. 16), thus providing more or less
944 continuous terrestrial connections to the Greater Antilles (Puerto Rico and Virgin Islands).
945 Such a connection has been previously proposed but only for the late Eocene (GrANoLA
946 land, Philippon et al., 2020). Whereas it has been unsuspected until now, with this thorough
947 geological and geophysical study of the Northern Lesser Antilles realm, we evidence that the
948 northern part of the Lesser Antilles has been a favourable area that may have allowed the
949 dispersal of terrestrial species between the Greater Antilles and the northern part of South
950 America, not only during the late Eocene but also from the Oligocene to recent times with the
951 episodic formation of emerged archipelagos. Moreover, this potential transit zone identified
952 here, from the Anguilla Bank to the Antigua Bank, can be extended southwards to the
953 Guadeloupe archipelago where, there too, vast island areas have been identified with a similar
954 schedule: at the early Miocene-middle Miocene transition, at the late Miocene-early Pliocene
955 transition and during the Early Pleistocene (De Min, 2014; De Min et al., 2015), aside from
956 Pleistocene sea-level drops controlled by glaciation (Railsback et al., 2015). Thus, the
957 northern Lesser Antilles might have contributed to faunal dispersals at multiple times since

958 the late Eocene. During the late Eocene, the emerged areas in the northern Lesser Antilles
959 were at their maximum and might have been connected to the supposed GAARlandia land
960 bridge, playing a role in the dispersal of South American terrestrial fauna to the Greater
961 Antilles (Iturralde-Vinent and McPhee, 1999). However, later dispersal events have also been
962 evidenced (Fabre et al., 2014; Brace et al., 2015; Courcelle et al., 2019) and they may be
963 supported by the repeated occurrence of more or less important emerged land masses in the
964 northern Lesser Antilles (this work) and possibly in the southern Lesser Antilles, too. The role
965 of the Lesser Antilles in the dispersal of land fauna during the last 40 Myrs must therefore be
966 reassessed, on one hand by searching for a terrestrial fossil record that is currently lacking,
967 and on the other hand by reconstructing the palaeogeography of its southern part between
968 Guadeloupe and Venezuela.

969

970

971 **7. CONCLUSIONS**

972 Our integrated onshore-offshore study of the Cenozoic deposits of the northern part of the
973 Lesser Antilles shows:

- 974 • An isolated reefal platform in Anguilla lasting the whole Aquitanian to Messinian
975 interval (23-*ca* 5.3 Ma); reefal to peri-reefal deposits fringing an island in St Martin
976 and covering the Aquitanian-Zanclean interval (23-3.8 Ma); peri-reefal to slope
977 deposits at Tintamarre with two episodes of mass wasting, which occurred during the
978 late Burdigalian (18-16 Ma) and the early Langhian (15.4-15 Ma), respectively; reefal
979 deposits at Barbuda from the Messinian-Piacenzan(?) (?11.6-?2.5Ma); reefal then deep
980 sea deposits in Antigua spanning the Rupelian-Chattian interval (?33.9-23 Ma).
- 981 • Offshore, we defined seven seismic megasequences (MS) bounded by regional-scale,
982 erosional unconformities. MS1 corresponds to a partly sedimentary Cretaceous to

983 lower Eocene deformed basement; MS2 is a middle-upper Eocene sequence
984 displaying inverted grabens; MS3 deposited during the late Eocene and the early
985 Oligocene; MS4 deposited between the late Oligocene and the early Miocene; MS5
986 deposited between the middle Miocene and the early Pliocene; MS6 and MS7
987 deposited during the early Pliocene and the Pleistocene.

- 988 • Our palaeogeographical reconstructions highlight uplifts and emergences of hundreds
989 km- long islands during the late Eocene, the late Oligocene, the early Langhian, and
990 the latest Miocene-earliest Pliocene. These uplift events have been interspersed by
991 drowning episodes that occurred during the early Oligocene, the middle Miocene-
992 earliest Pliocene and from the early Pliocene to the present-day. Uplift episodes
993 generated archipelagos with mega-islands and/or neighbouring islands in the Greater
994 Antilles, the Lesser Antilles, and the northern Aves Ridge.
- 995 • A major, first order geodynamical change occurred by the late Eocene (37.8-33.9 Ma):
996 a convergent event occurred during the late middle-early late Eocene (42-37 Ma),
997 related to the collision between the Caribbean Plate and the Bahamas Bank; later, only
998 extension is recorded with alternating uplift and drowning episodes related to an
999 increasing curvature of the trench. The Kalinago Basin opened as an intra-arc basin
1000 during the Priabonian-Rupelian (37-28 Ma). The role of the northern Lesser Antilles
1001 concerning the dispersal of terrestrial organisms, between the Greater Antilles and
1002 northern South America, has to be re-evaluated in the light of our palaeogeographic
1003 reconstructions.

1004

1005 **Acknowledgements**

1006 This work was supported by the INSU TelluS-SYSTER grant call 2017, the
1007 GAARAnti project (ANR-17-CE31-0009), the GARANTI Cruise (2017) and the

1008 ANTITHESIS Cruise (2013). We are indebted to Saba Bank Resources N.V. for the provision
1009 of seismic lines of the Saba Bank area. We gratefully thank the captain and crew of *R/V*
1010 *L'Atalante*, as well as the technical staff of Genavir for having successfully completed the
1011 acquisition of seismic data and dredge samples during the GARANTI and ANTITHESIS
1012 cruises (<https://doi.org/10.17600/17001200>). Multichannel seismic processing was performed
1013 with Geovation software of CGG and Seismic Unix. All geophysical data of the
1014 ANTITHESIS and GARANTI cruise are available on demand at SISMER
1015 (www.ifremer.fr/sismer/). Thin-sections were made by D. Delmas and C. Nevado
1016 (Montpellier) and F. Zami (Pointe à Pitre). Paul Mann, an anonymous reviewer and Editor
1017 Christopher Fieding are thanked for their constructive reviews.
