**HAL** is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

## COMMUNICATION

## A Near-infrared Emitting MOF Excited with a Low Energy Wavelength: Controlled Encapsulation of Fluorescein Sensitizer at the Time of Crystals Growth†

Received 00th January 20xx,  
Accepted 00th January 20xx

DOI: 10.1039/x0xx00000x

Guillaume Collet,<sup>a,b</sup> Antonio Hrvat,<sup>a,c</sup> Svetlana V. Eliseeva,<sup>a</sup> Céline Besnard,<sup>d</sup> Anton Kovalenko<sup>a</sup> and Stéphane Petoud<sup>\*a</sup>

**We report here a near-infrared (NIR) emitting lanthanide-based metal-organic framework (MOF) in which Yb<sup>3+</sup> cations are sensitized by fluorescein (FL) as a low energy absorbing chromophore (FL@CD-MOF-161). The unique design of CD-MOF-161 allows for the entrapment of FL molecules in its pores during the synthesis and crystal growth, ensuring the efficient loading and spreading of chromophores within the crystal volume.**

The emission in the near-infrared (NIR) spectral range offers breakthrough perspectives in fields of applications such as material science and biology. As examples, NIR-emitting probes and materials have a strong potential for the creation of secret tags and night-vision devices<sup>1</sup> while the in vivo fluorescent optical imaging will benefit from an improved light penetration due to a reduced tissue absorption, a lower scattering and the minimization of the detrimental contribution of tissues autofluorescence.<sup>1–3</sup> NIR signals can be advantageously used for diagnostic imaging in which the ability to accurately detect small foci is a key advantage to act early in order to treat a pathology.<sup>4</sup> The applications for intra-operative optical imaging and guided surgery can also be considered with NIR wavelengths as they allow to perform surgical acts in ambient light.<sup>5, 6</sup>

Despite the large amount of attractive theoretical evidences related to the use of NIR signals for in vivo imaging and promising experimental demonstrations<sup>3, 7</sup>, the number of NIR-emitting probes that can potentially be used in vivo remains scarce. The chemistry and the spectroscopy of lanthanide(III) cations (Ln<sup>3+</sup>) is an active field of research as several of them have a unique potential to fulfil the needs described above by emitting light at wavelengths above 800

nm.<sup>8, 9</sup> In addition, Ln<sup>3+</sup> offer complementary advantages such as very narrow emission bands, the wavelengths of which are not affected by experimental conditions (pH, temperature, biological environment).<sup>10</sup> Moreover, most of Ln<sup>3+</sup>-based compounds are insensitive to photobleaching which allows (i) their excitation with powerful sources such as lasers, (ii) the extension of the experimental time or their repetition.

As most of f-f transitions are forbidden resulting in very low absorption coefficients of free Ln<sup>3+</sup>, the presence of highly absorbing sensitizers is required to generate their characteristic emission, an approach named “antenna effect”.<sup>9</sup> In this process, the antenna absorbs the light from the excitation source and transfers the resulting energy to the accepting electronic levels of the Ln<sup>3+</sup> resulting in the enhancement of its emission intensity.<sup>9, 11</sup> The antenna effect is mainly controlled by the electronic structure of the sensitizing chromophore, by the nature of the Ln<sup>3+</sup>, by the Ln<sup>3+</sup>-sensitizer distance and by their ratio. Various approaches have been tested to obtain such sensitization.<sup>12</sup> The vast majority of Ln<sup>3+</sup> compounds described in the literature have excitation wavelengths located in the UV range. Such high energy light can induce damages to biological systems. Another limitation of most of currently described Ln<sup>3+</sup> compounds emitting in the NIR are their quantum yield values that are often modest. To create Ln<sup>3+</sup> compounds able to emit a large number of photons despite low quantum yields, we took advantage here of the “polymetallic” approach that we have used previously in which a high density of luminescent Ln<sup>3+</sup> and sensitizers are located in a given volume.<sup>10, 13, 14</sup> To achieve this goal, the use of metal-organic frameworks (MOFs) is of particular interest due to the unique rigidity and the crystalline nature of this family of materials.<sup>15</sup> The specific advantages are (i) the precise location of all atoms determined by single crystal crystallography, including Ln<sup>3+</sup> and distances separating them allowing the rationalization of their photophysical properties, (ii) the possibility to synthesize large amounts of materials that are often essential for practical applications and (iii) the use of MOFs as carriers of molecules, drugs, etc. within their pores.<sup>16–18</sup>

Several structures of MOFs have been used for the sensitization

**Figure 1.** Schematic representation of the NIR-emitting FL@CD-MOF-161. Ligands: black lines; Yb<sup>3+</sup> and its coordination sphere: red and purple; FL: green spheres. The cartoon in the square exemplifies the Yb<sup>3+</sup> sensitization mechanism: the excitation light (< 600 nm) is absorbed by the FL entrapped in the MOF pores followed by the energy transfer to Yb<sup>3+</sup> which emits a narrow NIR signal with a maximum at 980 nm.

of NIR-emitting Ln<sup>3+</sup>, however only a few of them demonstrated to be compatible with practical applications such as biological imaging.<sup>19-22</sup> As a major breakthrough, we have described in 2013 the first example of the use of a nano-MOF as a NIR-imaging agent in living cells.<sup>13</sup> The limitation of this MOF is the excitation wavelength around 355 nm which is incompatible for *in vivo* biological imaging. Moreover, the excitation wavelength of this system is controlled by the nature of the rigid chromophoric ligand that is forming the network. To shift the excitation wavelength toward lower energy, we have tested different post-synthetic strategies, including the entrapment of chromophores such as the LDS 750 into pores of the widely used Yb<sup>3+</sup>-BPDC MOF,<sup>20</sup> the covalent modification of MOF linkers,<sup>23</sup> or the *in-situ* coupling of acetylene units to form a high density of  $\pi$ -conjugated systems throughout MOF pores.<sup>24</sup> An alternative strategy for long-wavelength excitation of NIR-emitting compounds would be by two-photon absorption. However, such approach requires the use of specific equipment including femtosecond lasers.<sup>25, 26</sup>

One of the originalities of the present work lies in the design, synthesis and characterization of a new NIR-emitting Yb<sup>3+</sup>-based MOF (FL@CD-MOF-161, Figure 1, S1-2) that possesses a biocompatible excitation wavelength. Fluorescein (FL) has been described as sensitizing the NIR emission of Yb<sup>3+</sup> and exhibits a high absorption of light in the range of 400-550 nm ( $\epsilon > 10^5 \text{ M}^{-1}\text{cm}^{-1}$ ).<sup>27</sup> When exposed to excitation light, a NIR emission signal arises from Yb<sup>3+</sup> cations that are used as coordination metals ions in FL@CD-MOF-161. In this tridimensional system, FL molecules located inside the MOF pores act as antennae to sensitize Yb<sup>3+</sup>.

**Figure 2.** Optical microscopy images of FL@CD-MOF-161 crystals. (A) Brightfield, objective 20 $\times$ , scale bar: 50  $\mu\text{m}$ . (B) Brightfield, objective 60 $\times$ , scale bar: 10  $\mu\text{m}$ . (C) NIR luminescence.  $\lambda_{\text{ex}}$ : 482 nm band pass 35 nm,  $\lambda_{\text{em}}$ : 996 nm band pass 70 nm,  $\tau_{\text{exp}}$ : 100 ms, objective 60 $\times$ , scale bar: 10  $\mu\text{m}$ .

As an additional novelty and advantage of our work, the FL has been introduced during MOF assembly at the time of crystal growth, leading to an easy, controlled and efficient loading up to the centres of crystals in contrast to a post-synthesis loading which is limited by diffusion.<sup>16</sup>

The new FL@CD-MOF-161 was synthesized using a methodology inspired by a protocol that we had described recently combining 9-anthracene carboxylic acid dimers (Di-9AC) as ligands, Yb<sup>3+</sup> as coordination metal ions and FL.<sup>28</sup> Crystallites with sizes around 50  $\mu\text{m}$  were isolated (Figure 2A, 2B, S3), showing a high level of reproducibility from one synthesis to another. They emit in the NIR range upon excitation at 400-550 nm (Figure 2C, S3). The PXRD analysis confirmed the isostructural nature of FL@CD-MOF-161 with the previously described CD-MOF-161 (Figure S4).<sup>28</sup> Therefore, the presence of the FL does not affect the structure of the CD-MOF-161. Monitoring the FL emission by itself, its distribution inside the entire volume of crystals was evaluated by confocal laser scanning microscopy. Resulting pictures show that FL molecules are entrapped in the CD-MOF-161 structure up to the crystal centre and are indeed distributed evenly inside the entire volume (Figure S5-7).

The photophysical properties of the FL@CD-MOF-161 crystals have been evaluated. The diffuse reflectance spectrum exhibits broad bands in the range 400-550 nm that correspond to typical FL absorption (Figure S8). Emission spectra were collected upon excitation at 480 nm. These data reveal the presence of a NIR emission band with a barycentre at 980 nm which can be attributed to the Yb<sup>3+</sup>  $^2F_{5/2} \rightarrow ^2F_{7/2}$  transition (Figure 3). As Yb<sup>3+</sup> does not possess electronic levels in the energy domain corresponding to the visible range<sup>29</sup> and as the Di-9AC ligands that form the architecture of the CD-MOF-161 exhibit absorption bands below 300 nm, the only way to sensitize Yb<sup>3+</sup> upon excitation at 480 nm is through the “antenna effect”, i.e. energy transfer from the excited electronic states of the FL encapsulated in the pores of the MOFs to the accepting levels of Yb<sup>3+</sup>.<sup>9</sup> Moreover, the excitation spectrum (Figure 3, left) recorded upon monitoring Yb<sup>3+</sup> emission at 980 nm coincides well with the diffuse reflectance spectrum (Figure S8). This type of sensitization process results in a large difference in energy ( $\sim 500 \text{ nm}$ ) between the maxima of the excitation and the emission wavelengths observed for FL@CD-MOF-161 crystals. Such large energy shift represents an important advantage for optical imaging experiments since the

**Figure 3.** Corrected and normalized (left) excitation ( $\lambda_{\text{ex}} = 480 \text{ nm}$ ) and (right) emission ( $\lambda_{\text{em}} = 980 \text{ nm}$ ) spectra of FL@CD-MOF-161 crystals at room temperature.

entire emission signal can be collected without taking into account (i) a compromise in filters choice as it is the case with most organic fluorophores due to small Stokes shift, (ii) the possible reabsorption by organic dyes of their own emitted photons, minimizing consequently the intensity of the detected signal. It is worth noting that the emission spectrum observed for the FL-free CD-MOF-161 crystals upon a 480 nm excitation does not contain any  $\text{Yb}^{3+}$ -centred emission bands in the range of 940–1100 nm, confirming that the NIR signal arising from FL@CD-MOF-161 is indeed obtained by the FL-mediated sensitization (Figure S9). However, the sensitization process is not quantitative and the residual broad-band emission of FL in the visible range was observed upon 480 nm excitation (Figure S13).  $\text{Yb}^{3+}$ -centred quantum yields ( $Q_{\text{Yb}}^{\text{L}}$ ) were determined in order to quantify the efficiency of the FL@CD-MOF-161 to convert the excitation light absorbed by the FL to generate the NIR emission of  $\text{Yb}^{3+}$ . A  $Q_{\text{Yb}}^{\text{L}}$  value of 0.308(3)% was obtained (Table S1). Remarkably, this value is 15- to 30-times larger than those observed for the post-synthetically modified MOF-1114(Yb) and MOF-1140(Yb), or for the LDS750@ $\text{Yb}^{3+}$ -BPDC that we have described previously, demonstrating a much higher sensitization efficiency.<sup>20, 24</sup> The experimental luminescence decay recorded for the FL@CD-MOF-161 crystals upon monitoring  $\text{Yb}^{3+}$  emission is best fitted by a three-exponential function indicating the presence of emissive  $\text{Yb}^{3+}$  in different coordination environments (Table S1). The calculated average lifetime value of the  ${}^2\text{F}_{5/2}$  state is equal to 10.8  $\mu\text{s}$  and is at least 2-times longer than those recorded for the other low-energy absorbing MOF-1114(Yb) and MOF-1140(Yb), or for the LDS750@ $\text{Yb}^{3+}$ -BPDC that we have reported previously.<sup>20, 24</sup> Such results probably reflect a better protection of  $\text{Yb}^{3+}$  in FL@CD-MOF-161 from high-energy vibrations.

Chemical stability of materials during extended periods of storage as well as the stability under continuous illumination referred to as photostability are both crucial properties to consider in view of potential applications. Both parameters were evaluated for FL@CD-MOF-161 crystals. The exact match of PXRD patterns recorded on freshly synthesized samples and on samples stored for one year in quartz capillaries at room temperature without protection from light (Figure S10) confirmed the extremely high stability of FL@CD-MOF-161 crystals. This stability was further supported by brightfield microscopy experiments that reveal a high level of similarity of crystals shapes for these two samples. Photophysical studies performed on the sample stored for one year showed that the characteristic  $\text{Yb}^{3+}$  emission is still efficiently sensitized by the entrapped FL (Figure S11) while the  $Q_{\text{Yb}}^{\text{L}}$  value

**Figure 4.** NIR fluorescence images of FL@CD-MOF-161 crystals obtained by epifluorescence macroscopy upon excitation with light selected with a 482 band pass 35 nm filter and collecting the  $\text{Yb}^{3+}$  emission with a 996 band pass 70 nm filter. (A) A capillary filled with crystals (Figure S6) was observed through a mask (500  $\mu\text{m}$  of diameter);  $\tau_{\text{exp}}$ : 5 s. (B) The same sample was observed through a 1 mm thick bio-mimicking phantom tissue positioned on the top of the mask;  $\tau_{\text{exp}}$ : 30 s. Macro-objective 5 $\times$ ; scale bar: 500  $\mu\text{m}$ .

decreased only by a modest factor of 1.7. On the other hand, the average luminescence lifetime value of the  ${}^2\text{F}_{5/2}$  state is 1.4-times longer for the FL@CD-MOF-161 crystals after the one year storage period (Table S1). Such phenomenon may be due to a redistribution of water, FL and/or DMA molecules inside of the MOF network that impacts the  $\text{Yb}^{3+}$  environment(s) and therefore the probabilities of non-radiative deactivations. These changes are also reflected by a slight variation of the relative intensities of the different Stark components of the  ${}^2\text{F}_{5/2} \rightarrow {}^2\text{F}_{7/2}$   $\text{Yb}^{3+}$  transition observed in the emission spectrum (Figure S11). It should be noted, however, that the UV-vis absorption spectrum recorded on the supernatant solution of the FL@CD-MOF-161 crystals measured after the one year of storage does not indicate the presence of any traces of free FL (data not shown). Moreover, FL-centered quantum yield in the visible range remains the same after storage (2.2(1)%). All these results confirm (i) the good stability of FL@CD-MOF-161 crystals over an extended period of time with no requirement of protection of the sample from light and from the temperature, and (ii) the efficient entrapment of FL inside of MOF pores demonstrated by the absence of detectable release. Such absence can be also explained by the perfect docking of the FL molecule in cavities of the MOF, which was confirmed by the crystallography-determined structure (Figure S12). In addition, the photostability of FL@CD-MOF-161 crystals upon continuous illumination at 480 nm was evaluated (Figure S13). Only minor decreases (less than 10%) of the  $\text{Yb}^{3+}$  signal at 980 nm or FL emission in the visible were observed after 2 hours of continuous irradiation, indicating an excellent photostability.

In order to establish a preliminary proof of principle of the FL@CD-MOF-161 to be used as *in vivo* NIR imaging agent, an epifluorescence macroscopy experiment was performed using a bio-mimicking phantom tissue. This model system contains haemoglobin and intralipids in order to simulate the absorption and the scattering of excitation and emitted light, respectively, and to reproduce the optical characteristics comparable to living tissues.<sup>30</sup> A mask with a 500  $\mu\text{m}$  diameter circular hole was used to spatially simulate a small size emitting foci that potentially could be an early pathological site (Figure 4A). This mask was positioned on the top of a capillary containing crystals of FL@CD-MOF-161 (Figure S14). The 1 mm thick bio-mimicking tissue was placed on the top of the mask and the specific  $\text{Yb}^{3+}$  NIR signal was monitored with a 996 band pass 70 nm filter upon excitation into FL-centred bands (482 band pass 35 nm filter). One of the important novelty provided by the creation of this

MOF lies in its ability to efficiently sensitize Yb<sup>3+</sup> using an excitation wavelength which is significantly shifted to the visible spectral domain in comparison to the actual NIR-emitting Ln<sup>3+</sup> compounds described in the literature.<sup>31, 32</sup> The reduced autofluorescence present in the NIR allowed to unambiguously record the specific Yb<sup>3+</sup> signal through the bio-mimicking phantom tissue (Figure 4B, S15). In addition, this macroscopy experiment was realized in challenging conditions by detecting the signal through a small size focus of 500 μm of diameter, reducing significantly the total amount of collected light. Its success shows that it is possible to monitor the Yb<sup>3+</sup> signal, non-invasively, with a good level of sensitivity highlighting the potential of FL@CD-MOF-161 for in vivo imaging.

In conclusion, taking advantage of the rigid cavity of a MOF to encapsulate an organic fluorophore in a controlled way and at the time of crystals growth, we have synthesized an Yb<sup>3+</sup>-based NIR-emitting MOF that can be excited with a low energy wavelength. Quantum yield are higher than those reported by us for other MOF systems with low excitation wavelength. This new MOF system is highly robust, being insensitive to long term storage and to photobleaching. The FL sensitizer remains in the cavity of the MOF. Proof of principle NIR imaging experiments were performed with the excitation and emission light passing through 1 mm of bio-mimicking phantom tissue. High quality pictures were obtained from the NIR signal arising from Yb<sup>3+</sup>. These results highlight the promising potential of FL@CD-MOF-161 for NIR imaging and diagnostic applications and ultimately for in vivo imaging.

The result incorporated into this study have received funding from the Ligue Régionale Contre le Cancer, comité du Loiret et d'Eure-et-Loir, the network «Molécules marines, métabolisme et cancer» from the Cancéropôle Grand Ouest, la Région Centre, l'Agence Nationale de la Recherche (NIRA-ANR-13-BS08-0011), the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 665790. A.H. and S.P. acknowledge support from Erasmus+ Programm (HR ZAGREB01) and the Institut National de la Santé et de la Recherche Médicale (INSERM), respectively.
