#### Abstract

The understanding of the thermal decomposition chemistry of chemical warfare nerve agents is largely limited by the scarcity of kinetic data. Because of the high toxicity of these molecules, experimental determination of their chemical properties is very difficult. In the present work, a comprehensive detailed kinetic model for the decomposition of sarin and some simulants, i.e. di-isopropyl methyl phosphonate (DIMP), diethyl methylphosphonate (DEMP), and triethyl phosphate (TEP) were developed, containing possible molecular and radical pathways. The importance of unimolecular pericyclic decomposition led to evaluate precisely the rate constants of these reactions with high level theoretical calculations. The $\operatorname{QCISD}(\mathrm{T}) / \mathrm{cc}-\mathrm{PV} \propto \mathrm{QZ} / / \mathrm{B} 2$ PLYPD3/6-311+G(2d,d,p) level of theory was selected after a benchmark. The contribution of hindered rotors was included with the 1D-HR-U approach. Tunneling was taken into account for H -atom transfer. Transition state theory was used to calculate high-pressure limit rate constants and pressure dependent rate constants were calculated using Master Equation modelling. The model was validated against experimental pyrolysis and oxidation experimental data available in literature. Flux analyses showed that whatever the conditions are, the first step of decomposition of the studied phosphorus compounds are pericyclic eliminations leading to successive decompositions, whereas bondbreaking or H -atom abstraction remain negligible, even at high temperature.

## Keywords

Organophosphorus compounds, chemical warfare agents, sarin, DIMP, DEMP, TEP, modeling, theoretical chemistry

## Introduction

Organophosphorus compounds are involved in many toxics such as pesticides (i.e. malathion) or in chemical warfare nerve agents such as sarin. Although these compounds have a relatively long lifetime at room temperature [1], their high temperature behaviour is not well known. Fighting fires in pesticide stockpiles or dimensioning processes for the thermal destruction of nerve agents requires a good knowledge of the reactivity and distribution of products. Despite their high toxicity, few experimental studies have been performed for the destruction of chemical warfare agents [2,3]. Incineration [4,5] belongs to the most widespread methods of destruction envisaged. However, the main studies have been carried out with simulants of nerve agents, as dimethyl methylphosphonate (DMMP), diethyl methylphosphonate (DEMP), di-isopropyl methyl phosphonate (DIMP), triethyl phosphate (TEP). These molecules are less toxic but do not contain the heteroatoms involved in real compounds, such as fluorine in sarin.

In pyrolysis, Durig et al. [6] studied reactions of six organophosphorus compounds, including DMMP, and proposed a decomposition pathway based on unimolecular eliminations. Zegers and Fisher investigated the thermal decomposition of DIMP [7], DEMP [8] and TEP [9] in the range of 700-900 K. They proposed a reaction scheme based on some successive pericyclic molecular eliminations. Some experimental studies in the literature investigated the inhibiting effect of nontoxic organophosphorus compounds as fire retardant in flames [10]. Korobeinichev et al. investigated the decomposition of several organophosphorus compounds such as DIMP in $\mathrm{H}_{2} / \mathrm{O}_{2} / \mathrm{Ar}$ premixed flames [11]. They quantified phosphorous oxides using molecular beam mass spectrometry with tuneable electron-impact ionization. Glaude et al.
$[12,13]$ have modelled the combustion of sarin, DMMP and DIMP. They pointed out the important role of molecular elimination reactions even in highly reactive combustion conditions and showed that DMMP, which cannot react through a six-membered elimination, was not a suitable surrogate for sarin, contrary to DIMP. In shock tube, Mathieu et al. [14] investigated the influence of DMMP on hydrogen, methane, and ethylene ignition in shock tube and Neupane et al. studied experimentally [15] and modelled [16] the decomposition of TEP.

Quantum chemical calculations have been used to determine mainly thermochemical properties[17,18], but also rate constants of molecular systems containing trivalent or pentavalent phosphorus [19]. Sullivan et al. [20] investigated the combustion of methylphosphonic acid (MPA) at the CBS-Q level of theory and evaluated several elementary reactions, such as the unimolecular decomposition of MPA and the hydrogen abstraction from MPA by OH radicals. Comparison with literature showed significant discrepancies especially for reactions involving P-O bonds and highlighted the fact that reaction rates based on analogous C-O bond chemistry are unreliable. More recently, a theoretical investigation of unimolecular decomposition of DMMP was reported by Yang et al. [21]. The most favourable elimination through a 4-membered transition state yields methanol and $\mathrm{O}=\mathrm{P}\left(\mathrm{CH}_{2}\right)\left(\mathrm{OCH}_{3}\right)$ and involves a barrier of $73.2 \mathrm{kcal} \mathrm{mol}^{-1}$ at the CBS-QB3 level of theory. These calculations are supported by the experimental investigation of the thermal decomposition of DMMP probed by VUV synchrotron radiation and photoelectron photoion coincidence spectroscopy [22], which showed that DMMP decomposes by successive losses of methanol and formaldehyde yielding $\mathrm{CH}_{3} \mathrm{PO}$, which eventually produces PO and methyl radicals. Unimolecular decomposition of sarin and soman have been investigated systematically at the CBS-QB3 level of theory by Ash et al. [23], showing the prominent role of the 6-membered ester elimination of propene over other pericyclic reactions, with an energy barrier around 40
kcal mol ${ }^{-1}$ much lower than in the case of DMMP. Shan et al. [24] evaluated the 6 -centered pericyclic reaction of sarin with high level methods. The rate constant reproduced very well experimental measurements of sarin decomposition over a temperature range $350-500^{\circ} \mathrm{C}$. These results show that unimolecular reactions could play a major role in the thermal decomposition of organophosphorus compounds. The present study aims to propose a comprehensive detailed kinetic model of the pyrolysis and combustion of sarin and its surrogates, i.e. DIMP, DEMP and TEP (Figure 1), containing both molecular and radical chain reactions. to unravel the relative importance of the pericyclic mechanisms over a wide range of pressure and temperature. The selection of the computational method to calculate theoretically molecular pericyclic reactions is discussed first. A second part details the potential energy surface for the molecular eliminations of the studied compounds and the calculation of rate constants. The detailed model is then presented and validated against experimental data from the literature.

## Quantum chemical calculation methodology

All $a b$ initio calculations have been performed using Gaussian 09 suite of quantum chemistry program [25]. Before choosing the correct method for calculating the electronic structure, we performed a benchmark of composite methods, such as CBS-QB3, G4, as well as
$\mathrm{PV} \infty \mathrm{QZ} / / \mathrm{B} 2$ PLYPD3/6-311+G(2d,d,p), these last methods being inspired from the work of Goldsmith et al. [26], using the more powerful double-hybrid density functional method B2PLYPD3 for geometry optimizations, which has shown a good ability for reducing the geometric and ZPE uncertainties [27]. Energies at the QCISD(T)/cc-pVDZ and QCISD(T)/ccpVTZ levels of theory were calculated with the DFT geometries. The complete basis set (CBS) limit energy was then calculated from the extrapolations of the cc-pVDZ and cc-pVTZ results. Extrapolations from the triple and quadruple- $\zeta$ basis set calculations have been tested for light species but are prohibitive for molecules of interest. Eventually the MP2 method was used to correct for the difference in the TZ and DZ basis sets based extrapolations [26]:
$E_{Q C I S D(t) / \infty(Q) Z}=E_{Q C I S D(t) / T Z}+\left(E_{Q C I S D(t) / T Z}-E_{Q C I S D(t) / D Z}\right) \frac{3^{4}}{4^{4}-3^{4}}$
$+E_{M P 2 / Q Z}+\left(E_{M P 2 / Q Z}-E_{M P 2 / T Z}\right) \frac{4^{4}}{5^{4}-4^{4}}$
$-E_{M P 2 / T Z}-\left(E_{M P 2 / T Z}-E_{M P 2 / D Z}\right) \frac{3^{4}}{4^{4}-3^{4}}$
In order to compare the methods, calculations of thermochemical data have been performed on organophosphorus species for which the thermodynamic data are well known. The results are presented in Table S1. These results agree with the experimental data whatever the method, with mean standard deviations from experiments around $3 \mathrm{kcal} \mathrm{mol}^{-1}$ in enthalpies. In the case of sarin, for which experimental data are not available, high level methods differ widely from the popular CBS-QB3 method. For all species involved in calculations, enthalpies of formation $\left(\Delta_{f} H_{298 K}^{\circ}\right)$ were estimated from the electronic energies using atomisation energies, excepted for hydrocarbons, for which experimental data have been used. The reference data for atoms are derived from NIST database [28].

To increase precision, the low-frequency modes of vibration corresponding to internal rotations have been treated as hindered rotors rather than harmonic oscillators. The energy barriers were calculated with the levels of theory previously described, while the internal rotor
processing was carried out using the 1-DHR-U method [29]. Classical Transition State Theory (TST) was used to deduce rate constants from the energy of reactants, transition states and products. The tunnelling effect was taken into account for reactions involving an internal H transfer by employing the Eckart method [30]. The kinetic parameters were fitted using the three parameters modified Arrhenius equation $\left(\mathrm{A} \times \mathrm{T}^{\mathrm{n}} \times \exp (-\mathrm{Ea} / \mathrm{RT})\right)$ over the temperature range $300-2000 \mathrm{~K}$. The calculation of the kinetic and thermodynamic parameters, following this methodology, was carried out using the THERMROT software [31]. This software, developed in our laboratory, makes it possible to easily retrieve the relevant data from Gaussian calculation files and to calculate the kinetic parameter as well as thermodynamic data in the form of NASA polynomials. Influence of pressure was evaluated using master equation (ME) modelling with the MESS code [32]. Rate constants at different pressure have been calculated in nitrogen as a bath gas. Details of the parameters used in the resolution of the ME can be found in Table S2.

## Choice of method

The various methods previously described have been tested for the calculation of kinetic data in order to draw the best option. The molecular elimination reactions of sarin and its decomposition product, respectively TS1 and TS2 in Figure 2, have been used as a test case. Note that the initial decomposition of sarin involves two transition states (TS1-1 and TS-2), related to the relative position of the non-reactive methyl group and F-atom, as mentioned by Shan et al. [24]. Energy barriers obtained at 0 K are presented in Table 1. The structure of TS1-1, TS1-2 and TS2 is displayed in figure S1.

Figure 2: Molecular decomposition of sarin, showing six-membered (blue) and fourmembered (red) elimination reactions.

Table 1: Molecular decomposition of sarin: energy barriers at 0 K computed at different level of theory.

|  | CBS- <br> QB3 | G4 | CCSD(T)/ <br> $\infty(\mathrm{Q}) \mathrm{Z}$ | QCISD(T)/ <br> $\infty(\mathrm{Q}) \mathrm{Z}$ |
| :---: | :---: | :---: | :---: | :---: |
| TS1-1 | 40.0 | 39.5 | 38.9 | 38.5 |
| TS1-2 | 40.2 | 39.7 | 39.2 | 38.7 |
| TS2 | 51.4 | 51.5 | 51.5 | 51.1 |

Subsequently, the kinetic constants obtained with the different methods were included in the detailed kinetic model of the thermal decomposition of sarin. The Senkin program of Chemkin II [33] was used to simulate the decomposition of sarin under pyrolysis. The simulations were done for temperatures ranging from 350 to $500^{\circ} \mathrm{C}$, the initial pressure was set at 1 bar, and the residence time ran up to 0.5 s , at the experimental conditions carried out by Shan et al. [24]. The results obtained are presented in Figure 3. It can be observed that the rate constants obtained at the $\operatorname{QCISD}(\mathrm{T}) / \mathrm{cc}-\mathrm{PV} \infty \mathrm{OZ} / / \mathrm{B} 2 \mathrm{PLYPD} 3 / 6-311+\mathrm{G}(2 \mathrm{~d}, \mathrm{~d}, \mathrm{p})$ level of theory are those that show the best agreement with the experimental results. This method will then be adopted for further calculations.

## Kinetic Modelling

A detailed chemical kinetic model has been developed to simulate the pyrolysis and combustion of sarin and its simulants. The structure and the name of reactant and specific products are displayed in Figure S2 in the Supplemental Material. The mechanism has been written in a comprehensive way, and includes both molecular and radical mechanisms. The model consists in four parts: (1) a C/H/O reaction base from our laboratory [34]; (2) a phosphorus reaction base from LLNL mechanisms for nerve agents surrogates [35]; (3) a submechanism of sarin and DIMP from Glaude et al. [13] updated in this work; (4) a molecular decomposition mechanism of DEMP and TEP developed in this work.

The first part (1) includes all the reactions involving radicals or molecules containing less than three carbon atoms, coupled with a reaction base for $\mathrm{C}_{3}-\mathrm{C}_{4}$ multi-unsaturated hydrocarbons $[34,36]$. Pressure-dependent rate constants and efficiency coefficients are included. Thermochemical data were taken from literature or computed software THERGAS based on group additivity [37]. The kinetic data were taken from the literature, or estimated from quantitative structure-reactivity relationships. The second part (2) consists in the
reaction base for phosphorus oxides from LLNL validated against TMP and DMMP reactions in flames [35].

The third part (3) contains the mechanisms for the degradation of sarin and DIMP. The primary mechanism was systematically built using generic rules of radical chain reactions [38], which represents all the possible reactions for the reactant and the radicals produced. Sub-mechanisms have been written in the same way for the reactions of the molecular products. Thermochemical data have been calculated theoretically for all the stable species and the free radicals produced, as well as the kinetic parameters of the molecular pericyclic reactions. Unimolecular initiations have been written in the reverse way as radical combinations and their rate constants were estimated by analogy with that of hydrocarbon radicals [39]. Parameters for the addition of OH on the $\mathrm{P}=\mathrm{O}$ bond and those for internal isomerization have been estimated with the correlation used for the alkenes [38]. Addition of H -atom on the $\mathrm{P}=\mathrm{O}$ bond has been neglected [35]. Rate parameters of radical decomposition by $\beta$-scission have been calculated theoretically with the methodology described above when the broken bond involves the P-atom. Reactions of alkyl chains were estimated by analogy with reactions of alkanes [38]. Rate constants of H -atom abstractions on the alkyl chain by H , OH and $\mathrm{CH}_{3}$ have been evaluated using an Evans-Polanyi correlation proposed for hydrocarbons [40]. The fourth part (4) includes the molecular mechanism of the degradation of DEMP and TEP and their primary products. Molecular decompositions were calculated theoretically as that of sarin and DIMP. These pericyclic reactions consist of concerted sixcentered and four-centered cyclic complexes as shown in Figure 2 for sarin and in Figure 4 for the simulants. Thermodynamic and kinetic parameters were calculated theoretically with the methods described above. The kinetic parameters were calculated for the high-pressure limit and for the low-pressure dependence from 0.01 to 100 atm . Note that the Master Equation calculations were computed together for the different unimolecular reactions
involved in each reaction scheme. All the data are displayed in the Table S3. A submechanism has been added for ethanol [41], which is formed during the decomposition of DEMP and TEP, to update the $\mathrm{C}_{0}-\mathrm{C}_{2}$ reaction base [34].

Figure 4: Molecular decomposition of sarin simulants (TEP, DIMP and DEMP), showing six-centered (blue) and four-centered (red) pericyclic reactions with their respective energy barriers at 0 K , computed at the $\mathrm{QCISD}(\mathrm{T}) / \mathrm{cc}-\mathrm{PV} \propto \mathrm{QZ} / / \mathrm{B} 2 \mathrm{PLYPD} 3 / 6-311+\mathrm{G}(2 \mathrm{~d}, \mathrm{~d}, \mathrm{p})$ level of theory and including ZPE (in kcal mol ${ }^{-1}$ ).

The final mechanisms were written in the format of CHEMKIN II [33]. The mechanism of sarin involves 226 species reacting in 1343 reactions, that of DIMP, DEMP and TEP (in one model), 313 species in 2048 reactions. The mechanisms are available among the Supplementary Materials.

## Results and discussion

The kinetic models were used to simulate the thermal behavior of sarin and its simulants and compare with available experimental data. Simulations were performed with the software SENKIN from CHEMKIN II [33].

Sarin pyrolysis was simulated at the conditions of Shan et al. [24], as shown in Figure 5. Figure 5 displays the percentage of remaining sarin as a function of temperature at various residence times. These results show a very good agreement with the experimental results, which ensures the quality of the methodology retained in this work. It confirms also that the thermal decomposition of this type of species occurs by a molecular decomposition mechanism, as already discussed in the literature [13,23,24].

Figure 5: Evolution of sarin decomposition as a function of residence time and temperatures using the comprehensive mechanism including the kinetic constants calculated at the QCISD(T)/cc-PV $\infty$ QZ//B2PLYPD3/6-311+G(2d,d,p) level of theory. Symbols: experiments [24]; lines, simulations.

The decomposition of the simulants were simulated at the conditions of Zegers and coworkers [7-9]. Experiments were conducted in a quartz-lined turbulent flow reactor with nitrogen as carrier gas, the pressure was kept at 1 atm for temperatures between 700 and 900 K. The initial compositions were 115 ppm for DIMP; 36 and 60 ppm for DEMP and 31 and 124 ppm for TEP. The decomposition products, as well as the reactants, were analysed by

FTIR, these products were: isopropanol and propene in the case of DIMP, while ethanol and ethylene in the cases of DEMP and TEP. Simulations reproduce the experiments at high working temperatures (Figure 6). In the case of lower temperatures, some discrepancies appear between simulations and experiences, which may be due to a deposition or a reaction of the reactants at the reactor walls, as mentioned by the authors. Such a heterogeneous effect should have a larger influence at lower temperature. For instance, in the case of TEP pyrolysis, the very high amount of ethylene observed at 802 K does not really match with TEP conversion and ethanol formation.

Figure 6: Mole fraction of the simulant and their respective alcohol and alkene formed during their thermal decomposition at various residence time and temperatures. Initial pressure, 1 atm; initial mole fraction of DIMP, 115 ppm ; DEMP, 36 ppm and TEP, 31 ppm . Symbols, experimental results: DIMP [7], DEMP [8] and TEP [9] ; lines, simulation.

At higher temperatures, the primary decomposition products, such as ethylene and ethanol, also react. Figures 7 compares the CO yields obtained during the reaction of TEP in shock tube, in pyrolysis (Fig. 6a-c) and oxidation (Fig. 6d-g) respectively, by Neupane et al. [15] and simulations carried out with the model from these authors [16] and our model.

Experimental uncertainty in the measured CO mole fraction was estimated to be $7.2 \%$ or $\pm 123$ ppm [15]. The results show that both models follow the same behaviour in pyrolysis and oxidation. In pyrolysis, the increasing amount of CO with temperature indicate a change in the ratio between ethylene and ethanol formation during TEP decomposition (see Figure 4), ethanol being the source of CO in pyrolysis. Sensitivity analyses show that in pyrolysis the most promoting reaction for CO formation is the decomposition of TEP into $\mathrm{C}_{2} \mathrm{H}_{5} \mathrm{OPO}_{2}$ and ethanol, whereas the competing reaction of decomposition into diethylphosphate and ethylene inhibits the most the production of CO. Note that the radical mechanism does not play any role in the decomposition of TEP and intermediates until decomposition of ethylene and ethanol. The better agreement of our model at the highest temperature may come from the increasing importance of the pressure effect on molecular decomposition of TEP and intermediates, which is included in our model.

In combustion, the model is able to predict both CO profile shape and maximum amount. An underestimation is observed at short residence times at the lowest temperature, whereas the decay of CO for longer residence times is underestimated at 1437K. Sensitivity and flow analyses show that in combustion, the reactions of CO are linked to the hydrocarbon mechanism and to its interactions with phosphorus oxide reaction bases, which need certainly to be improved. The most promoting reactions for the formation of CO are reactions of oxidation of ethylene with O atoms and OH radicals.

Figure 7: CO time history during TEP pyrolysis (a-c) and oxidation (d-g). Pyrolysis: (a, b, c) $X_{\text {TEP }}=0.25 \%$ in Ar, $P=1.3-1.4$ atm. Combustion: (d, e) $X_{\text {TEP }}=0.076 \%, \varphi=0.075$, bath gas Ar, $\mathrm{P}=1.42-1.32 \mathrm{~atm},(\mathrm{f}, \mathrm{g}) \mathrm{X}_{\mathrm{TEP}}=0.038 \%, \varphi=0.078, \mathrm{P}=1.27-1.17 \mathrm{~atm}$. Symbols, experimental results [15]; simulations, this work (solid curve), literature model [16] (dashed curve).

Figure 8 compares the conversion of sarin and its surrogates in a close vessel at the conditions of Figure 4. It appears that the decomposition of sarin is the fastest whereas DEMP is the less reactive simulant. DIMP appears to be the best surrogate for sarin among these species since it shows a close reactivity and similar hydrocarbon products, i.e. propene. An interesting point is that at all conditions, radical reactions remains negligible in the conversion of the organophosphorus reactant and of the intermediates described in Figure 3. A flux analysis performed for sarin in presented in Figure S3. Whatever the temperature is, sarin decomposes by the loss of propene followed by the elimination of HF , producing $\mathrm{CH}_{3} \mathrm{PO}_{2}$, which eventually breaks into a methyl radical and $\mathrm{PO}_{2}$ and initiates radical reactions. The final decomposition products of sarin and its surrogates, which do not contain phosphorus, are propene and isopropyl alcohol in the case of sarin and DIMP, ethylene and ethanol in the
cases of DEMP and TEP. These products react then in radical reactions. Whatever the conditions are, even when the pool of radicals due to the combustion of hydrocarbon and alcohol increases, the organophosphorus species decompose only by the low barrier pericyclic reactions. H -atom abstractions remain always negligible in sarin consumption, and account for only $1 \%$ of the flux at 2000K. Same conclusions can be done for DIMP, DEMP and TEP.

Figure 8: Conversion of sarin and its simulants $v s$. temperatures in pyrolysis in a closed vessel. Initial pressure, 1 bar; residence time, 0.5 s .

## Conclusions

The effect of molecular decomposition reactions on thermal degradation of organophosphorus species is investigated. High level theoretical calculations of the pericyclic rate constants have been performed with an original methodology, taking into account the tunnel effect, the effect of the pressure and an exhaustive treatment of internal rotations both in the reagents and in the transition states. Comprehensive detailed mechanisms were developed for the thermal decomposition and combustion of sarin, DIMP, DEMP, and TEP which includes radical chain reactions and all the molecular pericyclic reactions. Simulations and comparisons with the experimental results of the literature show that our model predicts correctly the thermal decomposition and the combustion of sarin and its simulants. It appears that these species decompose uniquely through the pericyclic reactions, until species without P-atom are produced. The models can then be drastically reduced to keep only these unimolecular decompositions in the primary mechanisms of organophosphorus reactants, while more complex radical reactions concern small phosphorus oxides, and hydrocarbon and alcohol products. Further improvements of the model would then focus on the phosphorus reaction base and its connexion with hydrocarbon reactions.

Table S2: Parameters used in the master equation simulation of the molecular decomposition of sarin and its simulants.

| Species | $\left\langle\boldsymbol{E}_{\text {down }}\right\rangle\left(\mathrm{cm}^{-1}\right)$ | $\sigma(\AA)$ | $\varepsilon(\mathrm{K})$ |
| :--- | :---: | :---: | :---: |
| N2 | 250 | 3.621 | 97.53 |
| Sarin |  | 6.020 | 701.584 |
| DIMP |  | 6.940 | 603.276 |
| DEMP |  | 6.377 | 587.218 |
| TEP |  | 5.936 | 629.241 |

The collisional energy transfer probability was described by the exponential down model, with $\left\langle\mathrm{E}_{\text {down }}\right\rangle=\left\langle\mathrm{E}_{\text {down }}\right\rangle \times(\mathrm{T} / 300)^{0.85}\left(\mathrm{~cm}^{-1}\right)$. The Lennard-Jones parameter were calculated from the method proposed by Tee et al. (L.S. Tee, S. Gotoh, W.E. Stewart, Molecular Parameters for Normal Fluids. Lennard-Jones 12-6 Potential, Industrial \& Engineering Chemistry Fundamentals. 5 (1966) 356-363).

Table S3: High-pressure limit ( $\mathbf{k}_{\infty}$ ) and dependent pressure rate constants calculated for the molecular decomposition of sarin and its simulants calculated using the QCISD(T)/cc-PV $\infty$ QZ//B2PLYPD3/6-311+G(2d,d,p) level of theory.
