30 **Abstract:**

31 To resolve the various types of biological ice nuclei (IN) with atmospheric models, an
32 extension of the empirical parameterization (EP) (Phillips et al. 2008; 2013) is proposed to
33 predict the active ice nuclei from multiple groups of primary biological aerosol particles
34 (PBAPs). Our approach is to utilize coincident observations of PBAP sizes, concentrations,
35 biological composition, and ice-nucleating ability. The parameterization organizes the PBAPs
36 into five basic groups: fungal spores, bacteria, pollen, viral particles, plant/animal detritus,
37 algae, and their respective fragments. This new biological component of the EP was
38 constructed by comparing predicted and observed concentrations of PBAP IN at the Amazon
39 Tall Tower Observatory (ATTO) site located in the central Amazon. In addition to the
40 observations from the ATTO site, PBAP IN activity from the literature is used in constraining
41 the fitting parameters of EP. The parameterization has empirically derived dependencies on the
42 surface area of each group (except algae), and the effects of variability in their mean sizes and
43 number concentrations are represented via their influences on the surface area. The
44 concentration of active algal IN is estimated from literature-based measurements.

45 Predictions of this new biological component of the EP are consistent with previous
46 laboratory and field observations not used in its construction. The EP scheme was implemented
47 in a 0D parcel model. It confirms that biological IN account for most of the total IN activation
48 at temperatures warmer than -20°C and at colder temperatures dust and soot become
49 increasingly more important to ice nucleation.

53

54

55 **1 Introduction**

56 Often referred to as bioaerosols, primary biological aerosol particles (PBAPs) are a
57 subset of biogenic particles emitted from the Earth's surface. They consist of biological
58 material such as viruses, algae, bacteria, fungal spores, pollen, plant and animal detritus, and
59 their fragments and secretions. In the ambient atmosphere, bioaerosols may be present in the
60 form of clusters, single particles, and agglomerates and exist in a variety of shapes such as rods,
61 spirals, spherical, or spheroidal forms. A review article by Després et al. (2012) describes the
62 typical concentrations of these PBAPs in the ambient air, their sizes, and sampling techniques.
63 Bioaerosols can act as ice nuclei (IN) to initiate ice at temperatures often warmer than -12°C ,
64 well above the homogeneous freezing point (Prenni et al. 2009; DeMott and Prenni, 2010;
65 Morris et al. 2012; Fröhlich-Nowoisky et al. 2016). To maintain consistency with previous EP
66 papers (e.g. for mathematical symbols), we will use the term, 'IN' rather than 'ice nucleating
67 particles' (INPs, Vali et al. 2015) for this paper. They can also act as giant cloud condensation
68 nuclei (CCN) (Barahona et al. 2010; Delort et al. 2010) and may play an important role in the
69 hydrological cycle. Bioaerosols may influence the formation of precipitation, especially in
70 pristine air over densely vegetated areas (Phillips et al. 2009; Pöschl et al. 2010; Huffman et
71 al. 2013; Prenni et al. 2013).

72 In warm-based convective clouds, rain production can occur through collision-
73 coalescence that facilitates the heterogeneous raindrop freezing to form graupel ('*warm rain*
74 *process*'). Heterogeneous nucleation of ice crystals and their subsequent growth to form snow
75 and graupel particles ('*ice crystal process*') plays an essential role in rain formation in
76 convective clouds with higher clouds bases (e.g. Rogers and Yau, 1989; Pruppacher and Klett,
77 1997). The role of bioaerosols in altering cloud microphysical properties, precipitation, and
78 ecosystem interactions has been recognized for many years and is a topic of increasing interest
79 (e.g. Pöschl et al. 2010; Huffman et al. 2013; Amato et al. 2015). The PBAPs can play an

80 important role in altering the cloud microphysical processes and precipitation formation
81 through warm rain processes. However, large uncertainty still exists regarding their potential
82 to facilitate precipitation, particularly their impact on global or on regional scales (Hoose et al.
83 2010a; Morris et al. 2011).

84 As reviewed in Després et al. (2012), several previously published studies have reported
85 ice nucleation activities of various biological species, including fungi, pollen, algae, and
86 bacteria. Among various PBAP species, higher ice nucleation activity is observed for bacterial
87 and fungal particles in clouds. The quantitative measurements of biological IN in the
88 atmosphere are rare. Biological IN in the atmosphere exhibit strong temporal and spatial
89 variations (Christner et al. 2008; Pouzet et al. 2017). For a better understanding of their impact
90 on clouds, more quantitative measurements of biological IN in the Earth's atmosphere are
91 required.

92 With the limited observations of biological IN, numerical models can serve as an
93 important tool for investigating their effect on cloud microphysical processes and hence on
94 precipitation. Using a 1.5-dimensional cloud model, Levin et al. (1987) studied the efficiency
95 of cloud seeding with bacteria. Ariya et al. (2009) showed that biological IN could trigger cloud
96 glaciation through ice multiplication processes. Diehl and Mitra (2015) implemented PBAPs
97 (pollen and bacteria) in a parcel model using the ice-active mass site density approach (Kanji
98 et al. 2017 and references therein) and found that they were not involved in significant ice
99 formation. Hummel et al. (2018) implemented PBAPs in the regional atmospheric model. They
100 showed that although PBAPs were very efficient IN at high subzero temperature, due to their
101 low atmospheric concentration, it is difficult to quantify their impact on cloud properties.
102 However, they also showed that PBAP can influence the cloud ice phase in the clouds with
103 cloud temperatures below $-15\text{ }^{\circ}\text{C}$ in the absence of any other IN. Hiron and Flossmann (2015)
104 studied the potential impact of the presence of bacteria as an extremely IN active PBAP on

105 cloud and rain development. They noticed a significant increase in the rainfall flux in the
106 simulation with only bacteria as IN. However, in the simulations where all other IN modes
107 were also forming ice, their influence on rainfall became negligible. Phillips et al. (2009)
108 showed that an increase in PBAP resulted in more numerous cloud droplets through their CCN
109 activity and reduced the precipitation production via warm rain process, boosting cloud lifetime
110 and extent. In the case of higher bioaerosol, the extra heterogeneous ice from biological IN
111 particles can only partially counteract that effect, indicating the CCN activity of PBAPs is more
112 important than their IN activity for the simulated warm-based convection. Several studies have
113 used regional as well as global models to understand the geographical variation and climatic
114 importance of bioaerosols (e.g. Burrows et al. 2009a, b; Hoose et al. 2010a; Sesartic et al.
115 2012). The empirical data included in these models are highly uncertain. Most of the
116 parameterizations of heterogeneous ice nucleation of biological particles are based on
117 laboratory measurements or derived from theory.

118 Consequently, the cloud-resolving numerical models need to be constrained and
119 confirmed by observational data of biological IN to have a better estimation of their effect on
120 clouds. Using a ‘bottom-up approach’ (i.e. measurements of ice nucleation activity of
121 biological species in the laboratory to represent atmospheric ice initiation) in the numerical
122 models can introduce significant bias in the active IN concentrations because the particular
123 biological species studied in the laboratory may not necessarily be a good representative of the
124 corresponding wider PBAP population in the atmosphere. Instead, there is a need for a better
125 parameterization of heterogeneous ice nucleation of biological IN that accounts for diversity
126 in their physical and chemical characteristics in the atmosphere. We have followed a ‘top-down’
127 approach in the current study to resolve the ice nucleation activity of multiple groups of PBAPs
128 collected directly from the atmosphere. The empirical parameterization (EP) for heterogeneous
129 ice nucleation presented here is based on the active surface site density approach (e.g. Phillips

130 et al. 2008; Niemand et al. 2012; Kanji et al. 2017 and references therein). The assumption of
131 active surface site density has some limitation on consistently describing freezing curves over
132 a wide range of surface area as described in Beydoun et al. (2016). They suggested an
133 alternative approach invoking a continuum assumption on the ice nucleating activity (contact
134 angle) of an aerosol particle's surface which does not require any assumptions about the size
135 or number of active sites.

136 The first empirical ice nucleation parameterization for biological particles was
137 proposed by Phillips et al. (2008) where biological particles were assigned as a part of insoluble
138 organic particles. An estimation of the number of active IN consisting of insoluble aerosol
139 species assumed that it was approximately proportional to the total surface area of its aerosol
140 particles. In the subsequent study, Phillips et al. (2013) revised the original EP scheme by
141 replacing insoluble aerosol species by the new group specifically for PBAP IN. However, their
142 scheme does not address the separate activity of various groups of PBAPs with different ice-
143 nucleating abilities.

144 In the present study, a framework for parameterizing the heterogeneous ice nucleation
145 of biological particles is formulated and accounts for contributions from various groups of
146 PBAPs including

- 147 1) Fungal spores and associated fragments;
- 148 2) Bacteria and their fragments;
- 149 3) Pollen and their fragments;
- 150 4) Viral, plant/animal detritus;
- 151 5) Algae.

152 Matthias-Maser and Jaenicke (1995) first described these groups of PBAPs through
153 observations. The EP's treatment applies to deposition and condensation-/immersion-freezing
154 modes.

155 The proposed scheme is empirical, mostly based on coincident observations of PBAP
156 size distributions and active biological IN sampled from the atmosphere over the Amazon
157 Rainforest with abundant PBAPs. Prenni et al. (2009) have revealed that over the Amazon
158 Rainforest the contribution of local biological particles to ice nucleation is increased at warmer
159 atmospheric temperatures, whereas the contribution of dust particles is increased at colder
160 temperatures, making this region ideal for biological IN measurements.

161

162

163 **2 Material and methods**

164

165 **2.1 Measurement site**

166 The samples for the present study were collected over the central Amazon basin at the
167 Amazon Tall Tower Observatory (ATTO; Andreae et al. 2015). The ATTO site is in the middle
168 of the Amazon Rainforest in northern Brazil (see Fig. 1), about 150 km northeast of Manaus
169 (120 m above sea level) with coordinates S 2° 08' 45.13" W 59° 00' 20.12". The measurement
170 facilities at the ATTO site consists of a 325 m tall tower and two 80 m towers, one of which is
171 a triangular mast currently used for a wide set of aerosol measurements (Andreae et al. 2015).
172 The immediate surroundings as well as the ATTO footprint region are covered by an old-
173 growth undisturbed forest with minimal anthropogenic impact.

174 Meteorological conditions vary throughout the year with a wet (February–May), a
175 dry (August–November), and a transition from wet to dry season (December–January)
176 (Pöhlker et al. 2019). This classification of seasons is consistent with seasonality of
177 atmospheric pollution, rainfall, and air mass origin. Over the Amazon rainforest the PBAPs
178 are ubiquitous throughout the year (Martin et al., 2010). During the wet season, the atmospheric
179 boundary layer over the Amazon is relatively clean with low aerosol number concentrations
180 (Artaxo et al. 2002; Martin et al. 2010; Zhou et al. 2002) and the hydrological cycle is strongly
181 influenced by biogenic aerosols. However, during the Amazonian dry season, the atmospheric
182 aerosol concentrations are considerably higher due to biomass burning (Andreae et al., 1988;
183 Artaxo et al., 2002; Pöhlker et al. 2018; Holanda et al. 2019) and mixed-pollution scenarios
184 (Pöhlker et al. 2018). A detailed description of the aerosol size distribution and the CCN
185 characteristics at the ATTO site are given by Pöhlker et al. (2016, 2018). Additional details
186 on the diurnal temperature and wind variations, precipitation amount, and aerosol
187 characteristics at the ATTO site can be found in Andreae et al. (2015).

188 Sampling was performed during the dry season in the Amazon between 5 and 18
189 September 2018. The sample collection was interrupted on a few days including September 9
190 and 15 due to damage to power supply, so sample collection was only possible for the twelve
191 days mentioned in Figure 5a. As shown in Fig. 1, the sampling took place at the triangular mast
192 site. The sampled air was carried through a stainless-steel tubing with a diameter of 0.75 inches
193 to the aerosol sampling unit installed in a laboratory container located at the base of a triangular
194 mast. A Total Suspended Particles (TSP) inlet was installed on a triangular mast at 60 m above
195 ground level to ensure that the air was sampled above the canopy, which has an average height
196 of ~23 meters. To avoid condensation in the filter holder, the sampled air from the TSP inlet
197 was dried to a relative humidity < 40% using silica gel driers.

198 The inlet used for sample collection in the current study has been optimized to achieve
199 a maximum sampling efficiency (Moran-Zuloaga et al. 2018), however, a certain amount of
200 particle loss is unavoidable. The particles smaller than 100 nm are more prone to diffusive
201 losses and not relevant for the current study. Daniel Moran-Zuloaga et al. (2018) documented
202 potential losses in the accumulation and coarse mode particles of aerosol particles in this inlet
203 system which are more relevant to the current study. They calculated the transmission
204 efficiencies of the PBAPs for the inlet used in the current by using standard density of 1 g/cm³
205 as best guess for typical PBAP densities. The aerosol transmission efficiency starts at about
206 100% (full transmission) for particles with diameter around 0.7 μm and then declines with
207 increasing particle size. Based on their calculation typical transmission efficiencies for PBAPs
208 with diameter 1, 2, 4, 8, and 10 μm were 98, 97, 91, 72, and 55% respectively. Correction to
209 PBAP size distributions was applied accordingly.

210 A detailed analysis about the back trajectories arriving at the ATTO site is presented
211 in Moran-Zuloaga et al. (2018) and Pöhlker et al. (2019). They showed that the ATTO-relevant
212 back trajectories followed a seasonal swing between a Northeast path during the wet season
213 and a Southeast path during the dry season as a response to the annual north–south Intertropical
214 Convergence Zone migration. Figure 1 shows the seven-day analysis from the Hybrid Single-
215 Particle Lagrangian Integrated Trajectory Model (Draxler and Rolph, 2003) on three sampling
216 days (11-13 September 2018) at 60 m above ground. Back trajectories revealed that the
217 anthropogenic emissions from Manaus did not significantly impact the sampled air mass,
218 however, the atmospheric conditions at the ATTO site during our sampling period were not
219 pristine.

220

221 **2.2 Aerosol measurements and sample collection**

222 *2.2.1 Aerosol size distribution measurements*

223 The aerosol size distribution and number concentration at the ATTO site was measured
224 by a Scanning Mobility Particle Sizer (SMPS; TSI Inc) and an Aerodynamic Particle Sizer
225 (APS; TSI Inc). The SMPS measures the electrical mobility diameter (10-430 nm), while the
226 APS gives aerodynamic diameters (0.5-20 μm) of the particles. There were frequent
227 interruptions in the aerosol measurements during our observational period due to severe
228 lightning strikes and associated damage to the power supply and installation. Therefore,
229 measurements of the aerosol size distribution from SMPS and APS was available only for a
230 few days.

231 *2.2.2 Aerosol collection by filter method*

232 Table 1 describes the sampling type, duration, flow rate, purpose, and corresponding
233 instrument in which the samples were analyzed. The aerosol samples were collected from
234 September 5-18, 2018, for a twelve-day period at the ATTO site. The collection of aerosol
235 samples for the drop freezing tests and microscopic analysis was carried out via the TSP inlet
236 through a four-stage stacked filter unit. Four Polytetrafluoroethylene (PTFE) membrane filter
237 papers (25 mm diameter) (Sartorius Stedim Biotech) with the pore sizes of 5 (outermost), 1.2,
238 0.45, and 0.2 (innermost) μm were used for the sampling. The filters were placed in an airtight
239 aluminum filter holder in order of decreasing pore size. Samples were collected with a vacuum
240 pump (VWR vacuum gas PM20405-86). The flow rate was controlled using a flow meter
241 (Kytola instruments) equipped with a needle valve. Collection efficiencies of PTFE membrane
242 filters of pore size 5 and 1.2 μm are much higher compared to Millipore and glass filters of
243 similar pore sizes (Soo et al., 2016) and thus inevitably most of the aerosol particles are
244 collected on the first two filters.

245 Cascade filter samples were collected with an average volumetric sample flow rate of
246 4 Lpm (Liters per minute) for approximately 4 hours each day. In addition, a set of cascade
247 filters with a sample flow rate of 1.5 Lpm was collected for about 16 hours. A set of aerosol
248 samples with a sample volume of about 200 L was collected using only a 0.2 μm filter to
249 estimate IN concentrations activated by the immersion-freezing mode in Frankfurt Ice Nuclei
250 Deposition Experiment (FRIDGE-IMM) chamber.

251 Samples were sealed carefully in a sterile container and stored at 4°C at the ATTO site.
252 The aerosol samples when stored for prolonged time under such conditions, can show changes
253 in their ice nucleation activity. Stopelli et al. (2014) found a degradation in the active IN
254 concentration by a factor of two at temperature between -8 to -12°C in snow water samples
255 stored at 4°C for 30 days. After the campaign was completed, the samples were transported to
256 the University of Sao Paulo and later to Lund (Sweden). The samples were stored in a deep
257 freezer at -25°C at Lund until they were analyzed by scanning electron microscopy (SEM) and
258 drop freezing tests.

259 *2.2.3 Aerosol collection by Programmable Electrostatic Aerosol collector (PEAC7)*

260 In addition to the filter method, aerosol sampling was performed using a Programmable
261 Electrostatic Aerosol collector (PEAC7) (Schrod et al. 2016). The PEAC samples were
262 analyzed to estimate IN activated by deposition and condensation-freezing mode in the
263 FRIDGE-STD chamber. A total of twelve samples were collected using PEAC during the field
264 campaign held from September 5-18, 2018 (see Figure 5).

265 In addition, PEAC samples were used for imaging PBAPs under SEM. On each
266 sampling day, aerosol particles were collected at a volumetric flow rate of 2 Lpm using the
267 PEAC7 for 50 minutes. The PEAC7 unit used in the current analysis is based on the single
268 wafer electrostatic aerosol collector described in Klein et al. (2010). In PEAC7, aerosol

269 particles are introduced through a central inlet into the field of electrons emitted by 12 gold
270 electrodes. The aerosols are negatively charged and carried to the positively charged silicon
271 (Si) wafers (Wacker-Siltronic, thickness: 0.7 mm, diameter: 45 mm) where they are deposited
272 on the surface (Klein et al. 2010).

273 We have applied the correction to the IN concentrations and size distribution of
274 bioaerosol particles by assuming the PEAC7 collection efficiency of 60% observed by Schrod
275 et al. (2016). Klein et al. (2010) and Schrod et al. (2016) provide additional details on the design
276 and working principle of PEAC7.

277

278 **2.3 Scanning electron microscopy analysis**

279 Primary bioaerosol particles were analyzed by using a variable pressure Tescan Mira3
280 High-Resolution Schottky FE-SEM located in the Geology department at Lund University. It
281 should be noted that the SEM analysis was limited to three days: 9 (night-time; hereafter
282 0911N), 12 (day-time; hereafter 0912D) and 13 (day-time; hereafter 0913D) September, as an
283 intensive collection of SEM images characterizing the size distributions for all the samples was
284 not practical. During each of the three days, the size distribution and IN number were estimated
285 for total biological aerosols (5 + 1.2 μm filters) and fractions obtained on 5 and 1.2 μm filters.
286 Thus, nine pairs of measurements of active IN and size distributions were available from three
287 intensive sampling days mentioned above and will be referred to as the nine ‘cases’ in the
288 remaining part of the manuscript.

289 To reduce charging under the electron beam, the samples were coated with a thin layer
290 (10 nm) of Palladium, sputter-deposited prior to the SEM analysis. The coated samples were
291 examined at a beam size of 15 keV with a working distance of 10 mm. The working distance

292 was lowered (between 5 and 10 mm) for Si wafer samples to obtain clearer images of particles
293 with diameter (D) $< 1.5 \mu\text{m}$.

294 To quantify the PBAPs, the main method of identification was purely based on the
295 morphological characteristics, following the method of Matthias-Maser and Jaenicke (1991,
296 1994). The organic nature of particles from energy-dispersive X-ray spectrometer (EDS)
297 analysis was confirmed if $(\text{C}+\text{O}) > 75\%$ and $1\% < \text{P, K, Cl} < 10\%$ (Coz et al. 2010). The SEM
298 system used in the current study was equipped with an energy-dispersive X-ray spectrometer
299 (EDS, X-Max^N 80, Oxford instruments, 124 eV, 80 mm²). The EDS could detect the
300 composition of individual particles semi-quantitatively for elements with an atomic number
301 greater than 6 including light elements such as C, N, O. Errors in measurements of the
302 composition of light elements by EDS vary for individual samples and are below 2 percent
303 overall. The EDS was performed at a beam intensity of 15 keV with a working distance of 10
304 mm. The Si and F peaks in the EDS spectra were not considered for particles from the Si wafer
305 and PTFE filter respectively, because of the interference from the substrate. The duration of
306 each EDS collection was limited to 10-12 seconds to avoid particle damage. Because other
307 elements like S, Ca, or Si can also be tracers of PBAPs, this analysis should be treated as a
308 conservative estimate.

309 Before imaging the individual biological particles, wide reference areas each 100 x 100
310 μm in size were chosen randomly and corresponding images of those areas were saved as
311 reference pictures along with their positions on the filter paper. Particles located in these
312 predefined reference spots were counted, and high-resolution images were acquired for those
313 particles. About five particles were observed roughly at each predefined reference spots on the
314 filter samples. The maximum dimension of particles was recorded and saved. In this study the
315 maximum dimension is treated as the diameter of the particle.

316 Based on the number of PBAPs detected in the scanned filter area, the bioaerosol
317 number was upscaled to the whole filter area. The size distribution of the PBAPs was classified
318 into 40 predefined size bins covering a size range from 0.2-40 μm . The measured number was
319 converted to an airborne concentration (per m^3 of air) based on the sampled air volume. The
320 recorded data was then used to classify the particles into the basic PBAP groups: fungal spores,
321 bacteria, pollen, viral particles, plant/animal detritus, algae, and their respective fragments. The
322 primary classification of PBAPs into different groups was based on similarity in morphological
323 characteristics with those reported in earlier studies. Despite all possible efforts to categorize
324 the identified PBAPs, not all of them could be attributed to any PBAP group. A small fraction
325 of the PBAPs ($\sim 5\%$) which did not find any similarity in morphology with the PBAP groups
326 considered here were classified as ‘unidentified’ PBAPs. These unidentified particles were not
327 included in the size distributions of PBAPs presented here.

328 Since the emphasis of the current study was to characterize the size distribution of
329 PBAPs, non-biological particles were excluded from the study. In addition to filter samples, Si
330 wafers were analyzed under SEM using similar methodology. Additional details about SEM
331 analysis including scanned area and number of bioaerosol images collected are given in Table
332 2. More than 0.1% of the total filter area was investigated under SEM and > 200 images were
333 collected for each sampling day considered for SEM analysis. For Si wafers, more than 0.06%
334 of the total area was scanned under SEM and ~ 100 images of PBAPs were collected.

335 Identification and counting of particles with $D < 1.5 \mu\text{m}$ (e.g. bacteria) on filter samples
336 was challenging as they were often hidden inside the dense membrane of filter material.
337 Therefore, the size distribution of biological particles with $D < 1.5 \mu\text{m}$ were determined mostly
338 by SEM imaging of Si wafers. This was justified as the size distributions from the Si wafer and
339 corresponding filter were in good agreement within the overlapping region between 1.5 and 5
340 μm . The collection efficiency of the 5 μm filter for various particle diameters was estimated

341 based on total aerosol number concentrations from the SMPS, APS and the size distribution of
342 total particles collected on the 1.2 μm filter. The SMPS and APS aerosol size distributions used
343 here were from 0914, a typical sampling day at the ATTO site. Based on the collection
344 efficiency of the 5 μm filter, the size distributions of biological particles on 5 and 1.2 μm filters
345 were estimated separately. The estimated collection efficiency for particles with a diameter
346 between 0.3-6 μm was variable between 0.81 and 0.99 whereas it was unity for other size
347 ranges. The collection efficiency of 1.2 μm filters was not measured and assumed to be unity
348 (for particles with $D > 0.1 \mu\text{m}$) based on measurements by Soo et al. (2016).

349 After acquiring the images of bioaerosols from SEM analysis, we classified them into
350 common PBAP groups based on size and morphology.

351

352 **2.4 Flow cytometry analysis**

353 In addition to SEM, we conducted flow cytometry (FCM) analysis to estimate the total
354 bioaerosol number concentration. FCM is widely used to detect and measure the physical and
355 chemical characteristics of cells or particles. This is a fluorescent technique, in which cells are
356 often labeled with fluorescent markers so that light is absorbed and then emitted in a
357 wavelength band. For each sample extract, cell counts were performed on 450 μL triplicates
358 added with 50 μL 5% glutaraldehyde (stored at 4°C). For analysis, samples extracts were
359 stained with SYBRGreen I (Molecular Probes Inc.). This stains nucleic acids, and thus reveals
360 all DNA-containing particulate matter (e.g. viruses, bacteria, archaea, fungi, pollen, plant and
361 animal cells). The parameters used with FCM did not detect chlorophyll, proteins, and
362 carotenoids. The wavelengths for excitation and emission were 488 and 530 nm, respectively.
363 The FCM counts were performed for 3 minutes. The flow cytometry technique used in the
364 current analysis can detect particles as small as 0.3 μm (Lippé, 2018).

365

366 **2.5 Measurement of Ice nucleating particles**

367 IN in the air were measured using the FRIDGE chamber of Goethe University,
368 Frankfurt. FRIDGE operates in two different modes: a) as a low pressure diffusion chamber
369 (here called FRIDGE-STD) for the detection of deposition/condensation freezing IN collected
370 onto Si wafers (see 2.2.3), and b) as a cold stage freezing array (here called FRIDGE-IMM)
371 for the measurement of immersion freezing IN in extracts of filter samples (see 2.2.2).
372 Additional details have been described in previous studies (Klein et al., 2010; Schrod et al.,
373 2016; DeMott et al., 2018, 2018a).

374 *2.5.1 Measurement of IN activated by deposition and condensation freezing mode using* 375 *FRIDGE-STD*

376 The FRIDGE-STD method applies a static low-pressure diffusion chamber for
377 activation, growth and counting of IN activated at temperatures between 0 and -30°C. For
378 analysis, a Si wafer substrate that was previously laden with electrostatically precipitated
379 aerosol particles (using PEAC-7) was placed on the cold stage in the chamber. The chamber
380 was then closed, evacuated, and cooled to the desired temperature. The surface temperature
381 was measured using a PT-1000 sensor. In the next step, water vapour was introduced into the
382 chamber by opening the connection to the vapour source. The supersaturation with respect to
383 ice over the Si wafer was then estimated as the ratio of vapour pressure in the chamber over
384 saturation vapour pressure at the surface temperature. The number of activated ice crystals
385 grown was counted using automatic picture analysis software. All the twelve samples collected
386 on Si wafer by PEAC-7 were processed for IN activation in the FRIDGE-STD mode (see
387 Figures 5a-c).

388 *2.5.2 Measurement of IN activated by immersion freezing mode using FRIDGE-IMM:*

389 The number concentrations of IN in the air activated by immersion freezing mode were
390 measured on the cold stage of FRIDGE-IMM with the drop freezing method of Vali (1971), as
391 described by Ardon-Dryer and Levin (2014) and DeMott et al. (2018). The aerosol samples
392 collected on 0.2 μm filters were used for the drop freezing experiment. Each filter was placed
393 in 5 ml of deionized water and stirred vigorously for a few minutes to create particle
394 suspensions. Around 60 droplets, each with a volume of 2.5 μL were pipetted onto on a clean,
395 salinized Si wafer, with the chamber almost closed, but at ambient atmospheric pressure. The
396 temperature of the cold stage was lowered by 1°C min^{-1} . A steady flow of synthetic air of 1 L
397 min^{-1} through the chamber to avoid the condensation and rime effects. The number of drops
398 that froze as function of temperature was recorded by the charge-coupled device (CCD)
399 camera. Two runs of drop freezing experiments were conducted for each sample. In FRIDGE-
400 IMM, eleven filter samples were treated to measure the IN concentrations activated by
401 immersion freezing mode (see Figure 5d).

402 *2.5.3 Quantification of biological IN*

403 The concentration of biological IN in the air, active between -5°C and -15°C , was
404 determined by conducting the drop freezing experiments in the LED-based Ice Nucleation
405 Detection Apparatus (LINDA) LINDA chamber as described below. The detailed technical
406 information and working principle of LINDA are described by Stopelli et al. (2014) and
407 summarized here. The LINDA device has an array (7×8) of red LEDs (Light Emitting Diodes;
408 645 nm wavelength). This array is mounted on a printed circuit board casted into a
409 polycarbonate housing and submersed in a cold bath. A liquid sample is distributed in a total
410 of 52 sample tubes (0.5 mL Eppendorf). These tubes are held in another polycarbonate plate
411 and placed onto the LED array so that each tube is located above one LED. The temperature is
412 recorded by four sample tubes with cast-in Pt-1000 temperature sensors placed in the corner
413 positions of the tube holder.

414 Before starting the freezing experiment, 75% of each filter sample was placed in 30 mL
415 of deionized water to create suspensions, of which 20 ml was used for the freezing experiment
416 in LINDA. The remaining 25% of the filter was saved and stored in a petri dish for SEM
417 analysis. The filter samples were cut using sterilized scalpel. To make the LINDA sample
418 extract clearer to facilitate the imaging, 2 ml of NaCl (in liquid form, 0.8% w/v) was added to
419 the solution. Adding NaCl to the LINDA sample extracts should not affect its freezing
420 characteristics since no freezing event was noticed for the solution containing deionized water
421 and NaCl. The remaining 10 ml solution was saved and stored in a refrigerator (at 4°C) for
422 subsequent flow cytometry.

423 The sample extract is distributed in a total of 52 sample tubes each of which contain
424 400 µL of the sample extract. The samples were analyzed at the cooling rate of 0.4°C min⁻¹.
425 Images of the tubes are recorded every six seconds using a Monochrome camera, during which
426 temperature was changed by 0.04°C. For each filter sample extract, two sets of freezing
427 experiments were carried out. In the first set of experiments, sample extracts were untreated
428 (no heating) for total IN concentration measurements. In the second set, the samples were
429 heated to 95°C for 10 minutes to denature the IN activity of biological IN following Christner
430 et al. (2008) and Garcia et al. (2012). The concentrations of active biological IN were calculated
431 as the difference between the concentrations of active IN measured with and without heating.
432 However, it should be noted that heat treatment may not inactivate every ice nuclei site of
433 biological material and hence the values presented should be considered as the lowest possible
434 estimates of biological IN.

435 Previous findings based on heat treatment (e.g. Garcia et al. 2012; Joly et al. 2014)
436 showed that the relative contribution of biological IN decreases with temperature, with 97% to
437 100% of total IN active at -8°C and 77% at -12°C as other particles including dust, become
438 active at colder temperatures. Hill et al. (2014) showed that heat treatment (at 95°C) of bacterial

439 samples obtained by leaf washing reduced the ice nucleation activity by >75% at -10°C .
440 According to Conen et al. (2011), heating to 100°C reduced IN active at -12°C by 70–98%.
441 O’Sullivan et al. (2015) showed that heat treatment (90°C) of soil samples containing organic
442 decomposing matter reduced ice nucleation activity at -12°C to $\sim 1/10$.

443 In addition, the concentration of active biological IN at temperatures colder than -15
444 $^{\circ}\text{C}$ was estimated for the sample extract of 0911 (from section 2.5.1) based on heating tests
445 (95°C for 10 minutes) in FRIDGE-IMM. The methodology of drop freezing experiment is
446 already described in section 2.5.1.

447

448 **2.6 Classification of PBAPs based on SEM images**

449 After collecting the bioaerosol images, we classified them into common PBAP groups
450 based on size and morphology. Table 3 presents the general size and morphological
451 characteristics of different PBAP groups, based on the literature available. These characteristics
452 form the basis for classifying PBAPs SEM images into basic groups. Typical images of the
453 bioaerosols collected from each group during this study are shown in Fig. 2.

454 Fungal spores and associated fragments (group 1) were one of the most common classes
455 of bioaerosols observed during the campaign. Fungi can grow in almost every ecosystem and
456 are efficient in aerosolization (Adhikari et al., 2009; Löbs et al. 2020). The morphological
457 characteristics of fungal spores have been well documented in global air and are summarized
458 in Table 3 (Després et al. 2012 and references therein; Shi et al. 2003; Tamer Vestlund et al.
459 2014; Valsan et al. 2015; Valsan et al. 2016; Priyamvada et al. 2017; Wu et al. 2019, Li et al.
460 2020). They appear in various forms including globular, sub-globular, elliptical, and elongated.
461 Many of the spores possess the attachment scar and appear either with smooth or ornamented
462 surfaces. The size range of particles from SEM images considered for classification of PBAPs

463 in this group is generally from 1 to 20 μm . The SEM images of fungal spores collected over
464 Amazon rainforest (e.g. Huffman et al. 2012, Cybelli et al. 2018, China et al. 2016) were also
465 referred while conducting the classification.

466 The images of bacteria (group 2) on Si wafer were clearer and were used for the size
467 distribution. The basic morphological features of bacterial particles are spheres (coccus) and
468 round-ended cylinders (bacillus). In addition, there may be few others with helically twisted
469 shapes. Some bacterial cells grow separately while some rods or cocci grow in chains, grapelike
470 clusters or form a cubic packet characteristically. The surface structures include flagella, pili,
471 and capsules. A few representative images of bacillus and cocci shaped bacteria from the
472 ATTO samples are shown in Fig. 2. We attempted to grow the bacteria from filter samples in
473 agar solution, but no bacterial growth was observed. It should be noted that the filter samples
474 were not immediately analyzed for bacterial growth and were stored in a freezer at -25°C after
475 sampling, which could have affected the number of viable bacteria.

476 The pollen grains (group 3) were broadly distinguished from fungal spores based on
477 size and morphology. Typically, its size ranges from 10 to 100 μm . PBAPs are classified into
478 pollen based on the general morphological characteristics of pollen grains given in table 3.
479 Cybelli et al. (2018) provided an extensive image database of pollen grains collected at the
480 ATTO site and was frequently used for classification. From our SEM imaging, the size range
481 of the pollen grains varied between 8 and 20 μm . The pollen grains with a diameter of 10 to 30
482 μm were frequently observed at the ATTO site and the large pollen grains were absent high
483 above the canopy except during some thunderstorm events (Cybelli et al. 2018). Accordingly,
484 our SEM analysis did not show pollen grain presence greater than 20 μm . Observed pollen
485 grains exhibited different shapes including ellipsoid, fusiform, globose/spheroidal.

486 For a given scanned area under SEM, 2-4 brochosome clusters have been detected on
487 the filter for each case and are assigned to group 4. (viral, plant/animal detritus). Each cluster
488 consists of 3 to 40 brochosomes with an individual diameter of about 0.45 μm .
489 Brochosomes are intricately structured microscopic granules secreted by leafhoppers that are
490 typically found on their body surface and more rarely, eggs (Wittmaack, 2005). The group 4
491 was dominated by the presence of leaf litter followed by epicuticular wax of plants, insect
492 scales, and other vegetation detritus. The viral particles were hardly accessible in our SEM
493 analysis.

494 Somewhat surprisingly, during a rather large number of SEM investigations, no particle
495 could be identified as algae (group 5; Sect. 1) and therefore algae are not shown in the size
496 distribution presented here. A near-by water source close to the ATTO site had no measurable
497 impact on algal aerosol number concentration. However, algae can grow on leaves and soil.
498 They could also be part of the long-range transport of marine particles from the Atlantic Ocean
499 into the Amazon Rainforest (Martin et al. 2010; Moran-Zuloaga et al. 2018). Backward
500 trajectories (at 2 km) using the HYSPLIT model (see Fig. 1) suggest that a marine air mass
501 from the Atlantic Ocean would have travelled over 5-6 days to reach the ATTO site. In
502 summary, the absence of algae in our SEM analysis can be attributed to their low concentration
503 in the air at the ATTO site and possible limitation in identifying them using SEM.

504 The identification and classification of fragments of various PBAP is challenging due
505 their complex and irregular shape. Consideration was given to the external features of the
506 background PBAPs on the filter paper that were easy to detach from main PBAP particle. On
507 this basis, the fragments in the form of external spines, hyphae, etc. are then assigned to the
508 parent particle. In addition, the characteristics of the cell wall and other visible features of the
509 fragments have been closely examined to identify its parent PBAP with matching features. The

510 fragments smaller than 1 μm that were not in the form of distinguished external features of
511 main particle are difficult to classify and referred to here as unidentified particles.

512

513

514 **3 Results and discussion**

515

516 **3.1 The size distributions of PBAPs based on SEM analysis:**

517 Based on the SEM analysis of the filter and Si wafer samples, the size distributions for
518 total bioaerosol as well as for various PBAP groups were constructed for 0911N, 0912D, and
519 0913D and are shown in Fig. 3. In general, no difference in the size distribution of total PBAPs
520 between day and nighttime samples is observed. The ‘coarse mode’ (diameter 1-10 μm)
521 bioaerosol particles were dominated by fungal spores as the corresponding size distribution
522 shows a peak between 3-4 μm . This is in agreement with the previous measurements by
523 Huffman et al. (2012) and Whitehead et al. (2016), in which they attributed the peak in the
524 coarse fluorescent biological size distribution to fungal spores. Several types of fungal spores
525 such as *Basidiomycota*, *Cladosporium*, *Inocybe calospora*, *Rhizopus* were frequently observed.
526 Most pollen grains observed during SEM were with $D > 8 \mu\text{m}$. ‘Fine mode’ ($D < 1 \mu\text{m}$)
527 bioaerosol particles were dominated by the plant or animal detritus as well as bacteria. Overall,
528 the total size distribution of PBAPs from the current study is in good agreement with previous
529 observations by Huffman et al. (2012) and Whitehead et al. (2016) from a similar geographical
530 location (see Figure 3d).

531 The mean number concentrations of four PBAP groups including fungi, bacteria,
532 pollen, and viral, plant/animal detritus from SEM analysis are given in Table 3. Typically the

533 number concentrations of fungal spores and pollens at the ATTO are $\sim 10^4 \text{ m}^{-3}$ and $\sim 10^3 \text{ m}^{-3}$
534 respectively, following typical concentrations in vegetated areas (Després et al. 2012 and
535 references therein). The estimated mean number concentrations of bacterial particles is $\sim 10^5$
536 m^{-3} , which is greater by one order of magnitude than their typical concentration of $\sim 10^4 \text{ m}^{-3}$ in
537 the air (Després et al. 2012 and references there-in).

538 To get an idea regarding the size distribution of total aerosol particles during the
539 campaign, a combined aerosol size distribution from the SMPS and APS on 0914 is shown in
540 Fig. 3d. The SMPS and APS data were not available at the ATTO site for other sampling days
541 considered here, as these instruments were not working on those days. Using aerosol size
542 distributions (by SMSP+APS) on 0914 as a reference, $\sim 11\%$ of coarse mode aerosol particles
543 are of biological origin.

544 The total PBAP number concentration (with $D > 0.3 \mu\text{m}$) from SEM was compared
545 with their independent estimations with FCM as shown in Fig. 4. Overall, a good agreement
546 is observed between SEM and FCM estimation of total PBAP number concentration for
547 samples from all three days discussed here. The number concentration of PBAPs from FCM
548 was slightly lower than those from SEM, since abundance of PBAPs by FCM represents an
549 approximately lower limit for the actual abundance of PBAPs. The concentrations of
550 fluorescent biological aerosol particles (FBAP) from the FCM analysis were 3.3×10^5 ,
551 1.06×10^6 , and $1.19 \times 10^6 \text{ m}^{-3}$ for 0911N, 0912D, and 0913D respectively. These values
552 are consistent with previously reported FBAP concentrations of about $2 \times 10^5 -$
553 $1.2 \times 10^6 \text{ m}^{-3}$ by Whitehead et al. (2016) in the central Amazon forest. Huffman et al. (2012)
554 reported coarse mode FBAP concentration of about $7.3 \times 10^4 \text{ m}^{-3}$ over Amazon rainforest.

555

556 **3.2 Observations of total IN**

557 The observations of total IN including deposition and condensation-freezing IN and
558 immersion freezing IN are shown in Fig. 5. Figure 5 (a, b, and c) shows the concentration of
559 IN activated by deposition and condensation-freezing modes determined as a function of
560 temperature and relative humidity over ice (RH_{ice}) obtained by the FRIDGE-STD
561 measurements. No active IN at temperatures warmer than -20°C were detected with this
562 instrument, suggesting that their concentrations may have been lower than the detection
563 threshold of 0.01 L^{-1} . For a given temperature and RH_{ice} , a large day-to-day variability in IN
564 concentration was observed. The results indicate that higher IN concentration was associated
565 with higher RH_{ice} at a given temperature. The mean IN concentration at -25°C ranged from
566 0.03 to 0.43 L^{-1} for RH_{ice} between 120% and 130%. During the field campaign, the highest
567 concentration of deposition and condensation freezing IN measured by FRIDGE-STD was 4.5
568 L^{-1} at -30°C .

569 Figure 5d shows the cumulative number concentration of immersion freezing IN from
570 separate experiments in LINDA and FRIDGE-IMM as a function of temperature. Overall, the
571 concentration of immersion freezing IN was in the range of 0.0027 - 40 L^{-1} at temperature
572 between -6 to -30°C . Absence of any active IN in FRIDGE-IMM at temperature $> -15^{\circ}\text{C}$
573 could be associated with IN concentrations below the detection threshold of 0.15 L^{-1} . The
574 sample volume for LINDA samples was higher than the FRIDGE-IMM samples (see Table 1),
575 as a result LINDA had a lower detection threshold of 0.0014 L^{-1} . The concentrations of IN
576 from FRIDGE-STD at water saturation are lower than the concentrations of immersion freezing
577 IN from FRIDGE-IMM as FRIDGE-STD does not encapsulate the full immersion freezing.

578

579 **3.3 Biological IN concentration from drop freezing experiments**

580 The cumulative concentrations of biological and non-biological IN determined by drop
581 freezing arrays in LINDA are represented in Fig. 6 for 0911N, 0912D, 0913D. The
582 concentration of active biological IN between -5°C and -15°C was determined by comparing
583 measurements with and without heating. Freezing was observed with wide variance in onset
584 temperature. Heating the sample extracts decreased the highest temperature of freezing, by 1°C
585 in 0911N and 0913D to more than 4°C in 0912D. The active biological IN concentrations in
586 air ranged from 0.0015 to 0.047 L^{-1} between -6.5°C and -15°C and are in the range of previous
587 biological IN measurements from rain samples (e.g. Bowers et al. 2009; Xia et al. 2013; Pouzet
588 et al. 2017). In general, the relative contribution of biological IN to the total IN decreased with
589 decreasing temperature. The relative contribution of biological particles in the sample extracts
590 of 0911N and 0912D ranged from $\sim 100\%$ of the total IN active at -8°C to as low as $\sim 86\%$ at
591 -15°C . In comparison, the contribution of biological particles to the total IN concentration in
592 the sample extract of 0913D was much lower ($\sim 62\%$ at -13°C).

593

594

595 **4. Empirical parametrization of heterogeneous ice nucleation for multiple** 596 **groups of biological particles**

597

598 **4.1 General equations for prediction of biological IN number concentration**

599 *4.1.1 Overview of existing empirical parametrization of heterogeneous ice nucleation*

600 The EP of deposition and condensation-/immersion-freezing modes was proposed
601 originally by Phillips et al. (2008, 2013). They assumed that for any scenario of aerosol
602 loading, the number mixing ratio of active IN has contributions from the three groups including

603 dust/metallic, black carbon, and organic aerosols. Thus, the number mixing ratio of active IN
 604 can be written as

$$605 \quad n_{IN} = \sum_X n_{IN,X} \quad (1)$$

606 where $X = \text{DM, BC, BIO}$ and solO for dust/metallic, black carbon, primary biological and
 607 soluble organic aerosols, respectively.

608 The number concentration of active IN activated by deposition and condensation-
 609 /immersion-freezing modes from group X is proportional with aerosol surface area as:

$$610 \quad n_{IN,X} = \int_{\log [0.1 \mu m]}^{\infty} \{1 - \exp [-\mu_X]\} \times \frac{dn_X}{d\log D_X} d\log D_X, \quad (2)$$

$$611 \quad \mu_X = H_X(S_i, T) \xi(T) \left(\frac{\alpha_X n_{IN,1,*}}{\Omega_{X,1,*}} \right) \times \frac{d\Omega_X}{dn_X} \quad \text{for } T < 0^\circ \text{C and } 1 < S_i < S_i^w \quad (3)$$

612 The Ω_X is the total surface area of all aerosols with dry diameters larger than $0.1 \mu\text{m}$,
 613 μ_X is the average of the number of activated ice embryos per insoluble aerosol particle of size
 614 D_X . The number mixing ratio of aerosols in group X is given by n_X . A simplified version of
 615 Eqs (2) and (3) are used for $X=\text{solO}$. The term $H_X(S_i, T)$ is the empirically determined fraction
 616 ($0 \leq H_X \leq 1$) representing scarcity of nucleation under substantially subsaturated conditions.
 617 The α_X is a fractional contribution from aerosol group X to the IN concentration.

618 The number of ice crystals generated in a time step Δt is given by

$$619 \quad \Delta n_i = \sum_X (n_{IN,X} - n_{X,a}, 0) \equiv \sum_X \Delta n_{X,a} \quad (4)$$

620 where $n_{X,a}$ is the number mixing ratio of IN from group X that has already been activated.
 621 Additional details about the scheme and associated terms can be found in Phillips et al. (2008;
 622 2013)

623 4.1.2 Modification in the existing scheme for parametrization of biological IN based on PBAP

624 IN examined here and literature

625 The original EP treated biological ice nucleation with only one species of IN. That
626 assumption is changed as follows.

627 Here we now replace the previous $X=$ BIO by five PBAP groups (1)-(5) (Sec. 1)
628 including fungal spores and associated fragments (FNG), pollen and their fragments (PLN),
629 bacteria and their fragments (BCT), viral, plant/animal detritus (DTS), and algae (ALG).
630 According to the EP for atmospheric ice nucleation by Phillips et al. (2008), the concentration
631 of active IN from the given group within the given size interval $d\log D_X$ depends on surface
632 areas of given aerosol species. The empirical formulation mentioned below was not applied to
633 algal particles since their size distribution from SEM measurements was not available. We used
634 literature values of their frozen fraction to measure their ice nuclei activity, and will be
635 discussed in the later part of this section.

636 For $X=$ FNG, PLN, BCT, and DTS

$$637 \quad n_{IN_BIO,X} = \int_{\log [0.1 \mu m]}^{\infty} \{1 - \exp [-\mu_X]\} \times \frac{dn_X}{d\log D_X} d\log D_X, \quad (5)$$

$$638 \quad \mu_X = H_X(S_i, T) \xi(T) \times \text{MIN}\{[\exp(-\gamma_X T) - 1], 40\} \times \frac{1}{\omega_{X,1*}} \frac{d\Omega_X}{dn_X} \quad \text{for } T < 0^\circ \text{C} \quad (6)$$

639 Here, $n_{IN_BIO,X}$ is the number mixing ratio of IN active at temperature T in the X^{th} bioaerosol
640 species; Ω_X is the total surface area mixing ratio of particles with diameters D_X greater than 0.1
641 μm in group X and is a prognostic variable of the atmospheric model; $d\Omega_X/dn_X \approx \pi D_X^2$;
642 $dn_X/d\log D_X$ is the normalized size distribution of given bioaerosol species X . The absence of
643 smaller particles with diameter 0.1-0.2 μm that were not measured during SEM analysis is
644 associated with technical limitation of setup. This is expected to have an insignificant effect

645 on our empirical formulation as the contribution of these smaller particles to the overall surface
646 area mixing ratio is negligible. In the empirical formulation provided here, the surface area of
647 a particle is more important than its mass. For 0911N, the contribution of particles in the size
648 bin 0.1-0.2 μm to the total surface area mixing ratio is about 0.15% when the number
649 concentration of particles in this size bin was assumed to be similar to that of in the neighboring
650 size bin with larger diameter. Shape factors should also be considered when estimating the
651 surface area of PBAPs. However, due to the complexity of the observed shapes of PBAPs we
652 assumed spherical shape for all PBAPs and refrained from considering the shape factor in the
653 estimation of surface area.

654 The factor μ_X is the average number of potentially activated ice embryos per aerosol
655 particle with diameter D_X . For lower freezing fractions $\mu_X \ll 1$, the Eq (6) can be written as
656 $n_{IN_BIO,X} = H_X(S_i, T) \xi(T) [\exp(-\gamma_X T) - 1] \times \Omega_X / \omega_{X,1*}$ showing surface area dependence
657 of predicted IN number concentrations. The $\omega_{X,1*}$ is an unknown parameter and depends on
658 bioaerosol type with the dimensions of area (m^2). In Eq (6), $H_X(S_i, T)$ is the empirically
659 determined fraction ($0 \leq H_X \leq 1$) representing suppression of nucleation under substantially
660 water-subsaturated conditions. The H_X is expressed as a function of S_i and T by Phillips et al.
661 (2008) with $H_X=1$ at water saturation. The slope of the fitted curve predicting activated IN is
662 given by γ_X . The factor ξ considers the fact that drops are not observed to freeze at temperatures
663 warmer than a threshold in the laboratory observations. Phillips et al. (2008) proposed $\xi =$
664 $\delta_1^0(T, T_1, T_2)$, where ξ is 1 for $T < T_1$ and 0 for $T > T_2$ with cubic interpolation between and
665 assumed T_1 (-5°C) and T_2 (-2°C) for all aerosol species.

666 For temperatures colder than -20°C , lower slope values (45% of original) of the fit
667 were prescribed based on observations of biological IN of 0911N at temperature between

668 -20°C and -27°C (see Fig. 9). The modified version of proposed parameterization (eq. 6 and
 669 7) for any $T < 0^{\circ}\text{C}$ can be written as

$$670 \quad n_{IN_BIO,X} = \int_{\log[0.1 \mu\text{m}]}^{\infty} \{1 - \exp[-\mu_X]\} \times \frac{dn_X}{d\log D_X} d\log D_X, \quad (7)$$

$$671 \quad \mu_X = \begin{cases} H_X(S_i, T) \xi(T) \times \text{MIN}\{\exp(-\gamma_X T) - 1, 40\} \times \frac{1}{\omega_{X,1*}} \frac{d\Omega_X}{dn_X}, & \text{for } T > -20^{\circ}\text{C} \\ H_X(S_i, T) \xi(T) \times \text{MIN}\{\exp(-\gamma_X T) - 1, 40\} \times \exp[0.45 \times (T + 20)] \times \frac{1}{\omega_{X,1*}} \frac{d\Omega_X}{dn_X} \\ & , \text{otherwise} \end{cases}$$

$$672 \quad (8)$$

673 Eqs (7) and (8) are applied for biological species, $X = \text{FNG, PLN, BCT, and DTS}$ (groups 1-
 674 4, Sec. 1)

675 Regarding algal particles (group 5; Sec. 1), a separate representation is proposed as
 676 follows. Since the concentrations of algal particles at the ATTO site were much lower than
 677 our detection threshold ($\sim 0.5 \text{ m}^{-3}$) we could not use a similar empirical treatment for them as
 678 was used for other PBAP groups. Generally, in atmospheric models there may be situations
 679 where algae are more prolific and can influence the ice initiation. In such a scenario, their
 680 contribution to the total biological IN can not be excluded. We therefore used the estimation
 681 of the frozen fraction for the algal particles (Diatom cell, *T. pseudonana*) available in the
 682 literature (Wilson et al. 2015) to estimate the algal IN in the atmosphere. The relationship
 683 between the frozen fraction (f_{algaee}) of algae and temperature was established and (see
 684 extended data Fig. 6 in Wilson et al. 2015) is given by

$$685 \quad f_{algaee}(T) = A_1 + \frac{(A_2 - A_1)}{1 + 10^{(B+T) \times p}} \quad (9)$$

686 here $A_1 = -0.03, A_2 = 0.993, B = 27.73,$ and $p = 0.399.$

687 with $f_{algaee}(T) = 0$ at $T > -24^{\circ}\text{C}$ and $f_{algaee}(T) = 1$ at $T < -35^{\circ}\text{C}$

688 If the concentration of algal particles (n_{algal}) in the air is known, then for $X= ALG$

689
$$n_{IN_BIO,X} = f_{algal} \times n_{algal} \quad (10)$$

690 Our scheme treats the algal particles over the ocean but does not apply to the prediction of
691 biogenic organic macromolecules which can act as efficient IN. Although they are biological
692 in origin, these organic macromolecules are not classified as PBAPs as they are dissolved
693 organic matter and therefore not primary (Knopf et al. 2018; Pummer et al. 2012; Pummer et
694 al. 2015; McCluskey et al. 2018). These ice nucleating macromolecules are accessible on the
695 surfaces of leaves, wood and bark and can be washed down by rainwater (Felgitsch et al. 2018).

696

697 **4.2 Empirical determination of values of parameters**

698 Based on the IN (Fig. 7 and C1) and size distribution measurements (see Fig. 3 and B1)
699 for nine cases mentioned earlier, the values of active biological IN from groups (1)-(4) were
700 estimated using proposed EP (Eqs. 5-8). Experiment-based estimate of all unknown parameters
701 for each PBAP category is constrained by several technical aspects of PBAP collection and
702 processing for ice nucleation. A key problem we faced in the observation of our samples was
703 size distribution of various PBAP groups overlap greatly. Consequently, it was not possible to
704 isolate each PBAP group on a single filter. In addition, two of the four PBAP groups, including
705 pollen and leaf litter, naturally have lower IN activity compared to fungi and bacteria (Després
706 et al. 2012 and references therein). We have tried to overcome these difficulties by collecting
707 our samples on different days under contrasting conditions in conjunction with inverse
708 modeling. But there was a limit to the number of parameters that could be constrained by the
709 inverse modelling. Some of these parameters were therefore constrained based on laboratory
710 measurements available in the literature.

711 The values of slope parameter γ at $T > -15^{\circ}\text{C}$ are prescribed based on observations
712 made by Vali (1994, equation 8 therein) and are assumed to be similar among PBAP groups
713 (1)-(4) (Sec. 1). This assumption has the basis as the slope of the observed biological IN
714 concentration is consistent with the observations of Pouzet et al. (2017) (See Figure 7). The
715 concentration of total active biological IN from the EP is then compared to the observed
716 biological IN concentrations for each of the nine cases (see Fig 7 and C1). The relative
717 abundance of the four groups of PBAPs and IN concentrations varies between the nine
718 contrasting cases. For agreement between observed and parameterized values, the least-square
719 fitting was used to estimate the universal law applicable to all nine cases to resolve the
720 optimized values of the unknown parameters for PBAP groups (1)-(4).

721 The optimum values of the parameters inferred for the empirical scheme are shown in
722 Table 4. It should be noted that in the variational analysis the values of unknown parameter
723 $\omega_{X,1*}$ of comparatively less active PBAP groups including pollen and viral, plant/animal
724 detritus were constrained so that their estimated IN activity match the laboratory observation
725 reported in the literature. The estimations of $\omega_{X,1*}$ for group (4) are based on previous
726 observations of leaf litter (major part of group 4) from the tropics by Schnell and Tan-Schnell
727 (1982). For pollen, the $\omega_{X,1*}$ was constrained based on laboratory observations on active sites
728 per gram of pollen mass (*Betula pendula*) by O'Sullivan et al. (2015). Additional details about
729 these measurements used in the construction of the EP are given in Table 5.

730 In the current study, the values of T_1 and T_2 for determining the factor ξ are assumed to
731 be variable for each bioaerosol type and are estimated based on the literature of previous
732 observations or laboratory measurements. Therefore, the values of T_1 and T_2 for each PBAP
733 group are denoted by $T_{X,1}$ and $T_{X,2}$. Several studies have documented the activation of pollen at
734 temperatures colder than -10°C (Després et al. 2012; Kanji et al. 2017, and references therein).
735 Freezing tests on leaf litter showed its activation at temperatures $\sim -7^{\circ}\text{C}$ (Schnell and Tan-

736 Schnell, 1982; Després et al. 2012). Based on these observations, T_I was assumed to be -10 to
737 -7°C for pollen and plant/animal detritus respectively. Comparatively, fungi and bacteria are
738 activated at temperatures warmer than -5°C (Richard et al. 1996; Després et al. 2012; Kunert
739 et al. 2019) and therefore -7°C and -2°C , respectively, were assumed for T_I of both.

740 Fig. 7 and C1 shows the predicted number concentrations of crystals nucleated by
741 various biological species based on size distributions from the total and 5, 1.2 μm filters,
742 respectively. The predicted values of total biological IN by the EP are of similar magnitude in
743 comparison with observations from the total (5 + 2 μm) and 5 μm filters. The total number
744 concentration was dominated by fungi and bacteria. The contributions from pollen and detritus
745 were lower by two orders of magnitude than those from fungi and bacteria at a given
746 temperature. Pollen grains can swell and explode from high humidity exposure to emit
747 numerous nanoscale particles which are 10 to thousand times smaller than intact particles.
748 These smaller fragments may become aerosolized and act as efficient IN (O'Sullivan et al.
749 2015; Knopf et al. 2018). Given this, the contributions of pollen grains to total biological IN
750 may be more important than suggested by our measurements. The predicted total IN
751 concentration is lower by 1-2 order magnitude when compared with the values obtained for the
752 1.2 μm filters (See Fig. C1). It can be attributed to the uncertainties in estimating the collection
753 efficiency of 5 μm filters and hence to the size distributions of bioaerosol particles on 1.2 μm
754 filters.

755

756

757 **5 Comparison of the empirical scheme with independent observations**

758 The new EP is also compared with previous laboratory data and field observations, not
759 used in its construction, as shown in Figure 7 and C1. Additional details on the origin of these

760 data sets and corresponding calculations are given in Table 5. The total concentration of PBAP
761 IN predicted by EP is in good agreement with previous observations for rainwater samples
762 from Opme (France) by Pouzet et al. et al. (2017). For fungi, estimations of nucleation sites per
763 gram of fungal mass (*Fusarium avenaceum*) (O’Sullivan et al. 2015) and active IN per fungus
764 (*Basidiomycota spores*) (Haga et al. 2014) were used to calculate their contribution as IN for
765 the observed mass and number concentration of fungi over the Amazon. According to previous
766 studies by Murray et al. (2012) and references there-in., the number concentration of birch
767 pollen as potential IN is $2 \times 10^{-3} \text{ m}^{-3}$ at -15°C . Based on ice nucleation activity of bacteria
768 isolated from cloud water by Joly et al. 2014, number concentrations of potential INA bacteria
769 were estimated ~ 0.32 and 5.8 m^{-3} of cloud air at temperatures -6 and -8°C respectively.
770 Murray et al. (2012) estimated the concentration of pollen IN at -15°C is $2.4 \times 10^{-3} \text{ m}^{-3}$. The
771 active IN concentration from leaf litter per m^3 of air based on measurements by Schnell and
772 Vali (1976) for leaf litter from tropical regions is also shown for comparison with
773 parameterized values. When the uncertainty limits are considered, the EP’s predicted PBAP IN
774 concentrations are in agreements with available literature data.

775 To represent ice nucleation abilities of various PBAP groups various metrics are used
776 in the previous studies. Most used metric includes 1) ice-active surface site densities (n_s), 2)
777 ice-active mass site densities (n_m), an analogue to n_s , but mass equivalent, 3) activated fraction
778 (Kanji et al. 2017 and references therein). To represent proposed EP in terms of these common
779 metric, we estimated the mean values of n_s , n_m for various PBAP groups based on PABP IN
780 activity, their surface area mixing ratio, and mass in nine cases considered in the study. Figure
781 8 shows the dependence of these variable from the EP on temperature. The values of these two
782 parameters for limited species of PBAP groups from the available literature are also shown for
783 reference. However, there is a considerable spread in the literature data.

784 At a given temperature, our estimated values of n_s and n_m for PLN and DTS by EP
785 were much lower (by three orders of magnitude) when compared with our prediction of FNG
786 and BCT as observed in the literature data (Kanji et al. 2017 and references therein). The values
787 of n_m for group 4 (mostly leaf litter) are in good agreement with literature data. The literature
788 values of n_s and n_m for snowmax and *Pseudomonas syringae* bacteria are much higher than
789 our estimated values (see Figure 8). For a given PBAP group, the published observations of n_s
790 and n_m show large variations among different biological species (Kanji et al. 2017 and
791 references therein) which limits their direct comparison with our estimated values of the EP,
792 which apply to entire groups of PBAPs. At a temperature of -10°C , for example, n_m of three
793 species of fungal spores showed variation over four orders of magnitude.

794

795

796 **6 Application of empirical parameterization in a parcel model for an** 797 **idealized case**

798 The EP is applied in an idealized 0D parcel model to shed light on some ramifications
799 for natural ice initiation arising from the formulation. It should be noted that there are no
800 microphysical processes included inside the parcel model except for the heterogeneous ice
801 nucleation. The adiabatic parcel starts at 20°C , rises to -50°C and humidity is prescribed
802 corresponding to exact water saturation. Input size distributions of PBAPs (group 1-4) to the
803 empirical scheme are prescribed based on observations from the case 0911N. An EP from
804 Phillips et al. (2013) was applied for IN species including dust, soot and PBAPs. The
805 climatological values (from Model of Ozone and Related Chemical Tracers [*MOZART*]) of
806 mass mixing ratios for dust (2.9×10^{-10} kg/kg) and soot (3×10^{-11} kg/kg) over the ATTO
807 site were prescribed for estimating their contribution as IN. The total PBAP size distributions

808 were prescribed based on observations on 0911N. For algae, quantitative measurements of their
809 abundance in the ambient air are rare. The algal particles were not included in the parcel model
810 simulation shown here.

811 Figure 9 shows the predicted number concentration of active biological IN from
812 multiple species as well as the total IN. Compared with Phillips et al. (2013), the total biological
813 IN predicted by the proposed empirical scheme differs by maximum one orders of magnitude
814 at $T > -15^{\circ}\text{C}$ and by half order of magnitude at $T < -15^{\circ}\text{C}$. It should be noted that the EP by
815 Phillips et al. (2013) does not resolve individual groups of PBAPs and was based on the ice
816 nucleation of a bacterial strain observed in the laboratory that may not represent the large
817 variations in ice nucleation characteristics observed among different PBAP groups. Overall,
818 total IN concentrations predicted by the model are in good agreement with the concentrations
819 observed at the ATTO site. The relative contributions to the total IN concentration of the
820 different PBAP groups as well as dust and soot particles from this simulation are shown in
821 Figure 10. Biological particles dominate the predicted total IN concentrations at a temperature
822 warmer than -20°C and at colder levels dust and soot particles became increasingly important
823 in determining the total IN concentrations in the cloud.

824

825

826 **7 Conclusions**

827 A modification to the flexible framework for treating multiple species of atmospheric
828 IN in terms of empirical observations from the real atmosphere, namely the ‘empirical
829 parameterization’ is proposed in the current study. The previous single species for biological
830 IN has been replaced by five major PBAP groups including FNG, PLN, BCT, DTS, and ALG.
831 The new treatment has been fitted to the coincident observations of ice nucleation activity of

832 PBAPs and their size distributions based on observation from a field campaign at the ATTO
833 site located in the central Amazon. In addition to the observations of PBAP IN from the ATTO
834 site, the literature data are used for the construction of the EP. The new empirical treatment
835 will allow atmospheric models to explicitly resolve the IN activity of these PBAP groups.

836 PBAPs were collected on PTFE membrane filters and Si wafers for use in drop freezing
837 experiments, ice nuclei activation in cloud chamber, and SEM/EDX analysis. An EP was
838 constructed to predict the active IN from multiple groups of PBAPs based on coincident
839 observations of PBAP size, concentration, and ice-nucleating ability.

840 The measured IN concentrations activated by deposition and condensation-freezing
841 modes varied over three orders of magnitude throughout the campaign and strongly depended
842 on the processing temperature and ice supersaturation in the chamber. At -25°C , the measured
843 IN concentrations activated by deposition and condensation-freezing mode ranged from 0.002
844 L^{-1} to 1L^{-1} for ice supersaturations of 21% and 28% respectively. The filter samples were
845 analyzed in LINDA to estimate biological IN active between -5 and -15°C . Filter and Si wafer
846 samples were analyzed under SEM to measure the size distribution of common PBAP species.
847 For each case, more than 300 images of bioaerosol particles were used for this purpose.

848 The observed bioaerosols included brochosomes, fungal spores, bacteria, canopy debris
849 (e.g. leaf and insect fragments, plant waxes), and less commonly pollen and insect scales.
850 Overall, size distributions were observed to be bimodal and were like previous measurements
851 from similar geographical locations (e.g. Huffman et al. 2012; Whitehead et al. 2016). The
852 observed size distributions of PBAP groups have provided constraints primarily on their
853 surface areas in determining their ice nucleation activity. The size distribution of total
854 bioaerosol particles was consistently dominated by a submicron peak associated with the viral,
855 plant and animal detritus and bacteria. The coarse mode of PBAP observed in the current study
856 was dominated by fungal spores consistent with previous observations (e.g. Huffman et al.

857 2012). The total number concentration of bioaerosols (with $D > 0.3 \mu\text{m}$) inferred by our SEM
858 analysis is in good agreement with FCM analysis.

859 The total number concentration of biological IN predicted by the proposed
860 parameterization scheme was dominated by fungi and bacteria followed by pollen and detritus.
861 For PBAP groups considered in the construction of the scheme, the values predicted from the
862 scheme and independent observational data not used in the construction of the scheme were
863 consistent with concentrations of the same order of magnitude. Implementation of the scheme
864 in the 0D parcel model showed that the biological IN account for most of the total ice nuclei
865 activation at temperatures $> -20^\circ\text{C}$. At colder temperatures dust and soot become increasingly
866 more important to ice nucleation. Previous observations in the Amazon basin by Prenni et al.
867 (2009) also emphasize the importance of biological IN in determining total IN concentrations
868 at warmer atmospheric temperatures. They showed that the dust became increasingly more
869 important for ice nucleation at temperatures colder than -27°C . In their transmission electron
870 microscopy, no soot IN was observed, suggesting that biomass-burning particles were not a
871 likely source of the carbonaceous IN. However, it should be noted that their observations were
872 limited to the wet season. The biomass burning conditions are characteristics of the Amazon
873 dry season and are maximum around September. Thus, the soot particles resulting from the
874 biomass burning can play an important role in determining the ice nucleation at colder
875 temperature during the dry season, as suggested by our parcel model simulation. It should be
876 noted that the relative contributions of dust and soot to the ice nucleation shown in our parcel
877 mode simulations are limited to a case study and it will be highly variable depending on their
878 abundance in the atmosphere.

941 APPENDIX D

942 **Implementation of empirical parameterization in an atmospheric model**

943 The present EP scheme slots into the EP framework for heterogeneous ice nucleation
944 already described in Phillips et al (2008, 2013). Their framework represents all modes of
945 heterogeneous ice nucleation. The EP described in this study is for ice nucleation through
946 deposition, condensation- and immersion-freezing mode.

947 To implement the scheme in a cloud model, each group X of IN is partitioned into
948 prognostic components which are interstitial and immersed in cloud droplets to reflect the in-
949 cloud scavenging of IN by precipitation. Extra scalars were introduced to track the depletion

950 in the number mixing ratio of interstitial IN by becoming immersed in cloud liquid without
 951 necessarily freezing ($n_{X,a,liq}$) and the actual number mixing ratio of immersed IN ($n_{X,imm}$).
 952 The cut off size for immersed and interstitial IN size distributions is determined by ($n_{X,a,liq}$)
 953 and mixing ratio of aerosol in group X (Q_X). To include the heterogeneous freezing of raindrops
 954 a temporary grid of size bins was created to discretize their size distribution. If the mass mixing
 955 ratio of each bin is dQ_r , the number of IN particles in the rain that activate in time Δt is given
 956 by

$$957 \quad d(\Delta n_{IN,rain}) \approx \Delta t \text{MIN}[(w - v_t) \frac{\partial T}{\partial z}, 0] \frac{d}{dT} [\exp(-\gamma_X T) - 1] \sum_X \frac{d\Omega_{X,rain}}{\omega_{X,1,*}} \quad (11)$$

958 For a given raindrop size bin $d\Omega_{X,rain} = \Omega_{X,rain} \frac{dQ_r}{Q_r}$ is the surface area mixing ratio of IN
 959 within the raindrops. The fall velocity of raindrops is given by v_t , while w is the vertical air
 960 velocity.

961 We have adopted the approach followed by Phillips et al. (2008) for inside-out contact
 962 freezing. It assumes that a given IN has a freezing temperature for the contact nucleation which
 963 is $\Delta T_{CIN} \approx 4.5^\circ\text{C}$ higher than for the immersion and condensation freezing mode. The number
 964 mixing ratio of potentially active, interstitial IN activated by contact freezing ($n_{X,cn}$) is given
 965 by

$$966 \quad n_{X,cn} \cong \xi(T) \{ \exp[-\gamma_X(T - \Delta T_{CIN})] - 1 \} \sum_X \frac{d\Omega_{X,int}}{\omega_{X,1,*}} \quad (12)$$

967 Here, $\Omega_{X,int}$ is the component of Ω_X for interstitial IN.

PBAP type	Typical size (μm) and number conc. (m^{-3} of air)	General morphological features	References
Fungal spores	Size: 1-50; most frequently 2-10 Concentration: 10^4	(i) shape: globose, elliptical, fusiform, asymmetric, lemon-shaped, barrel-shaped, curved (ii) wall characteristics: smooth, granular, reticulate, spines, warts (iii) attachment scars, attachment pegs (iv) other features: branched hyphae	Després et al. (2012) and references therein, Priyamvada et al. 2017, Li et al. 2020, Huffman et al. 2012, Cybelli et al. 2018, China et al. 2016,
Bacteria	Size: 0.5-4 Concentration: 10^4 (over land), 10-1000 (over ocean)	(i) shape: spherical, rodlike, helical (ii) wall: flagella, pili, capsules (iii) Arrangement: pairs, tetrads, clusters, chains	Després et al. (2012) and references therein, Li et al. 2020
Pollen	Size: 10-50 Concentration: 10-1000	(i) shape: ellipsoid, fusiform, globose/spheroidal (ii) presence of forrows (iii) outer exine is usually sculptured (iv) exine ornamentation like fossulate or microrugulate	Després et al. (2012) and references therein, Cybelli et al. 2018 and references therein, Xu et al. 2013
Plant/animal detritus	Size: brochosomes-0.5, leaf litter 0.5-5 Concentration: NA	Various shapes (i) shape: football (brochosomes), spiral (epicuticular wax of plants), elongated (leaf litter)	Després et al. (2012) and references therein, Wittmaack, 2005
Algae	Size: 1-10 Concentration: 100	(i) shape: Unicellular flagellates or amoeboids, colonial and nonmotile forms	Després et al. (2012) and references therein

1330

1331 **Table 3:** Typical size ranges, concentrations in air and general morphological characteristics
1332 of different PBAPs, based on literature available. Based on this information, PBAPs have been
1333 classified into different groups. Also enlisted are various studies referred to for classification
1334 of PBAPs.

1335

1336

PBAP group	Typical Size	Mean number concentration (m⁻³ air) from SEM analysis
Fungal spores and associated fragments	1-10 μm	7.6×10^4 ($\mp 2.8 \times 10^4$)
Bacteria and their fragments	0.5-2 μm	4.2×10^5 ($\mp 1.98 \times 10^5$)
Pollen and their fragments	6-50 μm	1.07×10^3 (∓ 673)
Viral, plant/animal detritus	0.2-5 μm	4.1×10^5 ($\mp 1.8 \times 10^5$)

1337

Species	Reference	Obs. Mass (kg m ⁻³) or Number conc. (m ⁻³)	IN conc. (m ⁻³) (in bracket temp in °C)
<i>Fungi</i>	1. O'Sullivan et al. (2015): Nucleation sites g ⁻¹ at -5, -10, and -15°C are 2.5 × 10 ⁵ , 4 × 10 ⁷ , 2 × 10 ⁸ respectively	<i>Mass:</i> 1.51 × 10 ⁻⁹ (0911N) 1.52 × 10 ⁻⁹ (0912D) 1.17 × 10 ⁻⁹ (0913D)	For 0911N: 0.38 (-5), 60.63 (-10), 303.16 (-15) For 0912D: 0.37 (-5), 60.5 (-10), 302.53 (-15) For 0913D: 0.29 (-5), 46.8 (-10), 234.4 (-15)
	2. Haga et al. (2014): Active IN per fungi at -10 and -15°C are 5 × 10 ⁻⁴ , 7 × 10 ⁻⁴ respectively.	<i>Conc.</i> 1.01 × 10 ⁵ (0911N) 0.73 × 10 ⁵ (0912D) 0.49 × 10 ⁵ (0913D)	For 0911N: 52.80 (-10), 73.93 (-15) For 0912N: 36.9 (-10), 51.70 (-15) For 0913N: 24.81 (-10), 34.74 (-15)
<i>Pollen</i>	1. O'Sullivan et al. (2015) (used in construction of scheme): Nucleation sites g ⁻¹ at -10, -15°C are 2 × 10 ³ , 10 × 10 ³ respectively.	<i>Mass:</i> 5.76 × 10 ⁻¹⁰ (0911N) 5.14 × 10 ⁻¹⁰ (0912D) 1.18 × 10 ⁻¹⁰ (0913D)	For 0911N: 1.15 × 10 ⁻³ (- 10), 5.76 × 10 ⁻³ (-15) For 0912D: 1.02 × 10 ⁻³ (- 10), 5.14 × 10 ⁻³ (-15) For 0913D: 2.36 × 10 ⁻⁴ (- 10), 1.18 × 10 ⁻³ (-15).
	2. Murray et al. (2012)		Pollen as Potential IN is 2 × 10 ⁻³ (- 15)
<i>Bacteria</i>	1. Joly et al. (2014): Bacterial conc. was variable from 1.6 × 10 ³ to 3.4 × 10 ⁴ mL ⁻¹ Mean fraction of ice nucleation active bacteria at -6, -8, and -12 °C are 0.01, 0.18, and 1.02% respectively. Liquid water content was assumed 0.5 g/m ³ .		0.32 (-6), 5.8 (-8), 32.5 (-10)
<i>Leaf Litter</i>	1. Schnell and Tan-Schnell (1982): Nucleus concentration (g ⁻¹) at -6.5°C and -10°C is 60 and 800 respectively (used in construction of scheme).	<i>Mass:</i> 3.86 × 10 ⁻¹⁰ (0911N) 2.56 × 10 ⁻¹¹ (0912D)	For 0911N: 2.3 × 10 ⁻⁵ (-6.5), 3.08 × 10 ⁻⁴ (- 10)

		2.67×10^{-10} (0913D)	For 0912D: 1.5×10^{-6} (-6.5), $2. \times 10^{-5}$ (-10) For 0913D: 1.6×10^{-5} (-6.5), 2.13×10^{-4} (-10)
	2. Schnell and Vali (1976): Nucleus concentration (g^{-1}) at -7°C and -12.7°C is 100 and at is 1000 respectively. (for leaf litter in tropical climate zone)		For 0911N: 3.8×10^{-5} (-7), 3.8×10^{-4} (-12), For 0912D: 2.5×10^{-5} (-7), 2.5×10^{-4} (-12), For 0913D: 2.67×10^{-5} (-7), 2.67×10^{-4} (-12),
Total biological IN	Pouzet et al. 2017 (Figure 1). Rainwater content was assumed 0.3 gm/m^3 to convert concentrations to per m^3 of the air.		0.06 (-5), 1.65 (-10), 6 (-12)

1367

1368 **Table 6:** Origin of estimations of various biological IN concentrations shown in figure 7. The
1369 mass of bioaerosol particles was calculated assuming aerosol particles to be spherical with a
1370 density of 1000 kg m^{-3} . Observation of IN activity of pollen and leaf litter used in the
1371 construction of the scheme are mentioned in brackets.

1372

1373

1374

1375

1376

1377

1378

Notation	Description	Value and Units
D	Diameter	m
f_{algae}	Frozen fraction of algal particles from Wilson et al. (2015).	
H_X	Fraction reducing ice nuclei activity at low S_i , warm T	
MAX	Maximum value	
MIN	Minimum value	
$n_{IN_BIO,X}$	Contribution to total biological IN from group X	kg^{-1}
n_s	Ice-active surface site density	m^{-2}
n_m	Ice-active mass site density	kg^{-1}
n_X	Number mixing ratio of particles in PBAP group X	kg^{-1}
n_{IN_BIO}	Total number m.r. of active biological IN predicted	kg^{-1}
$n_{IN_BIO,X}$	Contribution to n_{IN_BIO} from PBAP group X	kg^{-1}
$n_{X,a}$	Number of aerosols in PBAP group X	kg^{-1}
$n_{X,cn}$	Number mixing ratio of contact IN for group X	kg^{-1}
$n_{X,a,liq}$	Number of interstitial IN in group X lost by becoming immersed	kg^{-1}
$n_{X,imm}$	Number of IN from group X immersed in cloud liquid	kg^{-1}
Q_r	Mixing ratio of rain	kg kg^{-1}
Q_X	Mixing ratio of aerosol in group X	kg kg^{-1}
RH_{ice}	Relative humidity over ice	%
S_i	Saturation ratio of vapor with respect to ice	
t	Time	s
T	Temperature	$^{\circ}\text{C}$
$T_{X,1}$	Colder threshold temperature for onset of freezing for group X	$^{\circ}\text{C}$
$T_{X,2}$	Warmer threshold temperature for onset of freezing for group X	$^{\circ}\text{C}$
v_t	Fall speed of raindrop in given size bin	m s^{-1}
w	Vertical velocity of air	m s^{-1}
X	Label for four PBAP groups (Fungal spores and associated fragments (FNG), Pollen and their fragments (PLN), Bacteria and their fragments (BCT), Viral, Plant/animal detritus (DTS), and Algae (ALG))	
$\xi(T)$	Fraction that is zero for $T > T_{X,2}$ ($^{\circ}\text{C}$) and 1 for $T < T_{X,1}$ ($^{\circ}\text{C}$), being $\delta_1^0(T, T_{X,1}, T_{X,2})$ for $T_{X,1} < T < T_{X,2}$ ($^{\circ}\text{C}$) for $X = \text{FNG, PLN, BCT, DTS}$	$0 \leq \xi \leq 1$
Ω_X	Total surface area of all bioaerosols $> 0.1 \mu\text{m}$ in diameter in group X .	[aerosol] m^2 [air] kg^{-1}
$\Omega_{X,int}$	Interstitial component of Ω_X	[aerosol] m^2 [air] kg^{-1}
$\Omega_{X,rain}$	Total surface area of all aerosols with $D > 0.1 \mu\text{m}$ in group X inside raindrops	[aerosol] m^2 [air] kg^{-1}

$\delta_a^b(y, y_1, y_2)$	Cubic interpolation function equal to a at $y \leq y_1$ and to b for $y \geq y_2$ While $\delta_a^b = a_0 + a_1y + a_2y^2 + a_3y^3$ for $y_1 < y < y_2$, where $a_0=B, a_1 = Ay_1y_2, a_2 = -\frac{A(y_1+y_2)}{2}$, and $a_3 = \frac{A}{3}$ with $A = \frac{6(a-b)}{(y_2-y_1)^3}$ and $B = a + \frac{Ay_1^3}{6} - \frac{Ay_1^2y_2}{2}$ (adopted from Phillips et al. 2008)	
μ_X	Average number of ice embryos per aerosol particle	
γ_X	Slope value of the fit for $X =$ FNG, PLN, BCT, and DTS each of four PBAP group.	$^{\circ}\text{C}^{-1}$.
α_X	Fraction of $n_{IN,1,*}$ from IN activity group $X = \{\text{DM, BC, O, solo}\}$	$\{2/3, 1/3-0.06, 0.06\}$
$\omega_{X,1*}$	Baseline coefficient of PBAP for $X =$ FNG, PLN, BCT, and DTS	m^2
Δt	Model time step	s
ΔT_{CIN}	Diff. in freezing temperature between contact and bulk water modes.	4.5°C

1415 FIG. 3. The size distribution of PBAPs based on SEM analysis of samples 0911N, 0912D, and
 1416 0913D (a, b, and c). The size distribution of PBAPs shown here is from the combination of 5
 1417 and 1.2 μm filters. The total PBAP size distribution from each day is compared with the
 1418 literature data (d). The total PBAP size distribution from our observations include unidentified
 1419 PBAPs in addition to the other PBAP groups considered for classification. The combined
 1420 aerosol size distribution from SMPS and APS on 0914 (thin black line) is also shown for
 1421 reference.

1440 FIG. 5. The concentration of IN activated by deposition and condensation freezing mode in
1441 the FRIDGE-STD chamber at $-20^{\circ}C$ (a), $-25^{\circ}C$ (b), and $-30^{\circ}C$ (c). The dotted vertical lines
1442 in a, b, and c indicate saturation w.r.t. water. Cumulative IN concentrations activated by
1443 immersion freezing mode from separate experiments in FRIDGE-IMM are shown (d). The
1444 cumulative immersion freezing IN concentrations for 0911N, 0912D, 0913D from analysis in
1445 LINDA are also shown.

1446

1447

1448

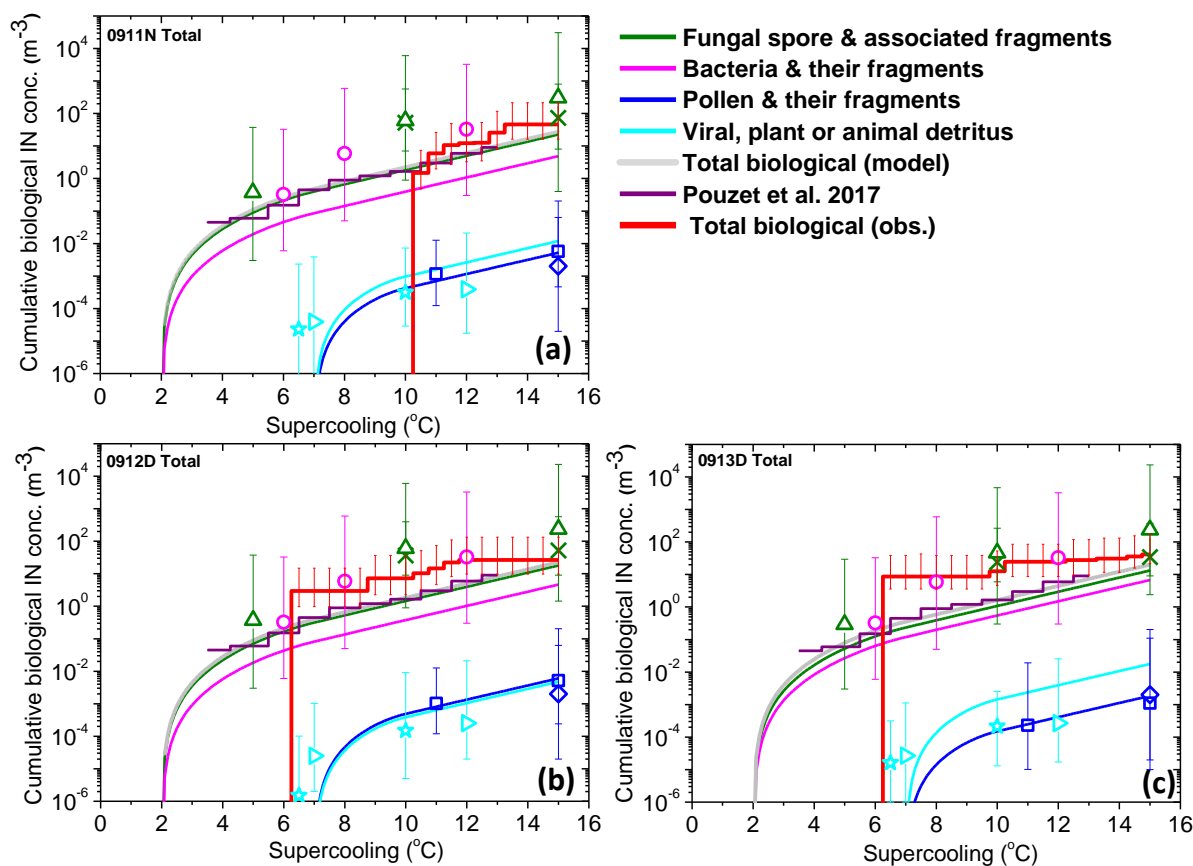

1450

1451 FIG. 6. Cumulative concentrations of biological (heat sensitive, bold lines) and non-biological
 1452 (heat-resistance, shaded area) IN. The sum of two categories corresponds to the concentrations
 1453 of total IN. The lower bound was considered for values below the detection limit. The IN
 1454 concentrations shown here are from 5 and 1.2 μm filters processed in LINDA.

1459

1460 FIG. 7. Prediction of biological ice nuclei concentrations by new empirical parameterization
 1461 based on size distribution of PBAPs, shown as a function of temperature for various bioaerosol
 1462 species. The total biological ice nuclei concentrations from the empirical parametrization (thick
 1463 black line) are compared with the observed values (thick red) from the drop freezing
 1464 experiments with LINDA. The prediction is based on the total size distribution ($5 + 1.2 \mu\text{m}$) for
 1465 each sampling day shown here. In addition, predicted values of biological IN are compared to
 1466 previous observations listed in Table 5. Biological ice nuclei concentration of fungi based on
 1467 active fractions measured by Haga et al. (2014) (green crosses) and O'Sullivan et al. (2015)
 1468 (green triangles) are shown for comparison. The number concentrations of pollen as biological
 1469 ice nuclei are shown based Murray et al. (2012) (blue diamonds) and O'Sullivan et al. (2015)
 1470 (blue squares). The bacterial ice nuclei concentrations based on Joly et al. 2014 (magenta
 1471 circles). The leaf litter as ice nuclei are also shown based on Schnell Tan-Schnell (1982),

1472 Schnell and Vali (1976). Black dotted lines in the plot of 1.2 μm filter represent the upper and
1473 lower bounds in predicting ice nuclei concentrations due to uncertainties in collection
1474 efficiency.

1542

1543 Figure C1: Prediction of biological ice nuclei concentrations by new empirical
1544 parameterization based on size distribution of PBAPs in 0911N, 0912D and 0913D shown as
1545 a function of temperature for various bioaerosol species. The total biological ice nuclei
1546 concentrations from the empirical parametrization (thick black line) are compared with the

1547 observed values (thick red) from the drop freezing experiments with LINDA. For each case,
1548 the prediction is based on PBAP size distribution from 5 μm , and 1.2 μm and is shown
1549 separately. Black dotted lines in the plot of 1.2 μm filter represent the upper and lower bounds
1550 in predicting ice nuclei concentrations due to uncertainties in collection efficiency.
