Abstract

We consider the problem of state estimation for a parameter-varying system that is unobservable for some values of time-varying parameters. The set of parameter values is divided into a finite number of subsets for which the system is observable, and a switched observer is proposed. A dwell-time condition is defined that ensures exponential convergence. The conditions of stability are formulated in the form of matrix inequalities, which can be used for gains tuning. The obtained theoretical results are supported with an illustrative example and experimental studies for a reaction-wheel pendulum testbench.

Key words: parameter-varying systems, switched observer, switched Lyapunov function, dwell-time

1 Introduction

State estimation for time-varying systems is a longstanding problem that has numerous engineering applications [20]. First solutions to this problem based on Kalman filtering were proposed in 1960s [10], however, this problem is not entirely solved and remains an active research topic. In [5] it has been shown that for a class of nonlinear systems the state estimation problem can be translated (via a change of coordinates) to the state estimation problem for a linear time-varying system, and an adaptive observer has been applied. Another adaptive observer for time-varying systems with parametric uncertainties has been reported in [29], which is also applicable to a class of state-affine nonlinear systems. Set-membership estimation and interval observers for time-varying systems have been proposed in [14,11], and estimation with finite and fixed-time for a class of time-varying system has been studied in [23]; see [7] and references therein for more details on observer design. However, these approaches typically assume that the estimated system is observable, or, more precisely, uniformly completely observable [7,15]. This assumption can be violated in some applications, e.g., in power converters [18], where a particular combination of input signals or time-varying parameters may make the plant unobservable, at least for some instances of time. Moreover, it is possible that for some combinations of input parameters, the system dynamics is changed significantly, and a single observer with constant parameters is not capable of tracking the states in different operation modes. This problem can be addressed by time-varying observers, where we are interested in the particular class of switched observers.
Switched observers are typically applied for state estimation in processes with commutations of dynamics, where the system can operate in a finite number of operation modes. Whereas there exist nonlinear observers for nonlinear switched systems [18,27], linear switched system state estimation is commonly addressed through linear switched observers. The conventional approach is to construct a common Lyapunov function that is suitable for all operation modes, such as [2], which has been also improved in [1] by applying a projection method. The key tools for this approach are Linear Matrix Inequalities (LMI), for which powerful numerical solvers are available [19]. However, the existence of a common Lyapunov function is a restrictive assumption, and, particularly, it does not hold if some operation modes are not observable. This problem has been addressed in [28], where authors proposed conditions under which the system is observable even if some individual modes are unobservable. The same problem has been considered in [17], where the authors studied when does there exist a trajectory making the system observable.

The common Lyapunov function requirement can be relaxed by imposing assumptions on the Average Dwell Time (ADT) of commutation, as in [21,6]. The ADT concept can also be used when the switching signal is not precisely known or is measured with a delay, as in [30]. Another interesting solution has been proposed in [22], where the switching signal is not available and has to be estimated. To this end, a switched observer has been constructed in such a way that it ensures boundedness of estimation error if the switching signal is unknown, and it guarantees convergence when the operation mode is identified correctly. It is worth noting that for some observers, e.g., [6,22], switches in operation modes can yield jumps in estimates, i.e., observer’s states, that makes these estimators rather hybrid than switched.

Novelty and Contribution. In this paper, we consider a class of linear time-varying (or parameter-varying) systems, which are not observable for certain values of the varying parameters. Considered systems are not switched themselves and do not have a finite number of operation modes. However, for the considered class of systems, we assume that the set of parameter values is divided into a finite number of subsets, where for each subset the system is observable, and that the observability is lost only when the vector of varying parameters travels from one subset to another. Motivated by this assumption, we propose a novel switched observer and show that its parameters can be designed as a solution to an LMI problem. We also derive the dwell-time conditions imposed on the switching signals to establish and estimate the exponential convergence rate. Moreover, we show that it is sufficient to solve the LMI for one set of parameters only, and other gains can be computed from the obtained solution; this property significantly simplifies the design procedure.

The rest of the paper is organized as follows. In Section 2, we present an illustrative example to motivate the considered problem and illustrate that some straightforward solutions do not apply. The formal problem statement is given in Section 3, and the main result is presented in Section 4. An illustrative observer design example is given in Section 5, and results of experimental studies for a reaction wheel pendulum are reported in Section 6. The conclusion of the paper is in Section 7. Finally, some technical details of proofs can be found in the Appendix.

Used notations. For integers \(n, m\), we define \(I_n\) as the \(n \times n\) unit matrix, and \(0_{n \times m}\) and \(I_{n \times m}\) as \(n \times m\) matrices of zeros and ones, respectively.

2 Motivating example

As a motivating example, we consider the reaction-wheel pendulum testbench that was also presented in [26], see Section 6 for more details. Neglecting the friction, the pendulum dynamics can be written as

\[
\dot{\theta}(t) = a \sin(\theta(t)) + bI(t),
\]

where \(a > 0\) and \(b > 0\) are constants depending on the system’s parameters, \(\theta\) is the pendulum angle, where the upward position is chosen as zero, and \(I\) is the current in the motor windings. Assuming an internal fast-time-scale current regulation, we consider \(I(t) = u(t)\), where \(u\) is our input control signal. The observer goal is to estimate the pendulum velocity \(\dot{\theta}\). However, due to possible imprecisions in sensor placement and pendulum alignment, the zero reading of the sensor does not coincide with the equilibrium position, and the angle \(\theta\) is measured with a certain constant offset, i.e., the measured signal \(y\) is given by

\[
y(t) = \theta(t) + d,
\]

where \(d\) is the constant bias.

Assuming that the bias is sufficiently small and approximating \(\sin(\theta) = \sin(y - d) \approx \sin(y) - \cos(y)d\), the problem of the velocity \(\dot{\theta}\) and the bias \(d\) estimation can be formulated as the state estimation problem of the system\(^2\)

\[
x = Ax + \beta(u, y), \quad y = Cx,
\]

\(^2\) When clear from the context, in the sequel the argument of time is omitted.
where $x := \begin{bmatrix} \theta + d, \dot{\theta}, -a \dot{d} \end{bmatrix}^\top$,

$$A(y) := \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & \cos(y) \\ 0 & 0 & 0 \end{bmatrix}, \quad C := \begin{bmatrix} 1 & 0 & 0 \end{bmatrix},$$ (3)

and $\beta(u, y) := [0, a \sin(y) + bu, 0]^\top$. We also assume that the input signal $u$ is such that trajectories of the system (2) exist and are unique for all $t \geq 0$.

It is worth noting that the observability matrix of the system (2) is given by

$$O = \begin{bmatrix} 1 & 0 & 1 \\ 0 & 1 & 0 \\ 0 & 0 & \cos(y) \end{bmatrix},$$

and it is singular for $\cos(y) = 0$. This obviously implies that some constraints should be imposed for the signal $y$, e.g., the states $x_1$ and $x_3$ cannot be reconstructed for $y(t) \equiv \pm \frac{\pi}{2}$. To simplify the example, assume that $y \in \Omega_y := \{ y | \cos^2(y) \geq \delta_y^2 \}$ for some $\delta_y \in (0, 1)$, i.e., the system is always observable but $\cos(y)$ may change its sign at some isolated instants of time.

One classic solution for linear time-varying systems is to construct a linear time-varying observer in the form

$$\dot{x} = A(y)x + \beta(u, y) - HC^\top (C\dot{x} - y),$$ (4)

where the time-varying symmetric gain matrix $H(t) \in \mathbb{R}^{3 \times 3}$ is the solution of the matrix differential equation

$$\dot{H} = HA^\top(y) + A(y)H - HC^\top CH + Q$$

for some $H(0) = H_0 > 0$, and $Q > 0$ is the design parameter. It is known (see, e.g., [25, 24]) that the observer (4) ensures exponential convergence if the system is uniformly observable, that is there exist $T_0, \delta_1, \delta_2$, all positive, such that for all $t$

$$\delta_1 I_3 \leq \int_t^{t+T_0} \Phi^\top(t, \tau) C^\top C \Phi(t, \tau) d\tau \leq \delta_2 I_3,$$

where $\Phi(t, \cdot)$ is the state-transition matrix of the system (2). The uniform observability can be connected with the assumption that the system (2) does not stick in the domain where $\cos(y) \approx 0$. However, the implementation of the observer (4) in embedded systems has certain drawbacks since computation of the gain matrix $H(t)$ requires to solve online 6 differential equations with quadratic terms that may be sensitive to numerical methods. Thus, in what follows we aim to designs that are less demanding for online computations than the observer (4), e.g., by the means of off-line gains precalculation.

Let us show that some straightforward solutions do not apply to this problem. To this end, consider the observer

$$\dot{x} = A(y)x + \beta(u, y) - L(y)(C\dot{x} - y),$$

where the parameter-varying gain vector $L(y)$ is to be defined, and $\dot{x}$ is the estimate of $x$. Define the estimation error as $e := \dot{x} - x$, then

$$\dot{e} = (A(y) - L(y)C) e.$$

A simple solution would be to find a constant vector $L$ stabilizing the system for all values of $y \in \Omega_y$, e.g., with a common Lyapunov function; however, such a solution does not exist. Indeed, if $L$ is stabilizing for all $y$, then for any $y \in \Omega_y$, the matrix $A(y) - LC$ should be Hurwitz. The characteristic polynomial of the error state matrix is

$$s^3 + s^2 (l_1 + l_3) + s l_2 + \cos(y) l_3,$$

where $l_i$ is the $i$-th element of the vector $L$, and the error dynamics cannot be stabilized for positive and negative values of $\cos(y)$ with the same gain $l_3$.

Hence, we have to calculate a vector function $L(y)$. Methods of design of LPV observers typically consider the quadratic Lyapunov function $V = e^\top P e$, where the matrix $P$ can be constant or parameter-varying, $P = P(y)$. The main drawback of the (continuous in $y$) parameter-varying matrix $P(y)$ is that the time derivative of the Lyapunov function will depend on the time derivative of the signal $y$ implying some probably restrictive assumptions on boundedness of $y$. Concerning the constant matrix $P$, it can be shown that the system (2) does not admit such a solution, or more precisely, there do not exist a parameter-varying gain vector $L(y)$ and a positive-definite constant matrix $P$, such that for all $y \in \Omega_y$ the linear matrix inequality (LMI)

$$(A(y) - L(y)C)^\top P + P (A(y) - L(y)C) < 0$$

holds, see Proposition 7 in Appendix.

Motivated by the discussed shortcomings, we propose to exploit the canonical form of the system (2) and design a switched observer. For this observer, we consider the Lyapunov function $V = e^\top P y e$, where $P(y)$ is piecewise constant. Thus, we do not impose assumption on the time derivative of $y$ but study possible jumps of the value of the Lyapunov function when switches occur. In next section, we consider a more general problem statement, for which the system (2) is a particular case.
3 Problem statement

Consider an LPV SISO system in the following form

$$\dot{x} = A(q)x + \beta(u, y, t), \ y = Cx,$$

where $x \in \mathbb{R}^n$ is the state, $u \in \mathbb{R}$ is the known input, $y \in \mathbb{R}$ is the measured output signal,

$$A(q) := \begin{bmatrix} 0 & q_1 & 0 & \cdots & 0 \\ 0 & 0 & q_2 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & q_{n-1} \\ 0 & 0 & 0 & \cdots & 0 \end{bmatrix}, \ C := \begin{bmatrix} 1 & 0 & 0 & \cdots & 0 \end{bmatrix},$$

with $q = (q_1, q_2, \cdots, q_{n-1})$, $q_i \in [-1, 1]$, $i \in \mathbb{Z} := \{1, \ldots, n-1\}$, being a known piecewise continuous time-varying signal. The function $\beta$ is known. We also assume that the input signal $u$ is such that trajectories of the system (5) exist and are unique for all $t \geq 0$. The goal is to design an observer for $x$.

The main issue for solution of this problem is that the system loses its observability for zero values of varying parameters $q_1, \ldots, q_{n-1}$. Indeed, the observability matrix of the system is

$$O := \begin{bmatrix} 1 & 0 & 0 & \cdots & 0 \\ 0 & q_1 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & q_{n-2} & \cdots & 0 \\ 0 & 0 & 0 & \cdots & \prod_{i=1}^{n-1} q_i \end{bmatrix}.$$

As it can be seen from the observability matrix, the system is observable when all elements of $q$ are not zero, the rank of the observability matrix equals $n-1$ and the state $x_n$ is not observable when the only zero element of $q$ is $q_{n-1}$, and for $q_{n-1} = 0$ only the state $x_1$ is observable. Thus, a hypothesis has to be introduced that the system does not spend much time in the mode where any element of $q$ equals zero. This hypothesis will be formulated as a sufficient condition for the signal $q$ ensuring observer convergence.

Remark 1 Since the input $\beta(u, y, t)$ is known, it can be canceled in the observer design and thus it does not impact neither the error dynamics nor the stability analysis. However, it allows us considering a wider class of systems with known inputs, e.g., the mechanical system example in Section 2.

Remark 2 In [3] it was shown that for $n = 3$ the state estimation problem can be solved with a nonlinear adap-
tive observer. To this end, an instrumental output signal was constructed via a nonlinear transformation, and a gradient-like update law was proposed. The exponential convergence was shown under assumptions on the trajectory in the vein of the persistency of excitation property. However, the instrumental signal construction was proposed only for $n = 3$, and its extension to a more general case $n > 3$ can be complicated. Thus, we do not consider that approach in this paper in detail.

4 Main result

4.1 Observer design

To present our solution, note that the vector $q$ belongs to the hypercube in $\mathbb{R}^{n-1}$ that has $2^{n-1}$ vertices of the form $(\pm 1, \pm 1, \cdots, \pm 1)$. Let us enumerate these vertices in any particular order, $v^k$, $k \in k := \{1, 2, \ldots, 2^{n-1}\}$. Let us subdivide the hypercube into $2^{n-1}$ closed smaller hypercubes $Q_k$. These hypercubes cover the original hypercube, and their interiors are disjoint. For each $k$, the corresponding smaller hypercube $Q_k$ is uniquely defined by two opposite vertices: the origin and the point $v^k$. For example, for $n = 3$, $i = \{1, 2\}$, and $k = \{1, 2, 3, 4\}$, one possible enumeration is

$$v^1 := (1, 1), \ v^2 := (1, -1),$$

$$v^3 := (-1, 1), \ v^4 := (-1, -1),$$

$$Q_1 := \{(q_1, q_2) \mid 1 \geq q_1 \geq 0, \ 1 \geq q_2 \geq 0\},$$

$$Q_2 := \{(q_1, q_2) \mid 1 \geq q_1 \geq 0, \ -1 \leq q_2 \leq 0\},$$

$$Q_3 := \{(q_1, q_2) \mid -1 \leq q_1 \leq 0, \ -1 \leq q_2 \leq 0\},$$

$$Q_4 := \{(q_1, q_2) \mid -1 \leq q_1 \leq 0, \ 1 \geq q_2 \geq 0\}.$$

Any point of the trajectory $q$ belongs to exactly one of the hypercubes, with an exception of the trajectory crossing the boundary between the hypercubes. For those points that belong to several hypercubes simultaneously, the notation $q \in Q_k$ implies that the smaller index $k$ among the considered hypercubes is chosen.

Define the sign function as

$$\text{sgn} \ (q_i) := \begin{cases} 1 & \text{if } q_i \geq 0, \\ -1 & \text{if } q_i < 0, \end{cases}$$

and the set of $2^{n-1}$ matrices

$$A_k := \begin{bmatrix} 0 & \text{sgn} \ (v^1_k) & 0 & \cdots & 0 \\ 0 & 0 & \text{sgn} \ (v^2_k) & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & \text{sgn} \ (v^k_{n-1}) \\ 0 & 0 & 0 & \cdots & 0 \end{bmatrix}.$$
In other words, the matrix \( A_k \) has the same structure as the matrix \( A(q) \) where the parameters \( q_1, \ldots, q_{n-1} \) are replaced by their extremes in the set \( Q_k, k \in \bar{k} \), and the matrices \( A_k \) form a convex polytope where the matrix function \( A(q) \) is embedded. Note that all pairs \((C, A_k)\) are observable.

Define the function \( f(q, x) : \mathbb{R}^{n-1} \times \mathbb{R}^n \to \mathbb{R}^{n-1} \), where the \( i \)-th component is
\[
f_i(q, x) = (q_i - \text{sgn}(q_i)) x_{i+1},
\]
c and consider the switched observer
\[
\dot{x} = A_s(q) \dot{x} + \beta(u, y, t) + B f(q, \dot{x}),
\]
where \( A_s(q) \) is the switched matrix, \( A_s(q) = A_k \) if \( q \in Q_k \),
\[
B := \begin{bmatrix} I_{n-1} \\ 0 \times (n-1) \end{bmatrix},
\]
and \( L_s(q) \) is the switched gain defined as \( L_s(q) := L_k \) when \( q \in Q_k, k \in \bar{k} \), and the gains \( L_k \) are computed as
\[
L_k = O_k^{-1} O_1 L_1,
\]
where \( O_k \) is the observability matrix of the pair \((C, A_k)\) and \( L_1 \) to be defined.

In what follows, we show that if a certain LMI is feasible, then there exists \( L_1 \) such that under some assumptions on the signal \( q \) the observer (7) ensures exponential convergence of the estimate \( \dot{x} \) to the state vector \( x \) of the system (5). To streamline the presentation and to gradually introduce all required definitions, we first present analysis of the estimation error dynamics, and then summarize it in Theorem 4.

4.2 Convergence analysis

With the definitions in use, we can rewrite the system (5) as
\[
\dot{x} = A_s(q)x + \beta(u, y, t) + B f(q, x).
\]
Then the error dynamics is given by
\[
\dot{e} = (A_s(q) - L_s(q)C) e + B \Delta f,
\]
where \( e = \dot{x} - x \) and \( \Delta f := f(q, \dot{x}) - f(q, x) \). Then for \( \Delta f \) it holds
\[
\Delta f^2 = e_{i+1}^2 - \gamma(q_i) e_{i+1}^2,
\]
where the function \( \gamma : \mathbb{R} \to \mathbb{R} \) is defined as
\[
\gamma(q_i) := |q_i| (2 - |q_i|) .
\]
Note that \( \gamma(0) = 0, \gamma(1) = 1 \), and \( \gamma(q_i) \) is monotonically increasing as \( |q_i| \) varies from 0 to 1.

Consider first the case \( q \in Q_1 \) and the function \( V_1(e) := e^T P_1 e \), where the matrix \( P_1 = P_1^T > 0 \). The time derivative of the function \( V_1 \) along trajectories of \( e \) is
\[
\dot{V}_1 = e^T \left( (A_1 - L_1) e + P_1 (A_1 - L_1) e \right) + 2 e^T P_1 B \Delta f + \Delta f^T \Delta f - \Delta f^T \Delta f.
\]
Choose \( \delta_q \in (0, 1) \) and compute \( \delta_i := \gamma(\delta_q), 0 < \delta_i < 1 \). Then by adding and subtracting the term \( \epsilon_i^2 - \delta_i |e|^2 \) and recalling that due to (9)
\[
\Delta f^T \Delta f = \sum_{i=1}^{n-1} (e_{i+1}^2 - \gamma(q_i) e_{i+1}^2),
\]
one obtains
\[
\dot{V}_1 = [e^T \Delta f^T] M_1 [e] - e^T Q(q) e,
\]
where
\[
Q(q) := \begin{bmatrix} 1 - \delta_i & 0 & \ldots & 0 \\ 0 & \gamma(q_1) - \delta_i & \ldots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \gamma(q_{n-1}) - \delta_i \end{bmatrix},
\]
\[
M_1 := \begin{bmatrix} F_1 + (1 - \delta_i) I_n & P_1 B \\ B^T P_1 & -I_{n-1} \end{bmatrix},
\]
and
\[
F_1 := (A_1 - L_1) e + P_1 (A_1 - L_1) e.
\]
Let \( P_1 \) and \( L_1 \) be a solution of the matrix inequality \( M_1 \leq 0 \) for some \( \delta_i \). Then
\[
\dot{V}_1 \leq -e^T Q(q) e \leq -\frac{(\min_{i \in 1} |q_i|) - \delta_i}{\lambda_M} V_1,
\]
where \( \lambda_M \) is the maximum eigenvalue of \( P_1 \).

Consider now the case \( q \in Q_k \) for \( k \neq 1 \) and the function \( V_k(e) := e^T P_k e \), where \( P_k = P_k^T > 0 \). Repeating the same steps as above, we obtain
\[
\dot{V}_k = [e^T \Delta f^T] M_k [e] - e^T Q(q) e,
\]
where

\[ M_k := \begin{bmatrix} F_k + (1 - \delta_t) I_n & P_k B \\ B^T P_k & -I_{n-1} \end{bmatrix}, \]

and

\[ F_k := (A_k - L_k C)^T P_k + P_k (A_k - L_k C). \]

Now we will show that if there exist \( L_1 \) and \( P_1 \) such that \( M_1 \leq 0 \), then there exist also \( P_k \) and \( L_k \) such that \( M_k \leq 0 \). Recalling that \( O_k \) is the observability matrix of the pair \((A_k, C)\), define the matrices

\[ R_k := O_k^{-1} O_1 \]

for \( k \in \bar{d} \). Due to the structure of the matrices \( A \) and \( C \), for any \( k \) the matrix \( R_k \) is diagonal and all its elements are either 1 or \(-1\). Thus, \( R_k \) is a unitary matrix and \( R_k = R_k^{-1} \). Moreover, it holds

\[ A_k = R_k A_1 R_k, \quad C R_k = C. \]

Choose

\[ P_k = R_k P_1 R_k, \quad L_k = R_k L_1. \]

Then

\[ M_k = \begin{bmatrix} R_k & 0 \\ 0 & I_{n-1} \end{bmatrix} M'_k \begin{bmatrix} R_k & 0 \\ 0 & I_{n-1} \end{bmatrix}, \]

where

\[ M'_k = \begin{bmatrix} F_1 + (1 - \delta_t) I_n & P_1 R_k B \\ B^T R_k P_1 & -I_{n-1} \end{bmatrix}, \]

and \( F_1 \) is defined in (10). Due to the structure of the matrix \( B \), the matrix \( B B^T \) is a diagonal matrix, thus

\[ P_1 R_k B B^T R_k P_1 = P_1 B B^T P_1 \]

and the matrices \( M_1 \) and \( M'_k \) have the same Schur complement (see [13]) of the upper-left block element. Then the implication \( M_1 \leq 0 \iff M'_k \leq 0 \) holds and the choice (11) ensures \( M_k \leq 0 \).

Note that due to (11), the matrices \( P_k \) have the same eigenvalues for all \( k \). Therefore, for all \( k \in \bar{d} \) and all fixed values of the switched matrix \( A_s(q) \), for the switched dynamics we have

\[ V_k \leq -e^T Q(q) e \leq -\frac{\gamma (\min_{i \in \bar{d}} |q_i|) - \delta_t}{\lambda M} V_k = (\eta_0 - \eta(q)) V_k, \]

(12)

where \( \eta(q) := \gamma (\min_{i \in \bar{d}} |q_i|) / \lambda M \) and \( \eta_0 := \frac{\delta_t}{\lambda M} \).

Next we analyze possible jumps in the Lyapunov function values when switches occur. To this end, assume that the trajectory \( q(t) \) crosses the border between the sets \( Q_k \) in isolated instants only. Define the Lyapunov function \( V^c = V_k^c \) for \( q \in Q_k \) and let \( t_c \) be the time instance when the commutation occurs and \( q(t) \) travels from \( Q_k \) to \( Q_j \). Then the variation of the Lyapunov function admits the following upper estimate:

\[ |\Delta V| = |V(t_c^+) - V(t_c^-)| = |e^T (P_j - P_k) e| \leq \mu V(t_c^-), \]

for all \( k, j \in \bar{k} \), where

\[ \mu := \frac{\lambda M}{\lambda_m} - 1 \geq 0, \]

(13)

and \( \lambda_m \) is the minimum eigenvalue of \( P_1 \). Note that a less conservative estimate of \( \mu \) can be found computing the maximum generalized eigenvalue of the pair \( P_j, P_k \) over all \( j, k \in \bar{k} \).

It can be seen from (12) that the Lyapunov function decays when \( \min_{i \in \bar{d}} |q_i| > \delta_q \), and may increase otherwise. To provide the exponential convergence, we must thus assume that the decrease of the Lyapunov function is in average (in the sense of an integral over a time interval) more important than the possible increase when \( \min_{i \in \bar{d}} |q_i| < \delta_q \) or due to switches of \( P_k \). It can be seen as a restriction that the trajectory \( q(t) \) should not cross the borders between the sets \( Q \) often and should not remain for a long time in small vicinities of the borders between these sets, where \( \min_{i \in \bar{d}} |q_i| < \delta_q \) and the Lyapunov function may be increasing. More formally, this assumption can be formulated as follows.

**Assumption 3** For the trajectory \( q(t) \) there exist \( T_q > 0, n_Q > 0, \) and \( \kappa > 0 \) such that for all \( t_0 \geq 0 \) during the time interval \([t_0, t_0 + T_q]\) the trajectory \( q(t) \) crosses the borders between the sets \( Q_k \) not more than \( n_Q \) times, and it holds

\[ \int_{t_0}^{t_0 + T_q} \eta(q(\tau)) d\tau \geq n_Q \ln(1 + \mu) + (\eta_0 + \kappa) T_q. \]

(14)

If Assumption 3 holds, then for any \( t_0 \geq 0 \) we have

\[ V(t_0 + T_q) \leq V(t_0) (1 + \mu)^{n_Q} e^{\eta_0 T_q} e^{-\int_{t_0}^{t_0 + T_q} \eta(q(\tau)) d\tau} \leq e^{-\kappa T_q} V(t_0) < V(t_0) \]

and \( V(t) \) remains bounded for all \( t \in [t_0, t_0 + T_q] \),

\[ V(t) \leq V(t_0) (1 + \mu)^{n_Q} e^{\eta_0 T_q}. \]

Then for all \( t \geq 0 \) it holds \( V(t) \leq \Gamma e^{-\kappa t} V(0) \), where

\[ \Gamma := (1 + \mu)^{n_Q} e^{\eta_0 T_q} e^{\kappa T_q}. \]
Thus, $V(t)$ is bounded and $V(t) \to 0$, where $\kappa$ is the exponential rate of convergence.

In Assumption 3, the inequality (14) depends not only on the trajectory $q(t)$ but also on the design parameters of the observer, i.e., on the eigenvalues $\lambda_M, \lambda_m$ of the matrix $P_1$. Thus, for the same trajectory $q(t)$ it is possible that Assumption 3 holds for one choice of observer parameters and does not hold for another. From this point of view, Assumption 3 may be considered as a convergence requirement for the designed observer.

Finally, applicability of the proposed switched observer is summarized in the following theorem, where the proof follows from the derivations above.

**Theorem 4** Consider the system (5). Choose $\delta_\gamma \in (0, 1)$ such that there exist $P_1 > 0$ and $L_1$ satisfying the matrix inequality

$$
\begin{bmatrix}
(A_1 - L_1 C) P_1 + P_1 (A_1 - L_1 C) \\
+ (1 - \delta_\gamma) I_n \\
B^T P_1 \\
- I_n^{-1}
\end{bmatrix}
\begin{bmatrix}
P_1 B \\
- I_n^{-1}
\end{bmatrix}
\leq 0,
$$

where $A_1 = A(1_{(n-1)\times 1})$, and $B$ is defined in (8). Then if the trajectory $q(t)$ satisfies Assumption 3 for $\eta(q)$ and $\eta_0$ defined in (12) and $\mu$ defined in (13), then the observer (7) ensures exponential convergence of the estimate $\hat{x}(t)$ to the state vector $x(t)$ of the system (5).

**Remark 5** Assumption 3 can be relaxed by choosing $T_q$ and $\kappa$ non-uniformly in $t_0$ yielding asymptotic convergence instead of exponential.

**Remark 6** Using standard methods for matrix inequalities, see [9], and defining $H_1 := L_1^T P_1$, the matrix inequality (15) can be rewritten as the LMI

$$
\begin{bmatrix}
A_1^T P_1 + P_1 A_1 - C^T H_1 - H_1^T C \\
+ (1 - \delta_\gamma) I_n \\
B^T P_1 \\
- I_n^{-1}
\end{bmatrix}
\begin{bmatrix}
P_1 B \\
- I_n^{-1}
\end{bmatrix}
\leq 0,
$$

which can be efficiently solved for $P_1$ and $H_1$, see [19]. Then $L_1 = P_1^{-1} H_1^T$.

5 **Illustrative Example**

In this section, we continue the illustrative example started in Section 4.1. We consider the system (5) for $n = 3$, where

$$
\beta(u, y, t) := - \begin{bmatrix} 3 \\ 3 \end{bmatrix} y(t) + \begin{bmatrix} 0 \\ 0 \sin(2\pi t) \\ 1 \end{bmatrix}.
$$

The trajectory $q = (q_1, q_2)$ is constructed as $q_1(t) := \cos(t), q_2(t) := \cos(1.3t)$, and the vertices $v^k$ and sets $Q_k$, $k \in \mathbb{N}$, are chosen as (6). Choosing $\delta_\gamma = 0.05$ and computing $\delta_\gamma \approx 0.1$, a feasible solution to the matrix inequality (15) has been computed yielding $L_1 = \begin{bmatrix} 74 & 451 & 69 \end{bmatrix}^T$.

The state vector $x(t)$ and the estimation errors $e(t)$ are depicted in Fig. 1 and illustrate convergence of the state estimation errors. Fig. 2 shows the path of $q$, which is a Lissajous curve, and the Lyapunov function curve, where the level jumps can be observed at the switch instances, i.e., where $q_1(t)$ or $q_2(t)$ change their signs.

(a) State $x(t)$. (b) Estimation error $e(t)$.

Fig. 1. State $x(t)$ of the plant and the estimation error $e(t)$ in the illustrative example.

(a) The path $q(t)$ and the borders between the sets $Q_k$. (b) The function $V(t)$.

Fig. 2. The path of $q$ and the Lyapunov function $V(t)$ in the illustrative example.

6 **State estimation for a mechanical system**

As described in Section 2, we consider the reaction-wheel testbench that has been also presented in [26]. The pendulum hardware and the corresponding notation are given in Fig. 3, and the numerical values of parameters can be found in Table 1 of [26].

(a) The path $q(t)$ and the borders between the sets $Q_k$.

Fig. 3. Reaction-wheel pendulum hardware and the corresponding notation, see [26].

7
Neglecting the friction, the motion equations are

\[ J_r \ddot{\theta}_r + J_c \ddot{\theta} = kI, \]
\[ (J + J_r) \ddot{\theta} + J_r \ddot{\theta}_r = mlg \sin \theta, \tag{16} \]

where \( \theta_r \) and \( \theta \) are the reaction wheel and the pendulum angles, respectively, \( I \) is the current in the motor windings, \( J, J_r, ml, \) and \( g \) are physical parameters, see [26]. From (16), the pendulum dynamics can be written as (1), where \( a := mlg/J \) and \( b := -k/J \). As discussed in Section 2, the angle \( \theta \) is measured with a certain constant offset, \( y(t) = \theta(t) + d \). It is well-known that such a bias affects stabilization performance and accuracy, see [8,12]. One possible solution is to estimate the bias constructing an extended observer. To this end, we recall that as discussed in Section 2, the velocity \( \dot{\theta} \) is measured with a certain constant offset, \( \dot{\theta}(t) = \theta(t) + \dot{d} \). It is well-known that such a bias affects stabilization performance and accuracy, see [8,12]. Our proposed solution is illustrated both by simulations and by experimental results for a reaction-wheel pendulum. For further researches, we intend to consider if the proposed approach can be extended for other classes of observers, such as interval observers and observers with finite/fix-time convergence.

A Infeasibility of a solution with a constant matrix $P$

**Proposition 7** Consider the matrices $A(y)$ and $C$ given in (3). For any $\delta_y, 0 < \delta_y < 1$ there do not exist constant positive definite matrix $P \in \mathbb{R}^{3 \times 3}$ and parameter-varying vector $L : \mathbb{R} \rightarrow \mathbb{R}^3$ such that the linear matrix inequality

$$
(A(y) - L(y)C)^T P + P (A(y) - L(y)C) < 0 \quad (A.1)
$$

holds for all $y$ such that $|\cos(y)| \geq \delta_y$.

**PROOF.** Assume that for some $\delta_y$, the matrices $P$ and $L(y)$ satisfying the LMI (A.1) exist. Since the LMI is satisfied for all $y$ such that $|\cos(y)| > \delta_y$, it is also satisfied for $y = 0$ and $y = \pi$, that is

$$
(A(0) - L(0)C)^T P + P (A(0) - L(0)C) < 0,
$$

$$
(A(\pi) - L(\pi)C)^T P + P (A(\pi) - L(\pi)C) < 0.
$$

Define $A' := A(0) + A(\pi)$ and $L' := L(0) + L(\pi)$. Then

$$
(A' - L'C)^T P + P (A' - L'C) < 0, \quad (A.2)
$$

implying that the matrix $A' - L'C$ is Hurwitz. However, due to the structure of the matrices $A' = \begin{bmatrix} 0 & 2 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}$ and $C$, the matrix $A' - L'C$ is singular for any $L'$, and the LMI (A.2) is not feasible. Thus, we obtained a contradiction.
