4 Abstract

1

2

3

Mass renovation goals aimed at energy savings on a national scale require a significant level of public financial commitment. To identify target buildings, decision-makers need a thorough understanding of energy performance. Energy Performance Certificates (EPC) provide information about areas of space, such as land plots or a building's footprint, without specifying exact locations. They cover only a fraction of dwellings. This paper demonstrates that learning from observed EPCs to predict missing ones at the building level can be viewed as a spatial interpolation problem with uncertainty both on input and output variables. The Kriging methodology is applied to random fields observed at random locations to determine the Best Linear Unbiased Predictor (BLUP). Although the Gaussian setting is lost, conditional moments can still be derived. Covariates are admissible, even with missing observations. We present applications using both simulated and real data, with a specific case study of a city in France serving as an example.

5 Keywords: climate governance, energy efficiency, multi-scale processes,

6 areal data, change of support

7 1. Introduction

⁸ 1.1. Classifying the EPC prediction problem in research

Energy Performance Certificates are delivered in many countries around 9 the world to assess the energy efficiency of buildings. Various approaches can 10 be found in the European Union, Turkey, the UK, the USA... An Energy 11 Performance Certificate (EPC) is defined in France as an energy consumption 12 associated with a qualitative labelling letter ranging from A to G as shown in 13 Figure 1. Energy consumptions associated with dwellings, identified by their 14 addresses, are inventoried in a database released in open access and mapped 15 in Figure 2. A second database matches each address with a land plot. 16 Finally, a third database gives the living area of every dwelling, be it house 17 or apartment, together with the land plot where they are located, and a few 18 other technical specifications. However, the exact location of these dwellings 19 on each land plot is not certain. From these datasets, decision-makers such as 20 municipalities, would like to infer the EPC (energy consumption and label) of 21 buildings that have not been observed in order to identify targets for energy 22 retrofit incentives. This problem is referred to as the EPC prediction problem 23 in the present paper. 24

In the literature, this problem can be approached from an engineering perspective, from a data management perspective or from a geostatistics point of view.

From an engineering perspective, heat engineers have physical models 28 that compute an energy balance in order to find a given building's energy 29 consumption. These models require a large number of technical features 30 and may be used to design a refurbishment (improvement) strategy (Baker 31 et al., 2021). To work at a larger scale, heat engineers define typologies of 32 buildings, compute a distribution of these types on a given territory, and 33 therefore infer a distribution of EPC labels. This approach has proven to 34 be efficient (Ballarini et al., 2017). However, the lack of knowledge about 35 the detailed technical features of each building is a strong limitation for a 36 prediction at the building level. Some feature reduction efforts have been 37 made (Ali et al., 2020), but the remaining features are still problematic to 38 infer and require extra efforts (Schetelat et al., 2020). The present work 30 considers an alternative approach wherein detailed technical knowledge of 40 each building is relinquished, and instead leverages the geolocated nature of 41 EPC information. 42

Figure 1: Prescribed vignette appearing on the French energy performance certificate up to 2021. Label A refers to energy-efficient dwellings, and label G refers to energy-intensive dwellings.

From a data management perspective, the EPC prediction problem re-43 quires a process to combine datasets from multiple sources available at mul-44 tiple scales, which is known as data fusion (Smith et al., 2008). These types 45 of problems are becoming increasingly complex due to the growing amount 46 of data available, whether it be ecological, social, or institutional. These 47 datasets relate to space units of varying shapes, dimensions, and cardinal-48 ity. And in some cases, it may be difficult to determine the exact position 49 of an observed object. This is the case with buildings, since many govern-50 ments lack a detailed map of the building stock in their country. Property 51 tax is typically based on intrinsic factors such as surface area and number 52 of bedrooms, but not extrinsic factors such as the floor number or window 53 orientation (see Table 1). As a result of this uncertainty, large-scale studies 54 on housing stock have to rely on an abstract concept of dwelling. This idea of 55 dwelling can refer to a house or an apartment; it is not clearly delimited but 56 it is described by a set of features such as an area or a number of bedrooms. 57 These features are gathered in a table with one dwelling per row, meaning 58 that the dwelling is the smallest unit of information. 59

dwelling ID	address	area (m^2)	bedrooms	 land plot ID	
024830065432	161 rue du Chateau	83	3	 024830000C0057	
	02089 BILLY				

Table 1: Structure of the dwellings table from the French Ministry of Finance. The actual table comprises 118 features. Geographic position is identified by a land plot ID.

⁶⁰ Similarly, the smallest unit of information for a table with one EPC per ⁶¹ row is a part of a building. It is not clearly defined as an object in a 3-

dimensional space, but it has features that describe it (see Table 2). And 62 to predict the EPC of buildings, one also has to define buildings. In the 63 same way, data fusion requires defining the smallest units of information, 64 also known as granules for each dataset: "Informally, a granule of a variable 65 X is a clump of values of X that are drawn together by indistinguishability, 66 equivalence, similarity, proximity, or functionality. For example, an interval 67 is a granule." Zadeh (2005). The field of study that focuses on representing, 68 constructing, and processing these information granules is called Granular 69 Computing (Pedrycz, 2013). Assuming that an appropriate data fusion pro-70 cess is implemented, dwellings, EPC observations, and complete buildings 71 are represented in the same data model. It remains to define a relevant 72 predictive model. Granular computing is multidisciplinary, but since we are 73 dealing with geo-localized information, the natural field of research is geo-74 statistics, which has been defined as "dealing with spatial processes indexed 75

⁷⁶ over continuous space" (Cressie, 1993, p7).

From a geostatistics perspective, the irreducible uncertainty about gran-77 ules' positions (dwellings, buildings, etc.) in their underlying space restricts 78 the use of traditional spatial interpolation models such as Kriging as well as 79 more recent models such as those proposed by Roksvåg et al. (2021), although 80 the latter efficiently combines point and areal observations. This work aims 81 to overcome the latter limitation and develop a comprehensive framework 82 capable of handling data with uncertainty about the position of observed 83 objects while still allowing for the definition of an optimal linear predictor 84 for spatial interpolation of EPC values. As is first presented below, the liter-85 ature shows that the problems to solve have already been identified and that 86 several solutions have been proposed with their benefits and shortcomings. 87

⁸⁸ 1.2. The limits of systematic averaging for spatial interpolation

Gaussian Process Regression (Williams and Rasmussen, 1996), also known 89 as Kriging, is one of the major spatial interpolation approaches (Comber and 90 Zeng, 2019). Kriging theory relies on the assumption that points close to each 91 other are more likely to have similar features. It achieves the Best Linear 92 Unbiased Predictor (BLUP) in the least squares sense for point spatial inter-93 polation. However, the EPC prediction problem deals with observations that 94 are not point observations but areal observations. Areal interpolation, as de-95 fined by Lam (1983), involves "the transformation of data from one set of 96 boundaries to another". Lam also used the terms source zone and target zone. 97 For the EPC prediction problem, source zones are dwellings and buildings' 98 parts that are observed, while target zones are whole buildings, including 99 those for which no part has been observed. Spatial or areal interpolation re-100 search is based on the assumption that granules close to each other are more 101 likely to have similar features. This is reasonably understandable for temper-102 atures that are continuously defined over space, but it may be more challeng-103 ing to observe and model when dealing with areal data where granules can 104 be of various sizes and shapes, sometimes uncertainly defined. Gotway and 105 Young (2002) highlighted the terms used to describe areal interpolation and 106 its challenges; this terminology includes block Kriging, multi-scale and multi-107 resolution modelling, the ecological inference problem, the modifiable areal 108 unit problem (MAUP), the scaling problem, the change of support problem, 100 and the reduction of variance problem. Below are the aspects of this work 110 that are more relevant for solving the EPC prediction problem. 111

Block Kriging is a derivative of Kriging designed for handling areal data. 112 It distinguishes point-to-area, area-to-point, and area-to-area predictions. It 113 assumes that a feature at block (granule) level is the average of the block's 114 point features. Point-to-area prediction produces an estimate "identical to 115 that obtained by averaging the point estimates produced by [Kriging]" (Isaaks 116 and Srivastava, 1989; Cressie, 1993). Kyriakidis (2004) described a complete 117 Kriging model for area-to-point prediction, proved that it is an optimal pre-118 dictor, and sketched area-to-area prediction. Goovaerts (2008) studied in 119 depth the problem of estimating the variogram, that is to say, measuring 120 the similarity between 2 points at different distances, for block Kriging. He 121 showed that averaging reduces the sill of the variogram and tried to tackle 122 this bias. Moreover, while point estimates obtained by Kriging are optimal, 123 area-to-area Kriging may not be the optimal predictor for the average value 124 over the block. 125

A known issue resulting from systematic averaging in areal Kriging models 126 arises in scenarios such as analysing crop yields, where the set of agricultural 127 fields to aggregate for a certain type of crop varies from year to year. It states 128 that correlations between features at areal level are heavily dependent on the 129 aggregation process, making it difficult to compare correlations between dif-130 ferent years. This is the Modifiable Areal Unit Problem (MAUP) for which a 131 measuring approach has been recently proposed (Briz-Redon, 2022). While 132 the MAUP refers to the correlation between aggregated features, the ecolog-133 ical inference problem is a result of the correlations at the individual level 134 being different from the correlations of the averaged features at the ecological 135 (group) level. A lack of information about the individuals' positions leads 136 to a bias when the averaged information about individuals distributed into 137 areal units is cross-classified by other individual (point-level) variables (sex, 138 race). According to Gotway and Young (2002), "The smoothing effect that 139 results from averaging is the underlying cause of both the scale problem in the 140 MAUP and aggregation bias in ecological studies." Apart from correlations, 141 the variance itself is affected by systematic averaging. Indeed, the average 142 of identical random variables has a smaller variance than the variance of the 143 individuals themselves. The specific issue of variance reduction at the block 144 level was partially addressed in Li et al. (2009) using rectangular blocks at 145 multiple scales. 146

Despite its limitations, the averaging method has proven to be effective for interpolating areal data. For example, Poggio and Gimona (2015) downscaled climate models and predicted soil wetness using Kriging on the residuals

of a generalized additive model (Wood, 2017). Area-to-point Kriging, also 150 called disaggregation, has also been implemented by Kerry et al. (2013); 151 Truong and Heuvelink (2013); Yoo and Kyriakidis (2006). Additionally, area-152 to-area Kriging (block Kriging) has been used effectively by Zhang et al. 153 (2018) and has been apply to downscaling by Jin et al. (2018) as well as 154 Pereira et al. (2018). The satellite imaging field has also notably benefited 155 from this framework, as in the pan-sharpening process, which is "a technique 156 to combine the fine spatial resolution panchromatic (PAN) band with the 157 coarse spatial resolution multispectral bands of the same satellite to create 158 a fine spatial resolution multispectral image" Wang et al. (2016). In this 159 process, points are weighted according to their distance from the centroid of 160 the satellite pixel when computing the average value. 161

Both the MAUP and the ecological inference problem belong to a fam-162 ily of problems related to the combination of different types of granules in 163 the same model, e.g. observing dwellings and predicting buildings. These 164 problems are gathered in the change of support problems family. Another 165 particular change of support problem known as spatial misalignment arises 166 when a given feature is observed at multiple scales, including point level. 167 Systematic averaging makes points and areas different objects with differ-168 ent different correlation structures and therefore different predictors. The 169 classification of problems such as "area-to-point" or "area-to-area" reflects 170 this categorization. To address spatial misalignment, a Bayesian framework 171 that can be iterated both with point observations and block observations has 172 been proposed by Moraga et al. (2017). However, this model is still based 173 on averaging at areal level for features that are continuously defined over the 174 territory. Like other models derived from Kriging, it considers blocks to be 175 connected surface areas in \mathbb{R}^2 that need to be discretized (Goovaerts, 2008), 176 which can distort reality for features that are not continuously defined over 177 the space. Such is the case of populations of individuals that are discrete 178 points heterogeneously located within a block, such as a county or census 179 tract. 180

181 1.3. Beyond systematic averaging

¹⁸² A way to try and overcome change of support problems is to define a new ¹⁸³ data model for which features at areal level do not require systematic aver-¹⁸⁴ aging. In this regard, Godoy et al. (2022) defined a Gaussian random field ¹⁸⁵ on the class \mathfrak{B}_D of closed subsets of a certain domain $D \in \mathbb{R}^n$. Distances

between elements of \mathfrak{B}_D are measured with the Hausdorff distance, and the 186 correlation structure between features is based on this distance together with 187 a Matérn kernel. Eventually, a Bayesian framework is used to fit the model 188 with respiratory cancer data, yielding encouraging results. This model seems 189 very general and will probably find other fields of application. However, it is 190 not interpretable in the sense that there is no obvious link between the fea-191 ture at the areal level and the feature at the point level, therefore eluding the 192 question of consistency. In other words, it is not known whether the aggrega-193 tion of cancer incidence predictions at a small scale would give the prediction 194 of cancer incidence at a larger scale. Beside this limitation, the Hausdorff-195 Gaussian process does not solve the problem of position uncertainty that is 196 found in the EPC prediction problem. 197

In this paper, a new model is proposed where learning and prediction can 198 be made from both aggregated and point support data. An object category 199 called grain is introduced to express this new approach, consistent with re-200 search realities where it may be desirable to complete large aggregated open 201 datasets with local observations and predict at various scales. Grains con-202 taining a continuous or discrete set of points are treated identically. As is 203 detailed above, a weighted average is the standard aggregation approach. 204 In this respect, the MAUP is related to determining a covariance model for 205 points from which the covariance between blocks and the covariance between 206 points and blocks are derived. Weights for averaging are assumed to be fully 207 determined for a given block; they are not regarded as a probability distribu-208 tion for a block, thereby ignoring some related statistics and other potential 209 sources of stochastic dependence between blocks. The present paper pro-210 poses a method of incorporating a mixture distribution to address this issue. 211 Kriging has already been developed for features that are mixtures at the 212 point level (Lin et al., 2010), but Lin et al. make no assumption about the 213 distribution of features at the areal level. Instead, we assume the aggregation 214 of information at the areal level to be a mixture. Averaging a large number 215 of random variables results in a variance reduction, whereas mixing a large 216 number of random variables does not tend to reduce the variance. We will 217 show that this approach effectively manages position uncertainty. However, 218 one drawback is that mixtures of Gaussian random variables are generally 219 not Gaussian, which means that the usual Gaussian process interpretations 220 and conditioning will no longer hold. 221

222

The present study proposes a new model for processing granular data,

as detailed in Section 2. In Subsection 2.1, a suitable data model is estab-223 lished, while in Subsection 2.2, we define the feature variables' means and 224 covariances. Moreover, a Best Linear Unbiased Predictor is derived in Sub-225 section 2.3. We illustrate the model with examples in Section 3, starting 226 with simulated rounded positions in Subsection 3.1, followed by simulated 227 areal data with varying area sizes in Subsection 3.2. Subsection 3.3 focuses 228 on presenting the EPC prediction problem with real data. Finally, in Section 229 4, we discuss the pros and cons of the new model. 230

231 2. Prediction model

This work is motivated by the will to handle data that is released in open 232 format by public or private institutions. The goal is to use institutional data, 233 such as the distribution of salaries at the municipality level, to estimate the 234 distribution of salaries at a smaller scale, such as a district in a city, while 235 also including known salaries at specific locations. To achieve this, we pro-236 pose here a general Kriging approach that extends the traditional Simple or 237 Ordinary Kriging and coKriging techniques. The model will explain some 238 variables (such as the energy consumption, the salary, etc.) using some ex-239 planatory variables (such as the location, the construction year, etc.). The 240 former will be referred to as output variables and the latter as input vari-241 ables. Let us consider a space (input space, sometimes known as study space) 242 over which is defined a field of multidimensional random variables (output 243 variables, features of interest) such as sociological variables, assumed to be 244 defined and potentially observed for both points in the input space and for 245 geographic areas, such as cities, regions, or countries. These areas are re-246 ferred to as "grains". The model predicts output variables at unobserved 247 points or grains, based on the assumption that the dependence between out-248 puts depends on the relative positions of the inputs. No assumption is made 240 regarding the shape of the grains, which can even overlap partially or com-250 pletely. 251

- 252 2.1. Data model
- Let us define the structure of the input space.

Definition 1 (Inputs). Let d be a positive integer. A territory and grains inside this territory are defined as follows:

• A territory is a subset χ of \mathbb{R}^d ;

• A point is any element $x \in \chi$;

257

258

• A grain is any non-empty subset $g \subseteq \chi$.

It is common in some application fields to use a different terminology 259 to talk about grains: blocks, pixels, or areas for instance. In the above 260 definition, there is no constraint on grains, contrary to pixels that are usually 261 forming a regular grid known as a raster. A set of grains does not have to 262 cover the whole territory, and its elements might overlap. Moreover, a grain 263 is not necessarily a connected set, contrary to blocks. And an area is usually 264 seen as associated with a surface area (a set of strictly positive measure) 265 whereas a grain may be a finite set of points. 266

For instance, suppose that the points are represented as pairs of latitude and longitude coordinates in an appropriate coordinate reference system. In this case, χ could be defined as the set of all latitude-longitude pairs that fall within a specific country, yielding d = 2 and $\chi \subset \mathbb{R}^2$. A grain may correspond, for example, to a specific city, to a specific land plot, or to a specific building's footprint. Previous Kriging models refer to blocks or areas for sets of points that are disjoint (see, for instance, Kyriakidis, 2004).

When dealing with geographic data, a set of grains is usually the minimum 274 scale at which information is available; that is to say, the data granularity. 275 For instance, it may be the set of land plots, the set of cities, the set of 276 buildings' footprints, etc. However, considered grains may have non-empty 277 intersections and may come from different datasets, at different scales, such 278 as land plots and census tracts. Definition 1 is general enough to include 279 such sets of grains. Data that describe population or buildings are not con-280 tinuously defined over a territory, as opposed to temperature or pollutant 281 concentration. Census data are anonymized at the census tract level before 282 being released. For instance, in a census table describing dwellings, a row 283 describes a dwelling that exists on a certain census tract, but we don't know 284 exactly where it is on this tract. Then dwellings' surface area is neither con-285 tinuous nor clearly geo-localized. Definition 2 below unifies output features 286 that are continuously defined over a territory and output features that are 287 not. 288

An originality of this work is to consider a set of random locations that model the uncertainty of explanatory variables over each considered grain. Let $\{X_g, g \in \mathcal{G}\}$ be a given sequence of random variables that are random locations, or more generally, random explanatory variables. Their joint distri²⁹³ bution is assumed to be known. As an example, for non-overlapping grains,
²⁹⁴ one can choose a sequence of independent uniform random variables over
²⁹⁵ each grain, but any other joint distribution, possibly dependent, can be cho²⁹⁶ sen. Definition 2 associates output variables with these random explanatory
²⁹⁷ variables.

Definition 2 (Outputs). Let \mathcal{G} be a set of grains. We assume that for each grain $g \in \mathcal{G}$, there is a random variable X_g with values the points of g. Output variables are defined over points and grains of \mathcal{G} as follows:

• Y is a p-dimensional multivariate random field over χ such that:

$$\forall x \in \chi, \ \mathbf{Y}(x) := (Y_1(x), \dots, Y_p(x))^\top \in \mathbb{R}^p$$

 For each g ∈ 𝔅, a p-dimensional real random vector Y(g) is defined to be the value of Y at a random location X_g ∈ g:

$$\forall g \in \mathfrak{G}, \ \mathbf{Y}(g) := \mathbf{Y}(X_g) \in \mathbb{R}^p$$

³⁰¹ Defined accordingly, $\mathbf{Y}(g)$ is a mixture distribution.

For a given set of grains \mathfrak{G} , the set of random variables $\{X_g : g \in \mathfrak{G}\}$, is assumed to be defined and known, and the dependence structure between those random variables is supposed to be known. Furthermore, these random variables are assumed to be independent from the random field Y.

Example 1. The importance of X_g should be stressed here. For instance, if one studies the distribution of capital owned by citizens of a given municipality, $P(X_g = x)$ gives the probability of a citizen x to be observed. $P(Y(X_g) = y)$ is the probability to observe y when a citizen picked randomly according to X_g unveils his capital:

$$P(Y(g) = A) = P(Y(X_g) = A) = \sum_{x \in g} P(X_g = x)P(Y(x) = A) .$$

It is clear that individuals are not distributed regularly (along a grid for instance) in the grain. However, in this example, it makes sense to consider that $\forall x \in g$, $P(X_g = x) = 1/[g]$ where [g] is the cardinality of g. This means that the contribution of all citizens are equally valued in Y(g). Let us now suppose that the outputs are partially known on a set of grains. For $(i_1, \ldots, i_n) \in \{1, \ldots, p\}^n$ and $g_1, \ldots, g_n \in \mathcal{G}$ the following n random variables are known:

$$\underline{\mathbf{Y}} = (Y^1, \dots, Y^n)^\top$$
 with $Y^j = Y_{i_j}(g_j)$ for $j \in \{1, \dots, n\}$

As an example, if ℓ observations of the whole random vector $\mathbf{Y}(g_h)$ are conducted for $h \in \{1, \ldots, \ell\}$, then $n = \ell \cdot p$ and the vector of observations is:

$$\underline{\mathbf{Y}} = (Y_1(X_{g_1}), \dots, Y_p(X_{g_1}), \dots, Y_1(X_{g_\ell}), \dots, Y_p(X_{g_\ell}))^\top .$$
(1)

If some observations are incomplete, that is to say some components of \mathbf{Y}_{g_j} are missing for some j, then $\underline{\mathbf{Y}}$ will be a subvector of $\underline{\mathbf{Y}}$ given in Equation (1). It means that there may be missing data in the outputs' observations.

321 2.2. Mean and covariances of output variables

The originality of the present work is that for a grain $g, \mathbf{Y}(g)$ is defined to 322 be $\mathbf{Y}(X_q)$, the value of \mathbf{Y} at a random location $X_q \in g$. If the random field 323 $\{\mathbf{Y}(x) : x \in \chi\}$ and the joint distribution of $\{X_q \in \chi : g \in \mathcal{G}\}$ are known, 324 then the joint distribution of $\{\mathbf{Y}(q) : q \in \mathcal{G}\}$ can be deduced. And, if one 325 only knows the moments of order one and cross moments of order two of 326 $\{Y(x) : x \in \chi\}$ together with the joint distribution of $\{X_q \in \chi : g \in \mathcal{G}\},\$ 327 then one can expect to be able to deduce expectation and cross covariances 328 of $\{\mathbf{Y}(q) : q \in \mathcal{G}\}.$ 329

In the rest of the paper, we assume that the first two moments of $\{\mathbf{Y}(x) : x \in \chi\}, \{X_g \in \chi : g \in \mathcal{G}\}\$ and $\{\mathbf{Y}(g) : g \in \mathcal{G}\}\$ exist. In the following proposition, we show that we can indeed deduce the moments of grains' outputs. **Proposition 1** (Mean and covariance of $\mathbf{Y}(g)$). From Definition 2, we derive the following results:

(i) For any grain $g \in \mathcal{G}$ and any index $i \in \{1, \ldots, p\}$, assuming that for all $x \in g$ we know $\mu_i(x) := \mathbb{E}[Y_i(x)] = \mathbb{E}[Y_i(g)|X_g = x]$, we have:

$$\mu_i(g) := \mathbb{E}\left[Y_i(g)\right] = \mathbb{E}\left[\mu_i(X_g)\right]$$

(ii) For any two grains g, g' in \mathscr{G} and any two indices $i, j \in \{1, \ldots, p\}$, assuming that for all $x \in g$, $x' \in g'$ we know $k_{i,j}(x,x') := \operatorname{Cov}[Y_i(x), Y_j(x')]$, we have:

$$k_{i,j}(g,g') := \operatorname{Cov} [Y_i(g), Y_j(g')] = \mathbb{E} [k_{i,j}(X_g, X_{g'})] + \operatorname{Cov} [\mu_i(X_g), \mu_j(X_{g'})]$$

In particular,

$$k_{i,i}(g,g) = \operatorname{Cov}\left[Y_i(g), Y_i(g)\right] = \mathbb{V}\left[Y_i(g)\right] = \mathbb{E}\left[k_{i,i}(X_g, X_g)\right] + \mathbb{V}\left[\mu_i(X_g)\right].$$

Proof. (i) is a direct application of the conditional expectation formula $\mathbb{E}[V] = \mathbb{E}[\mathbb{E}[V|U]]$ where $Y_i(x)$ is the result of conditioning $Y_i(g)$ with X_g . (ii) is derived from the conditional covariance formula:

$$\operatorname{Cov}\left[U,V\right] = \mathbb{E}\left[\operatorname{Cov}\left[U,V|W\right]\right] + \operatorname{Cov}\left[\mathbb{E}\left[U|W\right], \mathbb{E}\left[V|W\right]\right]$$

after conditioning by the joint random vector $(X_g, X_{g'})$ (random variable X_g).

Note that $\operatorname{Cov} [\mu_i(X_g), \mu_j(X_{g'})] = 0$ when $\mu_i(x)$ is constant over g or g'or when X_g and $X_{g'}$ are independent. Also note that this framework yields the expected result that if a grain is restricted to a point, then the output variables associated with this grain are the same as those associated with the underlying point.

Example 2. For two distinct and finite grains g and g' of cardinalities [g], [g'], assuming in this example that X_g and $X_{g'}$ are independent uniform ³⁴⁶ random variables, we get:

$$\mu_{i}(g) = \frac{1}{[g]} \sum_{x \in g} \mu_{i}(x)$$

$$k_{i,j}(g,g') = \frac{1}{[g][g']} \sum_{(x,x') \in g \times g'} \operatorname{Cov} [Y_{i}(x), Y_{j}(x')]$$

$$k_{i,j}(g,g) = \frac{1}{[g]} \sum_{x \in g} \operatorname{Cov} [Y_{i}(x), Y_{j}(x)]$$

Remark 1 (Comparison with average – block-to-block covariances). Previous models using the concept of blocks define $\bar{Y}_i(g) := \mathbb{E}[Y_i(X_g)|\{Y_i(x), x \in g\}] = \int_g Y_i(x) dF_g(x)$, with F_g the cumulative distribution function (cdf) of the, possibly discrete, random variable X_g , $i \in \{1, \ldots, p\}$. One can check that with this setting, the mean of the mixture $Y_i(g)$ and the average $\bar{Y}_i(g)$ are identical:

$$\mathbb{E}\left[Y_i(g)\right] = \bar{Y}_i(g) \,.$$

Regarding the covariances, when X_g and $X_{g'}$ are two independent random variables, one can check that

$$\mathbb{E}\left[k_{i,j}(X_g, X_{g'})\right] = \operatorname{Cov}\left[\bar{Y}_i(g), \bar{Y}_j(g')\right]$$

However,

$$\mathbb{E}\left[k_{i,j}(X_g, X_g)\right] \neq \operatorname{Cov}\left[\bar{Y}_i(g), \bar{Y}_j(g)\right]$$

because the independence assumption does not hold any more. As a consequence, $\mathbb{V}[Y_i(g)] \neq \mathbb{V}[\bar{Y}_i(g)]$, even in the specific case where $\forall i, j, g, g', \operatorname{Cov}[\mu_i(X_g), \mu_j(X_{g'})] = 0$. The difference between a mixture and an average is retrieved here: $\mathbb{V}[Y_i(g)] \geq \mathbb{V}[\bar{Y}_i(g)]$.

351 2.3. Best unbiased linear predictor

A Gaussian Process is a collection of random output variables indexed over points in the input space of explanatory variables, typically denoted as Y(.). An observation is therefore a random variable Y(x) evaluated at a given point x, and the covariance between Y(x) and Y(x') is a function of (x, x'). But we rather consider here an uncertainty on the explanatory variable, meaning that an observation is modelled as a random field Y(.)

evaluated at a random location X_q over a given gain g. Thus, one observes 358 a mixture of Gaussian random variables that are not Gaussian any more. 359 Moreover the covariance between $Y(X_q)$ and $Y(X_{q'})$ depends on the joint 360 random variables $(X_q, X_{q'})$. In the previous subsection, some assumptions 361 have been made that are sufficient to be able to compute the covariance be-362 tween two observations. In the present subsection, it is proved that, given 363 the above defined framework and a learning set of observations, a best linear 364 predictor can be inferred to predict the output features associated with a 365 grain $g \subset \chi$ that has not been observed, given a learning set of observa-366 tions. Note that the problem amounts to predicting any component of the 367 output variable and that the specific covariance structure resulting from the 368 uncertainty on the explanatory variable requires the development of a new 369 software package, as usual packages such as DiceKriging can not fit such a 370 model. 371

Let $\underline{\mathbf{Y}}$ be the vector of observations forming the learning set, and let $g \subset \chi$ be a grain such that for some $i \in \{1, \ldots, p\}$, $Y_i(g)$ is to be predicted. Denote:

$$\begin{split} \underline{\boldsymbol{\mu}} &:= \mathbb{E}\left[\underline{\mathbf{Y}}\right] & \in \mathbb{R}^n \\ \mathbf{K} &:= \left(\operatorname{Cov}\left[Y^j, Y^{j'}\right]\right)_{j,j' \in \{1,\dots,n\}} & \in \mathcal{S}_n^+(\mathbb{R}) \\ \mathbf{h}_i(g) &:= \left(\operatorname{Cov}\left[Y^j, Y_i(g)\right]\right)_{j \in \{1,\dots,n\}} & \in \mathbb{R}^n \end{split}$$

where $S_n^+(\mathbb{R})$ is the set of semi-definite positive, $n \times n$, real matrices. In the following, **K** is assumed to be invertible.

With a given set of weights $\alpha(g) = (\alpha^1(g), \ldots, \alpha^n(g)) \in \mathbb{R}^n$, is associated a linear predictor $M_{\alpha(g)}$:

$$M_{\boldsymbol{\alpha}(g)} = \sum_{j=1}^{n} \alpha^{j}(g) Y^{j} = \boldsymbol{\alpha}(g)^{\top} \underline{\mathbf{Y}}.$$

The optimal weights $\alpha_i(g)$, provided that they exist and are unique, are defined to be those minimizing a quadratic error over all unbiased linear predictors:

$$\boldsymbol{\alpha}_{i}(g) \in \arg\min_{\boldsymbol{\alpha}\in\mathbb{R}^{n}} \mathbb{E}\left[\left(Y_{i}(g) - \boldsymbol{\alpha}^{\top} \mathbf{\underline{Y}}\right)^{2}\right]$$

382

Given the optimal predictor $M_i(g)$, the prediction error and the Kriging

383 (co)variance are denoted as:

$$\epsilon_i(g) := Y_i(g) - M_i(g)$$

$$c_{i,j}(g,g') := \mathbb{E} \left[\epsilon_i(g) \, \epsilon_j(g') \right]$$
(2)

$$v_i(g) := c_{i,i}(g,g) \tag{3}$$

The following proposition gives an optimal predictor that can be computed under the minimal assumptions of Proposition 1. Given the first two moments of random variables $\{X_g : g \in \mathcal{G}\}$, all components of $\underline{\mu}$, **K**, and $\mathbf{h}_i(x)$ can be computed.

Proposition 2 (Mixture Kriging prediction). Given a set of observations $\underline{\mathbf{Y}}$, for any $g, g' \subset \chi$, and in particular for a single point $g = \{x\}$, for any $i \in \{1, \ldots, p\}$, the weights $\boldsymbol{\alpha}_i(g)$ yielding the best linear unbiased predictor (BLUP) of $Y_i(g)$ and the associated cross errors are as follows:

(i) Simple Mixture Kriging. If $\boldsymbol{\mu} = (0, \dots, 0)^{\top}$ and $\mu_i(g) = 0$ then

$$\boldsymbol{\alpha}_{i}(g) = \mathbf{K}^{-1}\mathbf{h}_{i}(g) \qquad (4)$$
$$c_{i,j}(g,g') = k_{i,j}(g,g') - \mathbf{h}_{i}(g)^{\top} \mathbf{K}^{-1}\mathbf{h}_{j}(g')$$

(ii) Ordinary Mixture Kriging. If $\underline{\mu} \neq (0, \dots, 0)^{\top}$ then the condition for unbiasedness writes $\mu_i(g) = \boldsymbol{\alpha}_i(g)^{\top} \underline{\mu}$ and

$$\boldsymbol{\alpha}_{i}(g) = \mathbf{K}^{-1} \left(\mathbf{h}_{i}(g) + \lambda_{i}(g) \underline{\boldsymbol{\mu}} \right)$$
(5)
where $\lambda_{i}(g) = \frac{\mu_{i}(g) - \underline{\boldsymbol{\mu}}^{\top} \mathbf{K}^{-1} \mathbf{h}_{i}(g)}{\underline{\boldsymbol{\mu}}^{\top} \mathbf{K}^{-1} \underline{\boldsymbol{\mu}}}$
 $c_{i,j}(g,g') = k_{i,j}(g,g') - \mathbf{h}_{i}(g)^{\top} \mathbf{K}^{-1} \mathbf{h}_{j}(g') + \lambda_{i}(g)\lambda_{j}(g) \underline{\boldsymbol{\mu}}^{\top} \mathbf{K}^{-1} \underline{\boldsymbol{\mu}}$

Proof of Proposition 2 is given in Supplementary material Appendix A.
 Proposition 2 is presented as an algorithm in pseudo-language for Simple
 Mixture Kriging in Algorithm 1.

Assume that $\{\mathbf{Y}(x) : x \in \chi\}$ is a vector-valued Gaussian random field and that each X_g is Dirac distributed for all grains. This last condition holds in particular when each grain is restricted to one singleton point. In this Gaussian case, one retrieves Simple Kriging and Ordinary Kriging predictors, as defined, for example, in Rasmussen and Williams (2006). In this sense, the Mixture Kriging results presented here can be seen as a generalization ofthe Kriging interpolation.

The above Proposition 2 is valid to predict a single component $Y_i(g)$ of the output variable $\mathbf{Y}(g)$, but it can be extended to the prediction of $\mathbf{Y}(g)$: the best linear unbiased predictor of $\mathbf{Y}(g) = (Y_1(g) \dots Y_p(g))^{\top}$ for the quadratic error $\mathbb{E}[||\mathbf{Y}(g) - \mathbf{A}\underline{\mathbf{Y}}||_2^2]$ is $M_{\mathbf{A}(g)} = \mathbf{A}(g)\underline{\mathbf{Y}}$ where $\mathbf{A}(g)$ is the matrix of which the *i*-th row is equal to $\boldsymbol{\alpha}_i(g)^{\top}$ given by Proposition 2.

403 2.4. Particular cases

In this subsection, two important particular cases are explored. The first one considers the Ordinary Mixture Kriging situation, where the output variable's expectation is the same everywhere. An estimator of this constant expectation is derived. The second particular case considers Mixture Kriging with noisy observations and shows that a nugget effect can be introduced the same way as for Kriging.

Particular case 1 (Constant mean $\underline{\mu} = \mu_0(1, \dots, 1)^{\top}$). Regarding Ordinary Mixture Kriging, assuming that all random variables $Y_i(g)$ have the same unknown expectation μ_0 , and setting $\mathbf{1}_n = (1, \dots, 1)^{\top}$, Equation (5) simplifies into:

$$\boldsymbol{\alpha}_{i}(g) = \mathbf{K}^{-1} \left(\mathbf{h}_{i}(g) + \frac{1 - \mathbf{1}_{n}^{\top} \mathbf{K}^{-1} \mathbf{h}_{i}(g)}{\mathbf{1}_{n}^{\top} \mathbf{K}^{-1} \mathbf{1}_{n}} \mathbf{1}_{n} \right) ,$$

and setting $\hat{m}(g) := \frac{\mathbf{1}_{n}^{\top} \mathbf{K}^{-1} \mathbf{Y}}{\mathbf{1}_{n}^{\top} \mathbf{K}^{-1} \mathbf{1}_{n}} ,$
 $M_{i}(g) \ becomes: \ M_{i}(g) = \hat{m}(g) + \mathbf{h}_{i}(g)^{\top} \mathbf{K}^{-1} (\mathbf{Y} - \mathbf{1}_{n} \hat{m}(g)) ,$

therefore $\hat{m}(g)$ is an unbiased estimator of μ_0 . \hat{m} can be compared with usual sample mean for independent observations $\overline{\underline{\mathbf{Y}}} = \frac{\mathbf{1}_n^{\top} \underline{\mathbf{Y}}}{\mathbf{1}_n^{\top} \mathbf{1}_n}$.

Particular case 2 (Noisy observations). Let us consider the case where, for a given $x \in \chi$, we can only observe $\tilde{Y}_i(x) = Y_i(x) + e_i(x)$ where $e_i(x)$ is independent from any $Y_j(x')$. We denote the resulting noisy output variables, observations and covariances as follows:

$$Y_{i}(g) := Y_{i}(X_{g}) = Y_{i}(g) + e_{i}(g)$$
$$\tilde{Y}^{j} := \tilde{Y}_{i_{j}}(X_{g_{j}}) = Y^{j} + e^{j}$$
$$\eta_{i,j}(x, x') := \operatorname{Cov} \left[e_{i}(x), e_{j}(x')\right]$$

Algorithm 1: Simple Mixture Kriging predictor presented as an algorithm in pseudo-language.

Data:

It is assumed that all grains are discretized and that for any grain g, X_q is uniform. A single output random field Y(.) is observed.

 \mathcal{G} : A list of *n* observed grains $\mathcal{G}_i, i \in \{1, \ldots, n\}$, each grain being a table with its points coordinates.

<u>Y</u>: Observed values $Y^i, i \in \{1, \ldots, n\}$, a numeric vector of same length as \mathcal{G} .

k(.,.): Covariance kernel, a function that takes 2 points and returns a positive real number.

 g_0 : An unobserved grain to be predicted i.e. a table with its points coordinates.

 ϵ : A positive real number giving the nugget effect.

Result:

Optimal weights $\boldsymbol{\alpha}$ for g_0 .

Conditional expectation M of $Y(g_0)$. Kriging variance $v = \mathbb{V}[Y(g_0) - M]$ (variance of the prediction error).

begin

420 Then the covariance between 2 grains' outputs is:

$$\tilde{k}_{i,j}(g,g') := \operatorname{Cov}\left[\tilde{Y}_i(g), \tilde{Y}_j(g')\right] = k_{i,j}(g,g') + \mathbb{E}\left[\eta_{i,j}(X_g, X_{g'})\right]$$

421 Therefore the observations covariance matrix writes:

$$\begin{split} \tilde{\mathbf{K}} &:= \left(\operatorname{Cov} \left[\tilde{Y}^{j}, \tilde{Y}^{j'} \right] \right)_{j,j' \in \{1,\dots,n\}} \\ \tilde{\mathbf{K}} &= \mathbf{K} + \left(\operatorname{Cov} \left[e^{j}, e^{j'} \right] \right)_{j,j' \in \{1,\dots,n\}} \\ \tilde{\mathbf{K}} &= \mathbf{K} + \mathbf{K}_{e} \end{split}$$

⁴²² And the covariance vector between the observations and a new grain writes:

$$\tilde{\mathbf{h}}_{i}(g) := \left(\operatorname{Cov} \left[Y^{j} + e^{j}, Y_{i}(g) + e_{i}(g) \right] \right)_{j \in \{1, \dots, n\}}$$
$$\tilde{\mathbf{h}}_{i}(g) = \mathbf{h}_{i}(g) + \left(\mathbb{E} \left[\eta_{i_{j}, i}(X_{g_{j}}, X_{g}) \right] \right)_{j \in \{1, \dots, n\}}$$
$$\tilde{\mathbf{h}}_{i}(g) = \mathbf{h}_{i}(g) + \mathbf{h}_{e, i}(g)$$

Typically, we can assume that $\mathbb{E}[\eta_{i,j}(X_g, X_{g'})] = \mathbb{1}_{\{i=j\}}\mathbb{1}_{\{g=g'\}}\eta_{i,i}(g,g)$. In which case \mathbf{K}_e is a diagonal matrix and $\mathbf{h}_{e,i}(g)$ is null as long as g is not among the observed grains.

⁴²⁶ Contrary to Gaussian Process Regression, the prediction cross error ⁴²⁷ $c_{i,j}(g,g')$ defined in Equation (2) is usually not equal to the conditional co-⁴²⁸ variance $\mathbb{E} \left[\text{Cov} \left[Y_i(g), Y_j(g') | \underline{\mathbf{Y}} \right] \right]$. However, under certain assumptions, one ⁴²⁹ can prove that if $M_i(g) = \mathbb{E} \left[Y_i(g) | \underline{\mathbf{Y}} \right]$, then the cross error can also be viewed ⁴³⁰ as a conditional expectation: $c_{i,j}(g,g') = \mathbb{E} \left[\text{Cov} \left[Y_i(g), Y_j(g') | \underline{\mathbf{Y}} \right] \right]$. Details are ⁴³¹ given in Supplementary material Appendix B.

432 3. Illustration

433 3.1. Unidimensional case: rounded inputs

A common issue when feeding geo-statistical models with real data is the precision of the input data and its impact on a model's performance. Usual applications of Kriging take this uncertainty into account when increasing output variables' variances by a value that is known as the nugget effect (e.g. Rocas et al., 2021). Precision being a typical case of input data uncertainty, the example below simulates the effect of rounding input values (coordinates

in the study space) to the nearest units. Let us consider a one-dimensional, 440 centred Gaussian random field $Y(x), x \in [1, 10]$ of constant variance. Let 441 us assume that this field is observed at some points for which coordinates 442 are rounded to the nearest unit, i.e., for 2 input values $x_1, x_2 \in [0.5, 1.5]$, 443 the observer sees the same value $\tilde{x}_1 = \tilde{x}_2 = 1$. For a Kriging model, these 444 are multiple observations of the same point, and it is necessary to introduce 445 a nugget effect in the model for the observations' covariance matrix to be 446 invertible. This nugget effect simulates an uncertainty on the output values, 447 while the uncertainty is really on the input values. It rather makes sense to 448 describe those input values as random positions $\tilde{x}_{1,q}$ and $\tilde{x}_{2,q}$ in g = [0.5, 1.5]449 instead of deterministic $\tilde{x}_1 = \tilde{x}_2 = 1$. Then, we can model the observed 450 objects as mixture distributions and fit a Mixture Kriging model. Let us 451 compare both approaches. 452

Using the geoR package in the R language, we simulate a 1-dimensional 453 random field realization with a Gaussian covariance kernel. The specific pa-454 rameters are detailed in Table 3. x is discretized between 0 and 10 with step 455 0.05. We pick 8 points for observations as listed in Table 4. These observa-456 tions are plotted on Figure 3. Observations $\{o1, o2, o6\}$ form the learning set, 457 observations $\{04, 05, 07\}$ form the validation set, and observations $\{03, 08\}$ 458 form the test set. These sets of observations are deliberately very small so 459 as to represent the Mixture Kriging's behavior in a readable graphic. 460

Underlying field		Mo	Validation	Total			
Variance	Range	Model	Variance	Nugget	Range	MSE	MSE
1	4	Kriging	1	10^{-9}	4	0.037	1.14
1	4	Mixture Kriging	1	0	4	0.027	1.18

Table 3: Parameters and performances of fitted models in the case of observations with rounded inputs. Note that the nugget effect for Kriging is the result of an optimization process. For Mixture Kriging, nugget is null by design. Validation MSE: Mean Squared Error on validation set. Total MSE: Mean Squared Error on the complete interval [0, 10].

The Kriging model (Figure 3 left) has repeated observations for x = 1and x = 3. The learning set is used to fit a family of models with the same kernel parameters as those used for simulation plus a nugget effect among $(10^{-i})_{i \in \{1,...,10\}}$. The nugget effect yielding the smallest mean squared error (MSE) on the test set is selected. A new model is fitted with both learning and test sets using the same kernel and the previously selected nugget effect. This model is applied to compute a validation MSE and a total MSE

			Input		Output
Set	Label	Underlying x (true value)	Rounded x (for Kriging)	Grain (for Mixture Kriging)	y
Learning	<i>o</i> 1	0.55	1	$g_1 = [0.5, 1.5]$	0.923
Learning	<i>o</i> 2	0.85	1	$g_2 = [0.5, 1.5]$	1.005
Validation	o3	1.65	2	$g_3 = [1.5, 2.5]$	1.127
Test	<i>o</i> 4	3.00	3	$g_4 = [2.5, 3.5]$	0.946
Test	o5	3.45	3	$g_5 = [2.5, 3.5]$	0.801
Learning	<i>o</i> 6	7.20	7	$g_6 = [6.5, 7.5]$	0.337
Test	o7	9.40	9	$g_7 = [8.5, 9.5]$	0.884
Validation	08	9.70	10	$g_8 =]9.5, 10]$	0.908

Table 4: Observations of the simulated Gaussian random field.

computed on all points in [0, 10]. The variance of the prediction error is also
 predicted using the formula given in Proposition 2.

Regarding Mixture Kriging (Figure 3 right), grains $g_1 = [0.5, 1.5]$ and 470 $q_3 = [2.5, 3.5]$ are observed twice each while the other grains are observed 471 once each. The Mixture Kriging model can handle repeated observations 472 by design. Uncertainty on the input is resulting from the random position 473 that generates the observation. The grain covariances are computed from 474 the point covariances as detailed in Proposition 1. The random positions 475 $(X_{g_i})_{i \in \{1,\ldots,8\}}$ are assumed to be uniform on the points of the associated grains. 476 Both the learning set and the test set are used to fit a model with the same 477 kernel parameters as for simulation and with no nugget effect. Validation 478 MSE and total MSE are computed for comparison with Kriging. 479

In this case, the mean prediction is almost the same for both models. But 480 Kriging variance (visible on the ribbons in Figure 3) differs. By construction, 481 Simple Kriging is supposed to interpolate observations exactly, resulting in a 482 very small Kriging variance near observations. Too many observations may 483 be outside the confidence band. If one increases the nugget effect on the 484 Simple Kriging model, mean predictions move towards 0 and their range is 485 reduced. Therefore, with a large nugget effect, one ends up with a nearly 486 constant mean prediction and a large Kriging variance. Mixture Kriging 487 takes into account the input uncertainty and predicts a significant Kriging 488 variance even near observations improving the coverage without any nugget 489 effect. 490

⁴⁹¹ In this very simple example, the reader may be surprised that both ⁴⁹² Kriging and Mixture Kriging yield remarkably good predictions. However,

Figure 3: *Rounded inputs.* Left and right: The dashed line shows the underlying simulated random field. The solid line labelled "predictions" shows the fitted model mean prediction (see Table 3). The ribbon shows an interval of radius twice the root square of the estimated prediction error variance. Left: *Kriging model.* Triangular points show observations. Right: *Mixture Kriging.* Horizontal line segments show observations. See Table 4 for more details about observations.

the prediction error value represented by the ribbon's height is important as compared with the predicted values. This means that if the underlying output is also noisy, error can quickly increase. This is the reason why, in real life, one needs much more observations to learn from, see Subsection 3.3.

497 3.2. Unidimensional case: grains of varying size

Imagine a company that wants to measure some performance indicator 498 for manufactured objects that are produced according to certain design spec-490 ifications. The design is denoted as x; it belongs to a set χ of permissible 500 values, and $\mathbf{Y}(x)$ is the performance indicator. For instance, \mathbf{Y} can measure 501 the lift of an aircraft wing depending on some shape parameter x. Because of 502 some unavoidable manufacturing precision issues, the manufactured object's 503 characteristics do not match the design's specifications exactly. This uncer-504 tainty about the manufactured object induces some uncertainty about the 505 performance indicator. Thus, the constructed design can be viewed as a ran-506 dom vector X_{q_x} , taking values in some tolerance set $g_x \subset \chi$ around the design 507 $x \in \chi$. When testing some designs x_1, \ldots, x_n , the industry observes perfor-508 mances $\mathbf{Y}(q_1), \ldots, \mathbf{Y}(q_n)$. Measuring both the expectation and the variance 509 of $\mathbf{Y}(x)$ for each permissible design $x \in \chi$ is one method to find the best de-510 sign, but this can be costly, so fitting an interpolation model with the set of k511 observations is preferable. In this setting, for the sake of simplicity, we assume 512 that $\mathbf{Y}(x)$ is conditioned by observations $\{\mathbf{y}(x_i) = \sin(x_i^2) : i \in \{1, \dots, n\}\}$. 513

In this case, we assume that the precision associated with a design x_i is an interval centred on x. The real characteristic of the object having performance $\mathbf{y}(x_i)$ is a random value in this grain, which is assumed to be uniform on all points of the grain.

- 518 We compare 3 models:
- P_1 : The manufactured object is produced exactly according to the design, the precision interval is restricted to a point.
- P_2 : The precision is the same for all designs, the associated interval is of fixed measure.
- P_3 : The larger is x, the larger is the uncertainty about the manufactured object, which means that intervals' measures are growing with the design x.

All three models have a null nugget effect and a Gaussian kernel having 526 for variance parameter the overall variance of y on $\chi = [0, 4]$. The range 527 parameter is optimized by minimizing the mean squared error between y 528 and point predictions on χ (see Table 4). When grains are restricted to 529 points (Figure 5 top), we get the usual results on Simple Kriging, in partic-530 ular, predicted values are exactly interpolating observations. When grains 531 are intervals of the same size (Figure 5 middle), predicted values are not 532 interpolating any more; predicted error is not null on the grains but far from 533 the grains, it is smaller than in the previous case. In the bottom figure, the 534 greater is x, the greater the uncertainty about the manufactured object as 535 compared to design. The predicted error (ribbon) is increasing with the grain 536 diameter. Overall, it is important to note that the Mixture Kriging model 537 accounts for the randomness of input values without any nugget effect. This 538 eliminates the adverse consequences of a nugget effect that could otherwise 539 shrink mean predictions towards zero. 540

In the previous example, a very small set of observations was enough to 541 make very good predictions. In the present one, the situation is different 542 because observations are not drawn from a Gaussian random field but from 543 a deterministic function. This underlying function is modelled as a noisy 544 random field. Therefore, the Kriging error is greater than in the previous 545 case. A potential extension of this illustration would be to optimize both the 546 range and the nugget effect, but the purpose here is to visualize the effect of 547 the uncertainty on the input and not the output. 548

Model properties					
Set of grains	Variance	Nugget	Range	Exact interpolation	
P_1 : Grains are singletons	0.36	0	0.3	Yes	
P_2 : Grains are of equal measure	0.36	0	0.4	No	
P_3 : Grains are of increasing measure	0.36	0	0.3	No	

Figure 4: Properties of models P_1, P_2, P_3 . Range is an optimal value so as to minimize mean squared error.

Figure 5: Mixture Kriging and grain sizes. The dashed line represents $\mathbf{y}(x)$. The solid line is the mean prediction. The ribbon shows an interval centred on the mean prediction, of radius twice the square root of the predicted error variance. Grey vertical columns show the grains as x intervals. Black triangles show the underlying observed point (observed X_g and associated output value).

⁵⁴⁹ 3.3. Energy Performance Certificate (EPC) prediction

Figure 6: Bar plot of EPC labels frequencies among all EPCs collected in France between 2014 and 2021. Classes A, B, F, G are rare while classes C, D and E are frequent.

Let us now address the EPC prediction problem, keeping in mind that 550 an Energy Performance Certificate (EPC) is given as an energy consumption 551 in $kWh/m^2/year$. The observed distribution of this energy consumption is 552 provided in Figure 6. One considers a model for which χ is a city viewed as a 553 2-dimensional space with latitude and longitude as coordinates after proper 554 projection, \mathcal{G} is the set of plots, and a point in χ is associated with a given 555 floor square meter of a building on the plot. A floor square meter is regarded 556 here as a granule and not as a set of points in χ . This would not make sense 557 since, for a multi-storey building, there are more floor square meters than 558 the building's footprint area. $x \in \chi$ is therefore a reference point for this 559 floor square meter the same way a point would be used to locate a citizen in 560 a city (see Example 1). Y(x) is the areal energy consumption in x, typically 561 the EPC of the dwelling to which belongs the floor square meter represented 562 by x. Then an EPC in the database is the observed energy efficiency rating 563 associated with one unknown point among those located on the plot indicated 564 by the address. Therefore, for a certain plot q, this EPC is an observation 565 of $Y(X_a)$. 566

⁵⁶⁷ EPC is given as a numeric energy consumption per square meter and ⁵⁶⁸ per year. This energy consumption is associated with a letter ranging ⁵⁶⁹ from A to G. A and B label the most energy-saving dwellings (less than ⁵⁷⁰ $90kWh/m^2/year$). F and G label the most consuming dwellings (more than

 $330kWh/m^2/year$). We want to model a situation where we observe EPC 571 with uncertainty on the location of the observed dwelling on the land plot, 572 where it lies, and where the observed dwelling can not be distinguished among 573 all the dwellings of this land plot. We also want to predict an EPC numeric 574 value at the whole land plot level, that is, for the set of dwellings it contains. 575 As can be seen in Figure 6, observations are strongly unbalanced, mean-576 ing that labels A, B, F, and G are rarely observed while labels C, D, and E 577 are very common. As a result, labels A, B, F, and G are difficult to predict, 578 although they are more interesting for decision-makers. Therefore, we intro-579 duce the Balanced Accuracy (BA) criterion. It is an asymmetric performance 580 measure that focuses on good results (Gösgens et al., 2021) and it gives the 581 same weight to each class. Denoting n_{ℓ} the number of observations with label 582 ℓ and $n_{\ell,\ell}$ the number of predictions ℓ with true label ℓ (true predictions of 583 label ℓ), the balanced accuracy is given by the formula: 584

$$BA = \frac{1}{7} \sum_{\ell \in \{A, \dots, G\}} \frac{n_{\hat{\ell}, \ell}}{n_{\ell}}$$

Given a real random variable X and F_X its cdf, supposed to be invertible. Let $H(X) := F_N^{-1} \circ F_X(X)$ where F_N is the standard Gaussian distribution cdf. H is invertible, and H(X) follows a standard Gaussian distribution by the probability integral transform theorem. Using H we normalize input and output variables.

Let us consider the model
$$M_1$$
 such that:

- χ is the territory of an urban area in the French city of Angers in a 3-dimensional space where coordinates represent the image through Hof the construction year, the latitude, and the longitude.
- A random field Y(x) is defined on χ . It represents the image through H of the energy consumption per square meter and per year at x.
- A grain g is defined as a set of points in a 3-dimensional space χ . A grain represents a land plot. Each point represents a square meter of living area. It has 3 coordinates. \mathcal{G} denotes the set of all grains.
- For any grain $g \in \mathcal{G}$, the random variable X_g is the uniform law on the points of g. It represents the uncertainty on the observations' location. On g, the output variable is defined as: $Y(g) = Y(X_g)$. By construction, Y is centred.

• A vector of observations of n distinct grains is given and denoted as $\underline{\mathbf{Y}}$. 603

Figure 7: An urban area in Angers: latitude is the vertical dimension, longitude is the horizontal dimension, and construction year is given by the colour. The side of the square is 1km. Construction years range from 1340 (first percentile) to 2019 (last percentile).

 \mathscr{G} is mapped in Figure 7. Note that the grains seem to be disjoint, but 604 they are not due to overlaps in the construction year dimension. The set of 605 observations is represented in Figure 8. 606

607 608

609

For this model, the following assumptions are made:

- For any two distinct grains g, g', random variable X_g is independent from $X_{g'}$. 610
- For any two points x, x', the covariance between Y(x) and Y(x') is 611 following a Matérn 3/2 model: 612

$$\operatorname{Cov}\left[Y(x), Y(x')\right] = \sigma^2 \left(1 + \sum_{i=1}^3 \frac{|x_i - x'_i|}{\theta_i}\right) \exp\left(-\sum_{i=1}^3 \frac{|x_i - x'_i|}{\theta_i}\right)$$

where $U = (\sigma^2, \theta_1, \theta_2, \theta_3) \in]0, 1] \times]0, +\infty[^3$

Figure 8: Left: Map of the 365 observations. Right: Map of all predicted values (labels derived from Mixture Kriging means). Each colour represents a label associated with a numeric value. See also Figure 1.

 σ^2 is called the variance coefficient, and $\Theta = (\theta_1, \theta_2, \theta_3)$ are the length scale coefficients. Note that no nugget effect is required because the model takes into account the spatial uncertainty of the input by construction.

The Mixture Kriging predictor described in subsection 2.3 is used to 617 predict energy consumption at the plot level. It can be proved that, without 618 the nugget effect, the mean prediction, in the case of a 1-dimensional output, 619 does not depend on σ^2 (the proof is simply deduced from the fact that for 620 an invertible matrix A, we have $(\lambda A)^{-1} = \lambda^{-1} A^{-1}$. σ^2 is therefore set to 621 1. Θ is chosen so as to maximize the BA criterion of the predicted labels 622 derived from the predicted energy consumptions. BA is computed using 623 leave-one-out cross-validation. Note that the leave-one-out cross-validation 624 predictor that is derived from Proposition 2 is also linear and optimal for 625 quadratic error. A code has been developed in the R language to implement 626 Mixture Kriging. 627

628

So as to assess the effect of balanced accuracy on the optimum, we also consider a model M1', which is the same as M1 except that parameters are assessed optimizing the accuracy. The accuracy is the total number of labels correctly predicted divided by the number of predictions. Let us now consider the Kriging model M2 to compare performances with the Mixture Kriging model M1. M2 has the same properties as M1presented above, except that:

• Grains are singletons. A grain $g = \{x^1, ..., x^q\}$ is replaced by a point x of coordinates the minimum construction year and the mean latitude and longitude values. Note that it is assumed that the year of construction of the eldest building portion is the most meaningful information for prediction. This makes sense, especially because the oldest part of a building is usually also the largest one.

• A nugget effect σ_e^2 has to be introduced so as to have a smooth predictor:

$$\mathbb{V}[Y(x)] = \sigma^2 + \sigma_e^2 \ .$$

For M2, the Kriging predictor is used. $V = (\sigma^2, \theta_1, \theta_2, \theta_3, \sigma_e^2)$ is chosen so as to maximize BA, the same way as for M_1 . The standard R package DiceKriging is used for prediction.

648

There are 365 observations on the given territory. The best parameters are estimated by optimizing the performance indicator, Balanced Accuracy or Accuracy, computed by leave-one-out cross validation. All models M1, M1'and M2 are optimized with the genetic algorithm provided by R package ga parametrized with population size 50, elitism 5, maximum number of iterations 100, maximum number of iterations without improvement 100. Other parameters are left as default.

With regards to the optimal parameters in Table 5, length scale parame-656 ters are smaller in M1 than in M2, meaning that M1 prediction is influenced 657 by fewer neighbours than M2. The nugget effect found for M2 is small. As 658 for the optimal performances in Table 6, M1 reaches a larger BA than M2659 by 37%. However, M1 has lower performances on other indicators with a 660 difference of approximately 10%. The range of all 365 mean predictions with 661 M1 is 150% larger than with M2. These figures are better understood by 662 examining the confusion matrices in Tables 7 and 8. Indeed, the percentage 663 of large errors (represented by the red area) is 3% with model M1 and 0.5%664 with model M_2 . We know that large errors have an important impact on 665

633

Model	ϵ^2	σ^2	$ heta_1$	θ_2	θ_3
Mixture Kriging $(M1)$ Mixture Kriging $(M1')$ Kriging $(M2)$	0.00* 0.00* 0.02	1.00^{*} 1.00^{*} 0.53	$0.28 \\ 0.93 \\ 0.98$	$0.44 \\ 0.78 \\ 0.82$	$1.22 \\ 0.91 \\ 1.49$

*: These parameters are treated as constant parameters.

Table 5: Optimal parameters for M1 and M2.

			EP(C int.		EPC num	1.
Model	BA	Acc.	MAE	RMSE	MAE	RMSE	Range
Mixture Kriging $M1$	0.26	0.40	0.93	1.37	78.93	106.16	6.66
Mixture Kriging $M1'$	0.21	0.42	0.93	1.38	79.46	108.55	6.54
Kriging $M2$	0.19	0.38	0.85	1.22	72.22	92.98	2.59
		a	a			- 0 - 1	

EPC int.: Energy Performance Certificate treated as an integer: 1 for A, ..., 7 for G. EPC num.: Energy consumption expressed in $kWh/m^2/year$.

BA: Balanced Accuracy.

Acc.: Accuracy.

MAE: Mean Absolute Error. RMSE: Root Mean Squared Error.

Table 6: Optimal performances achieved by M1, M'_1 and M2. For each indicator, best value is indicated in bold font.

MAE and RMSE. However, the percentage of true labels A and B that are predicted as A or B is 25% with M1 and 10% with M2. For labels F and G, these figures are 16% and 0% respectively. This information is valuable for decision-makers seeking to identify energy-efficient and/or energy-intensive dwellings.

These results suggest that Mixture Kriging (M1, M1') predictions have 671 an improved range as compared to Kriging (M2): the range of mean pre-672 dictions by Mixture Kriging is greater than by Kriging. This allows better 673 predictions for extreme labels A, B, F, and G. Despite having fewer param-674 eters (ϵ^2 and σ^2 are regarded as constants), Mixture Kriging improves the 675 BA, although it also leads to more frequent large errors. Mixture Kriging ac-676 counts for uncertainty in the input data, eliminating the need to add a nugget 677 effect. In this example, it avoids grouping predictions near the mean value 678 (shrinkage) and yields a better BA as compared to Kriging that requires the 679 introduction of a nugget effect. 680

Among Mixture Kriging models, as expected, M1 has a better Balanced Accuracy than M1', and M1' has a better Accuracy than M1. Other indi-

Range: Variance of the predicted values $(\times 10^3)$ viewed as a measure of the predictions' range.

Table 9: Confusion matrix of M1' predictions

Table 10: Distribution of labels in M1

cators are very similar, let alone the smaller variance of M1''s predictions. 683 Optimizing parameters based on Balanced Accuracy forces the model to pre-684 dict more often labels A, B, F, and G so that the distribution of predicted 685 labels is very close to the distribution of observed labels as can be seen in 686 Table 10. In our case, the confusion matrices show that this effect is positive 687 for labels A and B, as more true A or B are predicted as A or B. But the 688 effect of balanced accuracy does not bring benefits for labels F and G, on the 689 contrary, it has a tendency to predict more F and G where the true label is 690 D or E. A possible explanation for this moderate benefit of introducing the 691 balanced accuracy is that we are missing some information. The moderate 692 size of observations (365 individuals) makes it difficult for a model to discrim-693 inate between rare labels and frequent labels. For instance, there are only 2 694 observed G labels. One can expect a model learning from a larger number 695 of observations to perform better. Moreover, in an area where buildings are 696

old for instance, our model cannot distinguish a building that has never been
renovated from the others. It may be useful in further studies to introduce
more variables, such as a comfort level. However, as discussed below, the
proposed model is quite heavy in terms of computation resources; therefore,
scaling up or adding variable has an important computational cost.

702 4. Discussion and conclusion

Since the discovery of Kriging, the issue of learning from and predict-703 ing areal data has been a concern. Proposed models have mainly assumed 704 that the output variable at the areal level is the mean of the point outputs. 705 which has proven helpful in various fields such as mining, climatology, or 706 satellite imaging, where averaging makes sense for interpretation and where 707 blocks tend to have similar shapes and sizes. However, in other fields such 708 as agriculture or social studies, blocks can have varying shapes or sizes, and 709 averaging is not always the most meaningful interpretation. In these cases, 710 problems like the Modifiable Areal Unit Problem (MAUP), the ecological 711 inference problem, and the variance reduction due to averaging can become 712 challenging to solve. Over the past few decades, researchers have been de-713 veloping methods to assess and/or correct the MAUP effect (Briz-Redon. 714 2022). Modifying territory partitioning (Li et al., 2009) is also an effective 715 solution for addressing variance reduction problems, but it is not always pos-716 sible. Both Kriging and block-Kriging incorporate uncertainties on input 717 and/or output values through the addition of a nugget effect to variances, 718 thereby simulating the addition of a white noise to the output variables. This 719 transformation smooths predicted values but also shrinks them; the range be-720 tween minimal and maximal predicted values is reduced, thus degrading the 721 prediction quality of values that are particularly large or particularly small. 722

The availability of new datasets with uncertainty on the inputs (uncertain 723 positions) and where averaging is not a meaningful interpretation has driven 724 us to seek a novel method of spatial interpolation. We have introduced a 725 new element in the model that is a random input value. It has been found 726 that resulting mixture distributions can be interpolated optimally, and the 727 resulting Best Linear Unbiased Predictor (BLUP) requires only the first 2 728 moments of the prior random field and a spatial covariance function. This 729 model can learn from and predict outputs associated with grains of any shape, 730 size, or cardinality. Even single points are acceptable. The term "grain" has 731 been introduced to describe these objects. 732

The new model called Mixture Kriging is still consistent with Kriging in 733 the sense that Kriging is a special case of Mixture Kriging where grains are 734 restricted to singletons. However, Mixture Kriging generates a mean pre-735 diction range that is not impacted by the grain's shape or size under usual 736 conditions. As a consequence, there is no reduction in the mean prediction's 737 range due to this factor. If the output variable's variance is the same every-738 where at point level, then it is also the same as the output variable's variance 739 at grain level, meaning that there is no variance reduction either. Similarly, 740 if the covariance between the output variable of interest and another output 741 variable is the same everywhere at the point level, then it will also be the 742 same as the covariance at the grain level, regardless of the grain's shape. 743 This implies that this model has no measurable MAUP effect in the sense of 744 Briz-Redon (2022). 745

Without any MAUP effect, the Mixture Kriging approach is able to han-746 dle multi-scale data. We hope that this can help handling datasets coming 747 from multiple sources in the same model. This model can potentially be 748 used to fit ecological data or social data. For instance, on a global scale, 749 the Intergovernmental Panel on Climate Change (IPCC) studies planetary 750 boundaries on water based on gridded data, but for the study of specific 751 territories, studies are commonly done on watersheds. The Mixture Kriging 752 model has the ability to combine these two scales of study in the same model 753 to benefit from both global and local studies. 754

The main computational distinction between block-to-block Kriging and 755 Mixture Kriging lies in the method of computing the observations variance 756 and the covariance between covariates associated with the same grain. This 757 results mainly in the diagonal of the observations covariance matrix being 758 greater than what is found with Kriging. This is precisely the sought ef-759 fect when introducing supplementary noise on the outputs (nugget effect) in 760 Kriging for smoothing predictions. This explains why Mixture Kriging has 761 smooth predictions but with limited shrinkage, hence a good performance 762 with Balanced Accuracy. In practical applications, Mixture Kriging is there-763 fore designed to handle data with uncertainty on the input values without 764 introducing the nugget effect. 765

Regarding computational differences, it should also be noted that Mixture Kriging (like block-to-block Kriging) has a higher computational cost than Kriging, this cost is growing like the squared value of the density of points in the grains. This is an important limitation of the model. For instance, in the models M1, M1' and M2 presented in Subsection 3.3, there are 395

observations. The Kriging model M2 requires $365 \times 366/2 = 66,795$ covari-771 ances to be computed. But the Mixture Kriging models M1 and M1' require 772 to compute 3,770,500,618 point-to-point covariance in order to compute the 773 66,795 covariances between grains. Scaling up the model may, therefore, be 774 difficult. This computational complexity is highly dependent on the defini-775 tion of the random position X_q for each grain and on its discretization. For 776 the above models, X_q is supposed to be uniform for all grains, and the num-777 ber of discretized points is the number of square meters of living space on 778 the grain. But any new model based on Mixture Kriging requires an appro-770 priate definition of these random variables, depending both on the grains' 780 geometries and on the studied output variable(s). Another limitation of the 781 model is the difficulty of assessing its parameters, especially the range. It is 782 difficult to compute a variogram because there is no natural definition of a 783 distance between grains. Estimating the range is also possible by minimizing 784 an error measure, but this process requires computing numerous different 785 models, which is costly, as mentioned above. 786

Keeping in mind its limitations, this new approach opens the way for 787 implementing Mixture Kriging models with new datasets that have been im-788 possible to fit in the usual Kriging framework or with usual Kriging software 789 packages. In particular, datasets that inform about granules that are un-790 certainly defined, such as dwellings, buildings, streets, human persons, and 791 households. It can also be used for datasets informing about granules, which 792 should have deterministic shapes or positions in the input space, but come 793 with numerical uncertainty such as measure precision, rounding effect, obser-794 vations' aggregations, or observations' anonymization. Moreover, the model 795 can handle multivariate outputs, even if some output components are miss-796 ing in the observations. Encouraging results have been found when studying 797 the prediction of Energy Performance Certificates (EPC). Results show that 798 Mixture Kriging can be useful to improve the prediction of values far from the 790 average and, in our case, to improve the detection of energy-saving homes. 800 Future studies should test the upscaling feasibility of the already developed 801 model and the benefits of using covariates. We also study the possibility of 802 developing a similar model with Universal Kriging. 803

⁹¹³ Appendix A. Proof of Proposition 2 (supplementary material)

This proof employs a classical statistical approach to compute a Best Linear Unbiased Predictor using a family of observed random variables that are not necessarily Gaussian but have known first and second moments.

It is interesting for the understanding of the problem to give it a geometrical approach. Let us denote $F_i(g)$ the set of linear unbiased predictors of $Y_i(g)$ given an observation vector $\underline{\mathbf{Y}}$. With previous notations, it means that:

$$F_i(g) := \left\{ \boldsymbol{\alpha}^\top \underline{\mathbf{Y}} : \mu_i(g) = \boldsymbol{\alpha}^\top \underline{\boldsymbol{\mu}} \right\}$$

⁹²⁰ And similarly, we denote:

$$G_{i}(g) := \{ \alpha Y_{i}(g) : \alpha \in \mathbb{R} \}$$

$$F := \{ \boldsymbol{\alpha}^{\top} \underline{\mathbf{Y}} : \boldsymbol{\alpha} \in \mathbb{R}^{n} \} \text{ (the feature space generated by observations)}$$

$$F_{0} := \{ \boldsymbol{\alpha}^{\top} \underline{\mathbf{Y}} : \boldsymbol{\alpha}^{\top} \underline{\boldsymbol{\mu}} = 0 \}$$

$$H := F \times G_{i}(g)$$

One can note that F_0 is a subspace of F of dimension $\dim(F) - 1$. Moreover $F_0 + F_i(g) = F_i(g)$, meaning that $F_i(g)$ is an affine subspace of F having F_0 for underlying vector space (see Figure A.9). But it also means that the sets of unbiased linear predictors for each output variable are parallel:

$$\forall i, j \in \{1, \dots, p\}, \ \forall g, g' \in \chi, \ F_i(g) \parallel F_j(g')$$

Now, given that we are minimizing the quadratic error between $Y_i(g)$ and $M_i(g)$, which can be seen as the distance between $Y_i(g)$ and $M_i(g)$ in H, the optimization process is geometrically a projection of $Y_i(g)$ on $F_i(g)$. This approach is illustrated in Figure A.9.

Figure A.9: Geometrical interpretation of the prediction process.

Proof. For given $i \in \{1, \ldots, p\}$ and $g \subseteq \chi$, let $M_{\alpha} = \alpha^{\top} \underline{Y}$ be a linear predictor of $Y_i(g)$, where $\alpha = (\alpha^1, \ldots, \alpha^n)$ is a vector of weights, and denote the associated error $v_i(g, \alpha) := \mathbb{E}[(Y_i(g) - M_{\alpha})^2]$, then:

$$v_{i}(g, \boldsymbol{\alpha}) = \mathbb{E}\left[\left(\boldsymbol{\alpha}^{\top}\underline{\mathbf{Y}} - Y_{i}(g)\right)^{2}\right]$$

$$= \mathbb{E}\left[\boldsymbol{\alpha}^{\top}\underline{\mathbf{Y}}\underline{\mathbf{Y}}^{\top}\boldsymbol{\alpha} - 2Y_{i}(g)\boldsymbol{\alpha}^{\top}\underline{\mathbf{Y}} + Y_{i}(g)^{2}\right]$$

$$= \boldsymbol{\alpha}^{\top}\mathbf{K}\boldsymbol{\alpha} + \boldsymbol{\alpha}^{\top}\underline{\boldsymbol{\mu}}\underline{\boldsymbol{\mu}}^{\top}\boldsymbol{\alpha} - 2\boldsymbol{\alpha}^{\top}\left(\mathbf{h}_{i}(g) + \underline{\boldsymbol{\mu}}\mu_{i}(g)\right) + \mathbb{V}\left[Y_{i}(g)\right] + \mu_{i}(g)^{2}$$

(i) If $\underline{\mu} = (0, \dots, 0)^{\top}$ and $\mu_i(g) = 0$ then

$$v_i(g, \boldsymbol{\alpha}) = \boldsymbol{\alpha}^\top \mathbf{K} \boldsymbol{\alpha} - 2 \boldsymbol{\alpha}^\top \mathbf{h}_i(g) + \mathbb{V}[Y_i(g)]$$

By differentiation over each component of α ,

$$\frac{\partial v_i(g, \boldsymbol{\alpha})}{\partial \boldsymbol{\alpha}} := \left(\frac{\partial v_i(g, \boldsymbol{\alpha})}{\partial \alpha^j}\right)_{j \in \{1, \dots, p\}} = 2\mathbf{K}\boldsymbol{\alpha} - 2\mathbf{h}_i(g) \,.$$

Without constraints, this value should be null at any extremum, and thus the optimal vector of weights is

$$\boldsymbol{\alpha}_i(g) = \mathbf{K}^{-1} \mathbf{h}_i(g)$$

⁹³⁰ Since **K** is symmetric positive, this only extremum is a minimum.

(ii) If $\underline{\mu} \neq (0, \dots, 0)^{\top}$ then the condition for unbiasedness writes $\mu_i(g) = \alpha^{\top} \underline{\mu}$ by linearity of expectation.

 $v_i(g, \boldsymbol{\alpha})$ rewrites again:

$$v_i(g, \boldsymbol{\alpha}) = \boldsymbol{\alpha}^\top \mathbf{K} \boldsymbol{\alpha} - 2 \boldsymbol{\alpha}^\top \mathbf{h}_i(g) + \mathbb{V}[Y_i(g)]$$

We introduce the Lagrangian operator:

$$\mathscr{L}(\boldsymbol{\alpha},\lambda) = v_i(g,\boldsymbol{\alpha}) - 2\lambda(\boldsymbol{\alpha}^\top \underline{\boldsymbol{\mu}} - \mu_i(g)) \;.$$

We are minimizing a quadratic function over a single affine equality constraint. A necessary optimality condition is:

$$rac{\partial \mathscr{L}}{\partial oldsymbol{lpha}}(oldsymbol{lpha},\lambda) = 0\,,$$

that is to say:

$$2\mathbf{K}\boldsymbol{\alpha}-2\mathbf{h}_i(g)-2\lambda\underline{\boldsymbol{\mu}}=0\,,$$

and therefore the optimal weights are

$$\boldsymbol{\alpha}_i(g) = \mathbf{K}^{-1}(\mathbf{h}_i(g) + \lambda \underline{\boldsymbol{\mu}}).$$

The unbiasedness condition is:

$$\underline{\boldsymbol{\mu}}^{\top}(\mathbf{K}^{-1}(\mathbf{h}_i(g) + \lambda \underline{\boldsymbol{\mu}})) = \mu_i(g) \,,$$

so that

933

935

$$\lambda_i(g) = \frac{\mu_i(g) - \underline{\boldsymbol{\mu}}^\top \mathbf{K}^{-1} \mathbf{h}_i(g)}{\underline{\boldsymbol{\mu}}^\top \mathbf{K}^{-1} \underline{\boldsymbol{\mu}}} \,.$$

Therefore this only solution is a minimum of $v_i(g, \boldsymbol{\alpha})$.

Let us consider now the cross-errors:

$$c_{i,j}(g,g') = \mathbb{E}\left[(Y_i(g) - M_i(g)) (Y_j(g') - M_j(g')) \right].$$

⁹³⁴ Due to unbiasedness condition, it means that:

$$c_{i,j}(g,g') = \operatorname{Cov} \left[Y_i(g) - M_i(g), Y_j(g') - M_j(g')\right] = \operatorname{Cov} \left[Y_i(g), Y_j(g')\right] - \operatorname{Cov} \left[Y_i(g), M_j(g')\right] - \operatorname{Cov} \left[M_i(g), Y_j(g')\right] + \operatorname{Cov} \left[M_i(g), M_j(g')\right] = \operatorname{Cov} \left[Y_i(g), Y_j(g')\right] - \operatorname{Cov} \left[Y_i(g), \boldsymbol{\alpha}_j(g')^\top \underline{\mathbf{Y}}\right] - \operatorname{Cov} \left[\boldsymbol{\alpha}_i(g)^\top \underline{\mathbf{Y}}, Y_j(g')\right] + \operatorname{Cov} \left[\boldsymbol{\alpha}_i(g)^\top \underline{\mathbf{Y}}, \boldsymbol{\alpha}_j(g')^\top \underline{\mathbf{Y}}\right].$$

Which rewrites:

$$c_{i,j}(g,g') = k_{i,j}(g,g') - \boldsymbol{\alpha}_j(g')^{\top} \mathbf{h}_i(g) - \boldsymbol{\alpha}_i(g)^{\top} \mathbf{h}_j(g') + \boldsymbol{\alpha}_i(g)^{\top} \mathbf{K} \boldsymbol{\alpha}_j(g') .$$
(A.1)

Note that equation (A.1) is true for any linear unbiased predictor. Which, in the case of simple Mixture Kriging, simplifies into:

$$c_{i,j}(g,g') = k_{i,j}(g,g') - \mathbf{h}_i(g)^\top \mathbf{K}^{-1} \mathbf{h}_j(g') \,.$$

And in the case of ordinary Mixture Kriging:

$$c_{i,j}(g,g') = k_{i,j}(g,g') - \mathbf{h}_i(g)^\top \mathbf{K}^{-1} \mathbf{h}_j(g') + \lambda_i(g) \lambda_j(g) \underline{\boldsymbol{\mu}}^\top \mathbf{K}^{-1} \underline{\boldsymbol{\mu}}.$$

⁹³⁷ The expressions of $v_i(g) = c_{i,i}(g,g)$ in both cases follow immediately. \Box

Appendix B. Cross-errors and conditional covariances (supplementary material)

It is well known that the best predictor of $Y_i(g)$ is also the conditional variable $\mathbb{E}[Y_i(g)|\underline{\mathbf{Y}}]$. However, this best predictor is not necessarily linear, especially in non Gaussian cases. The following proposition proves that if the Best Linear Unbiased Predictor is the best overall predictor then the error covariances can also be seen as conditional covariances.

Proposition 3 (Cross-errors and conditional covariances). Consider the assumption

(A):
$$\forall i \in \{1, \dots, p\}, \forall g \in \mathcal{G}, M_i(g) = \mathbb{E}[Y_i(g)|\underline{\mathbf{Y}}].$$

Under assumption (A), cross errors for both Simple Mixture Kriging and Ordinary Mixture Kriging are:

$$c_{i,j}(g,g') = \mathbb{E}\left[\operatorname{Cov}\left[Y_i(g), Y_j(g')|\underline{\mathbf{Y}}\right]\right].$$
(B.1)

Moreover, if $\operatorname{Cov}[Y_i(g), Y_j(g')|\underline{\mathbf{Y}}]$ does not depend on $\underline{\mathbf{Y}}$, as it is the case for conditional Gaussian vectors, Equation (B.1) simplifies: $\mathbb{E}[\operatorname{Cov}[Y_i(g), Y_j(g')|\underline{\mathbf{Y}}]] = \operatorname{Cov}[Y_i(g), Y_j(g')|\underline{\mathbf{Y}}].$

Assumption (A) holds for example when $\{\mathbf{Y}(x) : x \in \chi\}$ is a vectorvalued Gaussian random field and when each X_g is Dirac distributed.

Proof. The proof uses a classical approach on orthogonality of Best Linear
Unbiased Predictors. It is presented here in three steps. The proof can be
simplified in the Simple Mixture Kriging setting.

• First, given the notations introduced in Appendix A, let $\delta \in F_0$ be a non-zero vector and β a real number.

951

953

955

- Let $M_i^{\beta}(g) := M_i(g) + \beta \, \delta \in F_i(g)$. Recall that $\epsilon_i(g) := Y_i(g) M_i(g)$ and $v_i(g) := \mathbb{E}\left[(\epsilon_i(g))^2\right]$.
- 954 We have:

$$\mathbb{E}\left[\left(Y_i(g) - M_i^\beta(g)\right)^2\right] = v_i(g) - 2\beta \mathbb{E}\left[\epsilon_i(g)\,\delta\right] + \beta^2 \mathbb{E}\left[\delta^2\right].$$

The minimum value of this polynomial expression is reached for:

$$\beta_0 = \frac{\mathbb{E}\left[\epsilon_i(g)\,\delta\right]}{\mathbb{E}\left[\delta^2\right]}$$

Since the only optimal point is $M_i(g)$, $M_i^{\beta_0}(g) = M_i(g)$ and therefore $\beta_0 = 0$. As a consequence, as both $\mathbb{E}[\epsilon_i(g)] = 0$ and $\mathbb{E}[\delta] = 0$:

$$\forall \delta \in F_0, \ \forall i \in \{1, \dots, p\}, \ \forall g \in \chi, \ \mathbb{E}\left[\epsilon_i(g)\,\delta\right] = \operatorname{Cov}\left[\epsilon_i(g), \delta\right] = 0.$$
(B.2)

From a geometrical point of view it is equivalent to say that the inner product of the error and any vector of F_0 , such as the difference of any linear unbiased predictors of $Y_j(g')$, is null. This approach can be found for example in Aldworth (1998), section 4.5.1. page 122, in the case of ordinary Kriging on a stationary process.

• Now, let δ and δ' be any two vectors of F_0 . As a consequence of the previous result in Equation (B.2), we have:

$$\operatorname{Cov}\left[\epsilon_{i}(g) + \delta, \epsilon_{j}(g') + \delta'\right] = c_{i,j}(g,g') + 0 + 0 + \operatorname{Cov}\left[\delta, \,\delta'\right] \qquad (B.3)$$

• On the other hand, using the conditional covariance formula, we have:

$$\operatorname{Cov}\left[\epsilon_{i}(g) + \delta, \epsilon_{j}(g') + \delta'\right] = \mathbb{E}\left[\operatorname{Cov}\left[\epsilon_{i}(g) + \delta, \epsilon_{j}(g') + \delta' \mid \underline{\mathbf{Y}}\right]\right] \\ + \operatorname{Cov}\left[\mathbb{E}\left[\epsilon_{i}(g) + \delta \mid \underline{\mathbf{Y}}\right], \mathbb{E}\left[\epsilon_{j}(g') + \delta' \mid \underline{\mathbf{Y}}\right]\right]$$

Given a $\underline{\mathbf{Y}}$, the random variables δ , δ' , $M_i(g)$ and $M_j(g')$ are constant, so that the first term is

$$\mathbb{E}\left[\operatorname{Cov}\left[\epsilon_{i}(g)+\delta,\epsilon_{j}(g')+\delta'\mid\mathbf{\underline{Y}}\right]\right]=\mathbb{E}\left[\operatorname{Cov}\left[Y_{i}(g),Y_{j}(g')\mid\mathbf{\underline{Y}}\right]\right].$$

Furthermore, we have assumed in Assumption (A) that

$$M_i(g) = \mathbb{E}[Y_i(g)|\mathbf{Y}] \text{ and } M_j(g') = \mathbb{E}[Y_j(g')|\mathbf{Y}],$$

966 therefore

$$\mathbb{E}\left[\epsilon_{i}(g)|\underline{\mathbf{Y}}\right] = \mathbb{E}\left[\epsilon_{j}(g')|\underline{\mathbf{Y}}\right] = 0$$

and $\operatorname{Cov}\left[\epsilon_{i}(g) + \delta, \epsilon_{j}(g') + \delta'\right] = \mathbb{E}\left[\operatorname{Cov}\left[Y_{i}(g), Y_{j}(g') \mid \underline{\mathbf{Y}}\right]\right] + \operatorname{Cov}\left[\delta, \delta'\right]$
(B.4)

Identifying the equations (B.3) and (B.4), we get the expected result.
