Submitted on 8 Jul 2021

HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

Highlights

Early Famennian MS values differ on N-Gondwana and on S-Laurussia margins

Famennian MS values correlate with conodont biofacies

MS is a powerful tool for geodynamics

19 **Abstract**

20 Large-scale magnetic susceptibility (MS) variations in ancient sediments are usually
21 interpreted as related to sea-level and climate changes affecting the erosional regime and the
22 amount of detrital input. To constrain such environmental changes during the Famennian, we
23 compared MS records in representative sections of pelagic limestones of (1) the Avalonian
24 margin of Laurussia [Sessacker (SES) and Beringhauser Tunnel (BHT), Rhenish Slate
25 Mountains, Germany] and (2) in Gondwana related terranes [Erfoud (ERF), Tafilalt,
26 Morocco; Col des Tribes (CT), Montagne Noire, France; Buschteich (BU), Thuringia,
27 Germany; Corona Mizziu (CM I, II), Sardinia and Pizzul West (PZW) in the Carnic Alps,
28 Italy]. Very low MS values throughout the Famennian characterize sections from Avalonia. In
29 contrast, MS values are high and oscillating in Gondwana during the early Famennian; they
30 drop significantly all together in the middle Famennian *Palmatolepis marginifera marginifera*
31 Zone to match the pattern of low MS values of the Avalonian margin thereafter. To evaluate
32 the importance of partial diagenetic overprint, MS data were compared to hysteresis
33 parameters and geochemical proxies in sections BU, CM I, II and CT. The degree of thermal
34 diagenesis is estimates taking into account the Color Alteration Indices (CAI) of conodonts.
35 Striking dissimilarities in MS records between Laurussia and Gondwana are in favor for an
36 existing remnant oceanic barrier between these continents during early Famennian times,
37 when the amount of detrital supplies was obviously different. Uniformity is reached after the
38 drop of MS values in N-Gondwana, when oceanic barriers could have vanished during the
39 early middle Famennian T-R fluctuations of the sea-level. All sites remained under a rather
40 similar regime of detrital supply through middle to uppermost Famennian. Comparison of MS
41 trends with trends of conodont biofacies in five sections (CT, BU, CM I, II and SES) allows
42 emphasizing the concordance of their relationship to sea level fluctuations.

47 **1. Introduction**

48 Low-field magnetic susceptibility (MS) is currently considered a proxy to assess the amount
49 of detrital inputs in relation to sea level changes, integrating mineralogical and
50 sedimentological information on their nature and origin (e.g. Ellwood et al. 2006, 2007, 2008,
51 Hladil 2002, Da Silva et al. 2009, 2010). As such it may constitute a powerful and
52 independent proxy to control global trends of sea level changes on condition that the primary
53 origin of low-field magnetic susceptibility is demonstrated. This can be done by comparing
54 MS values with hysteresis parameters and/or elemental concentrations (Devleeschouwer et al.
55 2010); Riquier et al. 2010). Color Alteration Indices (CAI) of conodonts are taken into
56 account to estimate the degree of thermal diagenesis of the rock samples (Epstein et al. 1977).
57 Indeed, the color of the conodonts is related to the temperature that affected the rocks. With
58 an average MS value for lithified marine deposits of $5.5 \times 10^{-8} \text{ m}^3/\text{kg}$ (Ellwood et al. 2011a)
59 most of Paleozoic limestones range between 0.1 and $10 \times 10^{-8} \text{ m}^3/\text{kg}$ (Ellwood et al. 2006).
60 This is the case in Devonian off-shore carbonate successions where a fair number of MS
61 investigations (e.g. Crick et al. 2002, Da Silva et al. 2009, Ellwood et al. 2011b, Riquier et al.
62 2010) were conducted since the first global sea-level curve was established by Johnson et al.
63 (1985).
64 Comprehensive spatio-temporal investigations combining variations of litho- and biofacies
65 with isotope data indicate a long term Famennian regressive trend (Johnson et al. 1985) that is
66 punctuated by short transgressive episodes/events such as at the base of the Famennian
67 (Sandberg et al. 2002). However, within-section MS evolution remains sometimes difficult to
68 correlate with precision between sedimentary sequences from different paleogeographic
69 entities (e.g., Crick et al. 2002). Attention is drawn to the possibility that MS signal in
70 carbonate systems may be affected by diagenesis (Da Silva et al 2012, Devleeschouwer et al.

71 2015), or casually indicate rather particular local conditions (Davies et al. 2013) in spite of
72 global eustasy.

73 Indeed, both the amount and nature of detrital material may possibly be disturbed by aeolian
74 or volcanic inputs, heterogeneity of climatic influence in the continental source areas, and by
75 the importance of physical action during gravitational transport (e.g., current-induced re-
76 working, debris-massflows). On the contrary, slow sedimentation rates or absence of
77 deposition leading to hardgrounds and hiatuses may result in different records of MS signals
78 and their amplitudes. MS studies have been mainly focused on episodes of major extinction
79 events such as the terminal Frasnian Kellwasser events that are particularly marked by
80 instabilities of the sea-level (e.g., Averbuch et al. 2005, Riquier et al. 2010). According to
81 these authors, the increase of detrital input related to the marked sea-level fall in the earliest
82 Famennian post-event period is expressed by a significant increase in the MS signals.
83 Noticeably, the values of this excursion is particularly less marked in sections on the
84 Avalonian margin of Laurussia than in those of the Gondwana margin (Averbuch et al. 2005,
85 fig. 4) (Fig. 1).

86 In this contribution we carry out investigations on the entire Famennian from representative
87 sites of both N-Gondwanan and Avalonian terranes to allow the evaluation of the extent to
88 which the environmental changes of approaching Laurussia/Gondwana margins may have
89 influenced the MS signals (Fig. 1a). To this end, we conducted an integrated study of MS,
90 hysteresis parameters and element concentrations, in some sections (CM I, CM II, PZW and
91 partially in BU), in order to test whether MS can be considered as a reliable detrital proxy.
92 Following Riquier et al. (2010), some elements characteristic of the terrigenous input are not
93 affected by diagenesis (e.g., Zirconium) and can be used as a proxy of the bulk magnetic
94 mineralogical component (Total Fe). Thereafter, we will compare MS measurements with
95 analyses of conodont biofacies in sections that provide sufficient amounts of conodont

1 96 elements. Indeed, conodonts can also characterize palaeo-environments because of the
2
3 97 different ecological preferences of the various genera (Sandberg 1976, Seddon and Sweet
4
5 98 1971, Girard et al. 2020), indicative of distance regarding the shoreline. According to this
6
7 99 view, the changes in the relative proportion of the different genera, namely biofacies, have
8
9
10 100 been proven useful to track environmental changes through time (e.g., Corradini 2003, Girard
11
12 101 et al. 2014, 2017, 2020). As a prerequisite, the continuity of MS records is controlled by fine-
13
14 102 scaled conodont biostratigraphy of Spalletta et al. (2017), updated in the latest Famennian by
15
16 103 Corradini et al. (2021).
17
18
19 104 Whether trends in combined MS and biofacies curves allow constituting characteristic
20
21
22 105 features of Famennian deposits in general, and to what extent they are permanent or are
23
24 106 restricted to a definite duration, are prime subjects of our investigations. They allow pointing
25
26 107 possible causes that we aim to discuss.
27
28
29
30 108

31 32 109 **2. Famennian sections**

33
34
35 110 The investigated sections, CT, BU, PZW, CM, ERF, BHT, SES (and DGHS for comparison)
36
37 111 are situated between north Gondwana and Laurussia at tropical to subtropical paleolatitudes
38
39
40 112 (Fig. 1a). The position of some samples, conodont zones and main lithofacies are shown in
41
42 113 columnar sections Figure 1b.
43
44

45 114 46 47 115 *2.1. North Gondwana sections*

48 49 116 50 51 52 117 **Col des Tribes (Montagne Noire, France).**

53
54 118 This section (72 m-thick) was described by Girard et al. (2014). It is composed of (from
55
56
57 119 bottom to top): - bioclastic limestones (17 m- thick) organized into dm- thick beds; - massive,
58
59 120 red mudstones to wackestones/floatstones (15 m- thick) organized into dm- thick beds
60
61
62
63
64
65

121 yielding abundant cheiloceratid goniatites (Griottes facies); - massive micritic limestones (20
122 m- thick) organized into dm- thick beds; - pseudo-nodular limestones (15 m- thick) composed
123 of cm- thick beds which have experienced pressure-dissolution processes; - massive micritic
124 limestones (5 m- thick). These sediments were deposited in mid ramp to basin settings.
125 Abundance of conodonts allows establishing a fine-scaled biozonation from the *Pa. rhenana*
126 (late Frasnian) to the *Bi. ultimus* Zone (*Pr. meischneri* Subzone, latest Famennian). In this
127 section conodonts are relatively well preserved, with a low Conodont Alteration Index (CAI)
128 ~ 2-2.5 (temperature range = 60 to 110°C).

129

130 **Buschteich (Thuringia, Germany).**

131 This section (35 m- thick) was studied by Girard et al. (2017). From bottom to top, it is
132 composed of: - cm bedded to pseudonodular wackstones (3 m- thick) (Frasnian); - dm to m-
133 thick beds of mudstones to wackstones (7 m- thick); - mud-wackstones and pseudonodular
134 mudstones (7 m- thick); mm to cm- bedded mud-wackstones (10 m- thick); - mm to cm
135 bedded to pseudonodular wackstones, and some clay (8 m- thick). These sediments were
136 deposited in outer ramp to basin settings. The section spans an interval from the *Pa. rhenana*
137 to *Bi. ultimus* (*Pr. meischneri* Subzone) conodont Zones, but the lowest part of the Famennian
138 is missing (from *Pa. subperlobata* to *Pa. minuta minuta* Zones). The CAI of conodonts is
139 high, estimated as 4 (temperature range = 190 to 300°C).

140

141 **Pizzul West (Carnic Alps, Italia).**

142 This section (24 m- thick) was described by Mossoni et al. (2014), and Corradini et al. (2017).
143 From bottom to top, it comprises: - massive to nodular grey mudstones to packstones (16.5 m-
144 thick); - red nodular wackstones to packstones (7.5 m- thick) (Griottes facies). The
145 limestones contain few fossils. The Griottes facies comprises nodules up to 1 cm of diameter

146 coated with hematite precipitations probably due to synsedimentary diagenesis. The
147 sediments were deposited in mid to outer ramp settings. The section spans an interval from
148 the *Pa. glabra prima* to *Pa. marg. marginifera* Zones. The CAI of conodonts is around 4
149 (temperature range = 190 to 300°C).

150

151 **Corona Mizziu I and Corona Mizziu II (Sardinia, Italia).**

152 The Corona Mizzu sections have been studied by Corradini (1998, 2003).

153 The Corona Mizziu I (CM I) section (30 m- thick) comprises beds of poorly fossiliferous
154 mudstones, with wackestone to packstone beds in the middle part of the succession.

155 Sediments were deposited in a pelagic setting. The conodont data allow discriminating twelve
156 conodonts zones from the *Pa. rhomboidea* Zone up to the *Bi. ultimus* Zone.

157 The Corona Mizziu II (CM II) section (18 m-thick) crops out a hundred meters apart from the
158 CM I section and exposes grey massive monotonous mudstones with poor fossil remains. The
159 tectonic imprint is marked by stylolite structures and calcite recrystallization. Sediments were
160 deposited in a pelagic setting. The section spans a time from the *Pa. crepida* to the *Pa. rugosa*
161 *trachytera* Zones. For these two sections (CM I and CM II), the CAI of conodonts is very
162 high, with values near 4.5 – 5 (temperature range = 300 to 400°C).

163

164 **Erfoud (Tafilalt, SE Morocco).**

165 The Erfoud section spanning the entire Late Devonian has been described by Buggisch &
166 Clausen (1972). The considered lower to middle Famennian part of the section (8 m- thick)
167 was re-sampled. It comprises from bottom to top: - 3 m-thick dark grey mud to wackestones
168 and black shales, with dm-thick beds with cephalopods and bivalve remains (Kellwasser
169 Limestone facies); - 0.45 m- thick platy red-brownish and grey-olive microsparitic calcilutites
170 with bioclasts and Fe-oxid coated oncoids ; - 1.10 m-thick grey-brown cephalopod calcilutites

171 with Fe-oxid coated intraclasts; - 1.95 m-thick thin-bedded nodular calcilutites with
172 cephalopods and trilobites ; -1.50 m- thick alternating cm- thick bedded beige argillaceous
173 nodular limestones and marls. In the lower part of the section the *Pa. crepida* Zone is
174 extremely condensed at the top of the dysoxic black Kellwasser-type limestone. The latter
175 characterises a dysoxic bottom sea depositional environment. Above the Kellwasser
176 limestones, the depositional conditions reflect low sedimentation rates in an open outer shelf
177 environment within the photic zone as testified by prevailing large-eyed trilobites (deep inner
178 to mid ramp). The section encompasses the interval of the *Pa. subperlobata* to the *Pa. rugosa*
179 *trachytera* Zones with a gap between the *Pa. termini* to *Pa. gracilis gracilis* Zones (Fig. 1b).
180 Conodonts have a CAI of 3-4 (temperature range = 150 to 300°C).

181

182 *2.2. South Laurussia sections*

183

184 **Beringhauser Tunnel (Rhenish Slate Mountains).**

185 This section (15 m- thick) was studied by Schülke & Popp (2005). It consists of mainly well-
186 bedded massive to subordinately nodular cephalopod limestones. At the top of the section,
187 facies change from massive limestones to nodular limestones. Sediments were deposited in
188 mid to outer ramp setting. The considered section spans a time from the *Pa. crepida* to the *Pa.*
189 *rugosa trachytera* Zones. The CAI of conodonts is high, about 4.5 (Joachimski et al. 2009),
190 (temperature range around 300°C).

191

192 **Sessacker (Rhenish Slate Mountains)**

193 This highly condensed section (2.5 m- thick) was studied by Ziegler (1962) and Schülke
194 (1999), and complemented by new data. It consists of red mudstones to wackestones with
195 cephalopods, and some sparitic intercalations occur. The sediments were deposited in outer

196 ramp setting. The section spans from the *Pa. delicatula platys* to the *Pa. rugosa trachytera*
197 Zones. The conodonts are well-preserved with a CAI around 2.5 (temperature range = 60 to
198 110°C).

199

200 **Dupont GHS drillhole (Illinois basin, Eastern North America).**

201 Drillcores in the Chattanooga Shale of Illinois revealed fine-grained siliciclastic sediments (9
202 m- thick) dating Famennian (Over et al. 2019). Conodont assemblages indicate that the
203 section spans the *Pa. glabra prima* to *Bi. ac. aculeatus* Zones. MS values are low, in the -
204 0.25/-0.75 interval.

205

206 **3. Methods**

207

208 *3.1. Magnetic Susceptibility*

209 The samples studied are from previous collections for CT (Girard et al. 2014), BU (Girard et
210 al. 2017), CMI and II (Mossoni 2014), PZW (Mossoni 2014). 129 new samples from sections
211 SES, BHT and ERF have been analysed. We measured the low field magnetic susceptibility
212 (χ_{LF}), abbreviates as magnetic susceptibility (MS) for the seven representatively distributed
213 Famennian sections.

214 At Col des Tribes (CT, Montagne Noire, France) the field magnetic susceptibility (MS) was
215 directly measured in situ with the Bartington MS2E sensor connected to the MS3 meter. To
216 ensure a representative result, five measures were performed and then averaged for the 74
217 successive stratigraphic levels (Supplementary Data, Table S1). Ex-situ measurements were
218 performed in the laboratory on block samples from German (63 samples for BU, 26 for SES,
219 and 15 BHT) and Moroccan (25 samples for ERF) sections with the same device and the same
220 protocol involving a minimum of 2 measurements per level (Supplementary Data, Tables S2,

221 S3, S4 and S5). Samples from the Italian sections (Pizzul West and Corona Mizziu I, II were
222 measured with the KLY-3S Kappabridge at the University of Liège (Supplementary Data,
223 Tables S6, S7, S8).
224 All the MS data figured represent an average of the measurements (Fig. 2) expressed in 10^{-8}
225 m^3/kg for readability. Following the age model published by Girard et al. (2020), the base of
226 conodont zones was dated by means of absolute age estimates provided by Becker et al.
227 (2012), and updated by Becker et al. (2020), and all MS data were figured based on the
228 estimated absolute ages (Fig. 2).

229

230 3.2. Hysteresis parameters

231

232 The Italian sections (CM I, CM II and PZW) were prepared for hysteresis loops (Mossoni
233 2014) with the objective to roughly estimate the nature of the ferromagnetic (*sensu lato*) Fe-
234 oxides. Indeed, as red nodular facies occur in Pizzul West but not in Corona Mizziu sections,
235 we have suspected significant differences in the nature, the oxidation state, and the
236 concentration quantity of strongly oxidized Fe-oxides such as hematite in the former section,
237 and non-oxidized Fe-oxides such as magnetite in the later section. The hysteresis loops were
238 measured with the J-Coercivity “rotation” magnetometer at Dourbes IRM Geophysical
239 Centre, respectively (Supplementary Data, Tables S8, S9, S10).

240 For the hysteresis measurements, the specimens were prepared from blocks taken every 10
241 cm all along the studied cross-sections. We calculated from the hysteresis loops the high-field
242 magnetic susceptibility (χ_{HF}) and the ferromagnetic susceptibility (χ_{ferro}) following methods
243 developed in Riquier et al. (2010), and Da Silva et al. (2012, 2015). These two parameters
244 allow assessing the respective contribution of the para/dia-magnetic minerals (χ_{HF}) and the
245 ferromagnetic minerals to the initial susceptibility. At the end of the hysteresis loop

246 acquisition, the magnetic viscosity coefficient was calculated from the remanence decay,
1
2 247 which was monitored for 100s after the field was removed.
3
4
5 248 Additionally, the major elements (Al, Si, K and Ti) were considered to estimate the
6
7 249 proportion of minerals in terms of their magnetic amounts for 17 samples in PZW, 13 samples
8
9
10 250 in CM I and 14 samples in CM II (Tables PZW, CM I and CMII). These analyses on major
11
12 251 elements were performed with an X-Ray Fluorescence (Panalytical MagiX PW2540) device
13
14 252 at the University of Cagliari. The powder disks were prepared using at least 20 grams of
15
16
17 253 the sample mixed with polyvinyl alcohol, on a base of boric acid. The total amount of oxides
18
19 254 and LOI (loss on ignition) has been considered acceptable for samples with an error of $\pm 2\%$.
20
21
22 255 In order to have comparable results between the studied sections, all analyses were
23
24 256 normalized to 100. In this way a small error percentage has been distributed between all the
25
26
27 257 measured parameters (Supplementary Data, Tables S8, S9, S10).
28

29 258

31 259 *3.3. Detrital vs authigenic Fe content*

32
33
34 260 To further constrain the diagenetic versus detrital imprints on MS, we compared the low-field
35
36 261 magnetic susceptibility (χ_{HF}) variations with selected geochemical proxies measured by
37
38
39 262 mean of the methods developed by Riquier et al. (2010). X-Ray Fluorescence analyses were
40
41 263 performed on the samples of Buschteich which presents no signs of strong oxydation and is
42
43
44 264 the most complete section of this study. The analyses were performed with the Niton XL3t-
45
46 265 900 Gold X-ray fluorescence portable analyzer (Thermo Scientific®, Waltham, MA, USA)
47
48
49 266 at the University of Montpellier. All the rock samples were carefully cleaned prior to all
50
51 267 treatment, and weathered surfaces were removed.

52
53 268 We selected elements that can be used as proxies for the terrigenous input. The Zirconium
54
55
56 269 (Zr) was selected here as the more reliable detrital proxy because it is not affected by
57
58 270 diagenesis; and the total Fe (Fe_{tot}) content will be used as a proxy of the bulk magnetic
59
60
61
62
63
64
65

271 mineralogical component. The total Fe was separated into an inherited detrital part and a
1
2 272 secondary authigenic part. Following Riquier et al. (2010), the detrital and authigenic
3
4 273 fractions of the total iron content were estimated considering that the Fe/Al ratio of the
5
6
7 274 detrital part of the studied rocks is supposed to be the same as that of the average shale value
8
9
10 275 ($Fe/Al_{average\ carbonate} ; 0.55$ Clarkson et al. 2014). The detrital fraction of iron (Fe_{det}) is
11
12 276 calculated as $Fe_{det} = Al_{sample} * Fe/Al_{average\ carbonate}$. Consequently, the iron fraction in excess
13
14 277 relative to the detrital fraction, namely, $Fe_{exc} = Fe_{tot} - Fe_{det}$, may be considered to be of
15
16
17 278 authigenic/diagenetic origin.
18

19 279

22 280 3.4. Biofacies

24 281 Five sections were sampled in detail for conodont biofacies based on conodont genera
25
26 282 abundances. Conodont biofacies are advocated to be mostly driven by water depth variations
27
28
29 283 due to the habitat preferences of the different conodont genera (e.g., Sandberg 1976, Seddon
30
31 284 and Sweet 1971). In this regard, the distribution of conodont genera is thought to be
32
33
34 285 controlled by water depth along a proximal-distal gradient (Klapper and Barrick 1978, Girard
35
36 286 et al. 2020), and as such may constitute a proxy of sea-level variations and indirectly of
37
38
39 287 detrital input. Several biofacies can be defined, based on the percentage of different genera
40
41 288 present in the samples from biofacies characterized by distal surface dwellers (*Palmatolepis*)
42
43 289 to proximal surface dwellers (*Icriodus*). The percentages of conodont elements per genus,
44
45
46 290 later on called biofacies, were estimated for samples of each section: 74 samples for CT
47
48 291 (Girard et al. 2014), 34 samples for BU (Girard et al. 2017), 12 samples for SES (Schülke
49
50
51 292 1995; this study), 13 samples in CM I and 13 samples for CM II (Corradini 2003, Mossoni
52
53 293 2014). All data are available in the Supplementary Data, Table S11. As MS is also known to
54
55
56 294 be related to detrital input, we compared the MS trends of these five sections with trends in
57
58 295 percentage of conodont genera (biofacies). A Principal Component Analysis (PCA on the
59
60
61
62
63
64
65

296 variance - covariance matrix) allows summarizing biofacies of the five considered sections
1
2 297 (CT, BU, CM I and CM II, and SES) on few synthetic axes. This analysis also provides a
3
4
5 298 representation of the records of CT, BU, CM I, CM II and SES on the same synthetic axes,
6
7 299 allowing a direct comparison of the biofacies variations in the five outcrops. The contribution
8
9
10 300 of each genus percentage to the axes allowed their interpretation in relation to the biofacies.
11
12 301 Correlations between the MS and PC values are calculated using Pearson's product-moment
13
14 302 correlation to investigate if MS and PC values are correlated or not.
15
16

17 303

19 304 **4. Results**

22 305 *4.1. Magnetic susceptibility data*

25 306 The relationship between the absolute age of the base of the biozone boundaries and
26
27 307 sediment thickness allows establishing an age model for each section. The ages estimated for
28
29 308 each sample were thereafter used to plot the variations of magnetic susceptibility through
30
31
32 309 time. When we compare the evolution of magnetic susceptibility (MS) of Famennian
33
34 310 sequences in the different sections, various types of record are documented (Fig. 2):

36
37 311 - In the investigated sections of the North Gondwana shelf (Morocco, Montagne Noire), MS
38
39 312 values vary markedly and congruently during early Famennian times: initially high and
40
41
42 313 fluctuating MS values shift all together to low ones within the *Pa. marginifera marginifera*
43
44 314 Zone (initial mid-Famennian), and remain constantly low thereafter, lower than the common
45
46 315 Paleozoic magnetic susceptibility values (around $5.5 \times 10^{-8} \text{ m}^3/\text{kg}$).

48
49 316 - In the most distal sections of the Gondwana shelf (Sardinia, Carnic Alps, Thuringia), the
50
51 317 same trend is observed but fluctuations are less pronounced during the lower Famennian with
52
53
54 318 temporary increases in MS values before the *Pa. marginifera marginifera* Zone.

319 - In south Laurussia (DGHS section), the MS values remain low throughout the record, almost
320 always less than the average of $5.5 \times 10^{-8} \text{ m}^3/\text{kg}$, being rather close to the common Paleozoic
321 magnetic susceptibility values.
322 - In the Avalonian outer shelf areas of Laurussia (SES and BHT), the MS values are very low
323 during the early Famennian and are similar to those of both Laurentian (DGHS, Fig. 1) and
324 north Gondwanan terranes during mid-through late Famennian times.
325 In summary, in the north Gondwana margin a two-fold stage subdivision of the magnetic
326 susceptibility curve is observed. During the lower Famennian, increasing high values are first
327 recorded then followed by decreasing values that culminate during the *Pa. marginifera*
328 *marginifera* Zone. During the middle to upper Famennian, MS values remain lower than the
329 common Paleozoic magnetic susceptibility values (vertical dotted line in Figure 2). The major
330 shift from high to low MS values during the *Pa. marginifera marginifera* Zone in Gondwana
331 is not recorded in the Laurussia section where MS values remain low through the entire
332 Famennian.

334 4.2. Magnetic hysteresis data

335 For the Italian sections PZW, CM I and CM II, the correlations of oxides representing
336 terrigenous input with the MS data are shown in the Supplementary Data (Fig. S1), and
337 detailed in Table 1.

338 For the Pizzul West section, a significant correlation exists between the low field magnetic
339 susceptibility (χ_{LF}) and ferromagnetic contribution (χ_{ferro}), but not with the high field magnetic
340 susceptibility (χ_{HF}). A correlation between low field magnetic susceptibility (χ_{LF}) and the
341 geochemical parameters is not observed ($\text{Al}_2\text{O}_3=0.005$, $\text{SiO}_2=0.12$, $\text{TiO}_2=0.12$, $\text{K}_2\text{O}=0.04$)
342 (Table 1). However, there is a highly significant correlation between the high field magnetic

343 susceptibility (χ_{HF}) and geochemistry ($Al_2O_3=0.84$, $SiO_2=0.81$, $TiO_2=0.85$, $K_2O=0.83$), that
344 demonstrates that the paramagnetic fraction is linked to Al, Si, K and Ti bearing minerals.
345 As most of the Hcr values are lower than 60mT, the MS variations are probably related to low
346 coercivity minerals as magnetite.
347 For the CM I section a strong correlation exists between the low field magnetic susceptibility
348 (χ_{LF}) and the high field magnetic susceptibility (χ_{HF}), and the ferromagnetic contribution
349 (χ_{ferro}). This demonstrates that the paramagnetic fraction is linked to Al, Si, K and Ti bearing
350 minerals. A very good correlation also exists between the low field magnetic susceptibility
351 and the four measured oxides ($Al_2O_3=0.68$, $TiO_2=0.70$, $K_2O=0.69$) (Table 1).
352 For the Corona Mizziu section II, the low field magnetic susceptibility has a good correlation
353 with χ_{ferro} ($r = 0.85$) and with χ_{HF} ($r = 0.82$) (Table1). This suggests that the low field magnetic
354 susceptibility of the Corona Mizziu II section is controlled by both the ferromagnetic and
355 paramagnetic contributions. All the MS values are extremely low (lower than 3.0×10^{-8}
356 m^3/kg , indicating the influence of the diamagnetic fraction, which may have diluted the
357 potential detrital signal.
358 The magnetic signal for Pizzul West section would be mainly controlled by ferromagnetic
359 contribution of low coercivity mineral (likely magnetite), whereas, for the Corona Mizziu I
360 and II sections, the magnetic signal seems to be influenced by dia and/or paramagnetic
361 contributions and, to a lesser extent, by ferromagnetic contribution.
362
363 *4.3. MS correlation to Fe content*
364 Both measured Fe_{tot} and calculated Fe_{det} correlate with the MS evolution ($r = 0.46$, $p = 0.002$
365 for Fe_{det} and $r = 0.41$; $p = 0.0005$ for total Fe). The Fe_{exc} does not show a correlation with the
366 MS variations ($r = 0.19$, $p = 0,157$). A correlation exists between MS and the Zr content
367 ($r=0.28$, $p = 0.037$) as well as between the MS and the Fe/Zr ratio ($r=0.73$, $p<0,001$).

368 (Supplementary Data, Fig. S2 and Supplementary Data, Table S2). Although this theoretical
1
2 369 calculation gives an estimate of the Fe-bearing fractions only, Fe_{det} and Fe_{exc} , it supports the
3
4
5 370 coexistence of a detrital component, controlling the MS evolution in Buschteich, and an
6
7 371 authigenic component, that could have induced the widespread remagnetization process
8
9
10 372 observed in these carbonates. This means that for the Buschteich section we cannot exclude
11
12 373 that a part of the signal results from diagenetic processes, but this part is not as significant as
13
14 374 the detrital part.

15
16
17 375 In summary, the geochemical data show that, although in part affected by diagenesis, as
18
19 376 shown by correlation between MS and Fe/Zr, MS can be used as an indicator of the detrital
20
21
22 377 input evolution in the studied Famennian sections. It is consequently possible to use it as a
23
24 378 proxy of sea level variations which can be compared to the conodont biofacies proxy.

25
26
27 379

28 29 380 *4.4. Comparison with conodont biofacies*

30
31 381 The principal component analysis performed on the proportions of different genera allows
32
33
34 382 summarizing the biofacies variations (Fig. 3) on main axes that express the total variance. The
35
36 383 record of the five sections CT, BU, CM I, CM II (North Gondwana) and SES (South
37
38
39 384 Laurussia) can be directly compared on these axes.

40
41 385 The first axis (PC1, 75.8% of the total variance) of the principal component analysis on
42
43
44 386 conodont percentages shows a progressive trend to positive values (from 0 to 1) through the
45
46 387 early Famennian. This trend reverses in the early mid – Famennian to negative values (Fig.
47
48
49 388 3b). The contribution of the variables (here, the percentages of the different genera) to the
50
51 389 axes (Fig. 3b) shows that positive values along the first axis correspond to a high proportion
52
53 390 of *Palmatolepis* whereas negative values correspond to a high proportion of *Bispathodus*
54
55
56 391 (Supplementary Data, Table S11). A correlation ($N = 115$; $r = 0.26$; $p < 0.005$) exists between
57
58 392 the PC1 and the MS data. The third axis represents only $< 4\%$ of variance, and mostly
59
60
61
62
63
64
65

393 corresponds to variations in the proportion of *Icriodus* in the early Famennian : peaks from
1
2 394 *Pa. triangularis* to *Pa. crepida* Zones in CT, peak in the *Pa. crepida* Zone in BU, peak from
3
4
5 395 the *Pa. glabra prima* to the *Pa. rhomboidea* Zones for CM, peak from *Pa. delicatula platys* to
6
7 396 *Pa. minuta minuta* in SES (Supplementary Data, Table S1, and Fig. 3c), but values on the
8
9
10 397 PC3 axis are not correlated with the MS values.

11
12 398

13 14 15 399 5. Discussion

16
17 400 Since pelagic carbonates are dominantly microsparites of diagenetic origin (Franke &
18
19
20 401 Walliser 1983), one can only speculate on the ultimate source of the MS signals as these may
21
22
23 402 be variously impacted by post-depositional processes. Following intervening aspects are
24
25 403 discussed:

26
27 404

28 29 30 405 5.1. Impact of diagenesis

31
32 406 The magnetic susceptibility of a rock depends on both the mineralogical composition
33
34
35 407 of the rock and the proportion of each mineral. The three main magnetic behaviours are:
36
37 408 diamagnetic minerals (such as carbonates and quartz) displaying extremely weak negative MS
38
39
40 409 values; paramagnetic minerals (e.g., clay minerals, particularly chlorite, smectite, illite and
41
42 410 glauconite, ferromagnesian silicates, iron and manganese carbonates, pyrite) displaying weak
43
44
45 411 positive values, and ferromagnetic minerals (mainly magnetite, pyrrhotite, maghemite, and
46
47 412 hematite) displaying strong positive values (Da Silva et al. 2010). Diagenetic and post-
48
49
50 413 diagenetic processes lead to mineralogical and chemical transformation of iron oxides that in
51
52 414 turn influences the MS values. Riquier et al (2010) showed that although submitted to
53
54
55 415 different burial histories and diagenetic conditions, consistent long-term trends can be
56
57 416 observed in the MS evolution from sections through the Frasnian-Famennian boundary. Their
58
59 417 data demonstrated that the MS evolution of the carbonate sections they studied can be
60

418 interpreted in terms of paleoenvironmental changes along the former margins of Laurussia
419 and Gondwana.

420 In Pizzul West and Corona Mizziu, the conodont Color Alteration Index (CAI) ranges
421 between 4.5 – 5.5. The temperature (200-400°C) which affected the rocks is far beyond the
422 temperature of the goethite-hematite transition. Thus, the high coercivity values measured are
423 related to the presence of hematite, visible also in the microfacies (Mossoni 2014). However,
424 where high coercivity minerals control the MS (χ_{LF}), the presence of hematite is here
425 interpreted to be of detrital origin because both the high field magnetic susceptibility (χ_{HF})
426 and the viscous decay do not correlate.

427 At Buschteich, the Fe in excess does not modify the general trend of MS, at least not
428 enough to overprint the detrital signal.

429 In the CT section, CAI values of 2 – 2.5 were measured by Wiederer et al (2002), that
430 corresponds to burial temperature of less than 100°C. Low illite crystallinity indicates that the
431 site underwent anchizonal metamorphism at maximum. We assume therefore that a part of the
432 MS signal, associated to iron-bearing primary clay minerals, has been preserved in the N-
433 Gondwana sections despite different diagenetic stories.

434 Trends in MS are similar on the N-Gondwana margin (CAI estimated to 4-5 in PZW,
435 CMI and II, BU and around 2-2.5 for CT), high values during the early Famennian and low
436 values during mid-late Famennian. Similar patterns also occur in the S-Laurussia margin
437 (CAI near 4 for BHT and only 2-2.5 for SES), but values remain low during the Famennian.
438 This indicates that, despite different burial histories, the primary MS signature was not
439 overprinted by the diagenetic signal, and it reflects in part its detrital origin.

440

441 *5.2. Relations between depositional setting and MS*

442 Variations in the amount of detrital ferromagnetic minerals in off-shore cephalopod
1
2 443 limestones may be of different origins, and, in consequence, it is often difficult to precisely
3
4
5 444 determine the cause of changing MS values and their amplitudes (e.g. Devleeschouwer et al.
6
7 445 2015). In this regard, the depositional conditions of the investigated sections could play a role
8
9
10 446 on the accumulation of ferromagnetic minerals.

11
12 447 In the Rhenish Slate Mountains (SES, BHT), the Upper Devonian cephalopod
13
14 448 limestones were deposited upon deep submarine rises beyond direct influence of sea-level
15
16
17 449 changes (Franke & Walliser 1983). Besides *in situ* precipitation, pelagic carbonate mud
18
19
20 450 originated from shallow-water areas. Fine-grained sand and clay fractions, originated from
21
22 451 distal turbidites deposition, have also probably reached the rises but they mostly have been
23
24 452 winnowed away by bottom currents. Consequently, rather low MS values might reflect
25
26
27 453 presence low amount of transported ferro-magnetic elements, as coarse detrital influxes from
28
29 454 northern shelf margins were concentrated in sandstone turbidite bodies that by-passed and
30
31
32 455 were dispatched in troughs between the rises.

33
34 456 In the Montagne Noire (CT), very high MS values are recorded during the *Pa. marginifera*
35
36 457 *marginifera* Zone prior to a sudden shift to low values under more stable environmental
37
38
39 458 conditions in deeper mid-Famennian outer ramp setting. This shift is coincident with an
40
41
42 459 abrupt change in facies: high though strongly oscillating values are found in the famous red-
43
44 460 colored Griottes facies (Tucker 1974) and low values in the overlying compact light grey
45
46
47 461 carbonate mudstones. The Griottes facies is a cephalopod-rich, nodular limestone with
48
49 462 abundant iron-clay coatings and some ferruginous hard-grounds. The MS values in this facies
50
51
52 463 are influenced by different chemical and/or physical constraints, not only the detrital inputs of
53
54 464 ferro-magnetic minerals. Indeed, ferruginous mineral phases accumulations may also be
55
56 465 influenced by changing both bottom sea oxygenation and rates of Fe-oxide –reduction related
57
58
59 466 to buried organic matter and to diagenetic re-precipitation of Fe-oxide (Franke & Paul 1980).

64
65

467 This is the case, for example, of condensed pelagic carbonates across the Givetian/Frasnian
468 boundary, where Devleeschouwer et al. (2015) drew attention to the fact that the ferro-
469 magnetic fraction may contain high coercivity minerals such as hematite and goethite of
470 secondary origin that could affect the MS signal. This is probably also the case in the CT
471 section, but no hysteresis analyses are available to confirm the assumption that the observed
472 positive excursions may be solely related to hematization during diagenesis. Post-depositional
473 transformation of paramagnetic clay minerals may also alter the detrital signal of MS.
474 However, this is not the case because the burial temperature was less than 100° (CAI 2-2.5) in
475 CT (Wiederer et al. 2002). It is noteworthy however, that, at CT, the Griotte limestones were
476 deposited on an unstable slope under current activity and underwent repeated intra-
477 formational submarine sliding (debris flows, slumping...) (Girard et al. 2014), leading to local
478 accumulation of Fe-rich sediments. These events may correspond to anomalously high
479 positive peaks in the MS curve at the base of the *Pa. marginifera marginifera* Zone (Fig. 2).

480 At the basins scale, the scenario of MS positive excursions coinciding with hematite-
481 rich early Famennian Griotte limestones has to be discussed. The Griottes limestones are
482 commonly found in southern Europe including the Pyrenees, Montagne Noire and Carnic
483 Alps. Nevertheless, they do not exist in contemporaneous strata in Sardinia despite a similar
484 MS signal. Moreover, this facies is not present in the Thuringian Buschteich section where the
485 MS variation pattern is the same. Conversely, at the beginning of the mid-Famennian, high
486 MS values characterize also compact reddish and brown calcilutites with iron-oxide coatings
487 on the shallow northern Tafilalt platform subjected to emergences (Buggisch & Clausen 1972,
488 Wendt & Aigner 1985). It is noteworthy that a different scenario prevails in the Rhenish slate-
489 mountains where condensed carbonate deposits on deep-water submarine rises upon volcanic
490 substrates at Sessacker are red-coloured despite rather low MS values. At BHT similar low

491 values, after a marked positive excursion in the earliest Famennian (Riquier et al. 2010),
1
2 492 occur in mud-mound carbonates which are not red-colored (Schülke & Popp 2005).
3
4
5 493 In summary, the MS variations during the Famennian is independant from the presence of red
6
7 494 facies (Griottes or others), and are consequently interpreted as primary. Consequently, the
8
9
10 495 effect of post-depositional processes probably did not significantly overprint those of sea level
11
12 496 changes during the Famennian to explain the differences between the records of Gondwana
13
14
15 497 and Laurussia, especially the high MS values during the early Famennian in North
16
17 498 Gondwana.

18
19
20 499

21 22 500 *5.3. Influence of sea-level changes*

23
24
25 501 Magnetic susceptibility and conodont biofacies are potentially interrelated: MS could
26
27 502 be a proxy to evaluate detrital input if the signal is of primary origin, and conodont biofacies
28
29
30 503 are interpreted as related to water depth due to habitat preferences of the different conodont
31
32 504 genera along a proximal-distal gradient in the surface waters. Conodont PC1 displays a strong
33
34
35 505 relationship with magnetic susceptibility in N-Gondwana terranes, and also on Laurussia, at
36
37 506 least for Sessacker, and as such suggests constituting a real indicator of sea-level variations
38
39
40 507 during the Famennian: low MS signals indicate a transgressive trend and correspond to distal
41
42 508 biofacies, and, inversely, high MS signals indicate a regressive trend and correspond to
43
44 509 proximal biofacies.

45
46
47 510 The shift towards lower values for MS and the trend to negative values on the PC1 in
48
49 511 N-Gondwana terranes coincides with a local T-R (transgressive - regressive) couplet called
50
51
52 512 “Enkeberg event” described in Laurussia (Rhenish Slate Mountains; House 1985). In
53
54 513 Avalonia (Laurussia), there is no major significant change in MS values but the Enkeberg
55
56
57 514 event was identified in the faunal record (Becker 1993). This event has not been yet identified
58
59
60
61
62
63
64
65

515 in the North Gondwana terranes. Consequently, the differences in the MS records of N-
516 Gondwana and S-Laurussia rely on other factors, such as paleoclimate and paleogeography.

517

518 *5.4. Paleoclimate and paleo-latitude*

519 During the Famennian, SES, BHT, BU, and PZW sections were located in the
520 subtropical zone of the southern hemisphere (Fig. 1). A long-term discrete cooling occurred
521 during the Famennian, but no major changes in temperatures of the sea-surface waters was
522 recorded (Joachimski et al. 2009); this may exclude a major role of physico-chemistry
523 parameters of sea water conditions on MS values. Following the draw-down of atmospheric
524 CO₂ concentrations and burial of organic carbon during the end-Frasnian Kellwasser crises,
525 oxygen isotope values in conodont apatite indicate a global mean temperature drop of low
526 latitude surface-water in post-event early Famennian times (Balter et al. 2008; Joachimski &
527 Buggisch 2002; Joachimski et al. 2009). Mean sea-surface temperatures estimated from
528 conodont apatite $\delta^{18}\text{O}$ values in the Rhenish Slate Mountains (Beringhauser Tunnel section)
529 seem to be slightly higher than in Gondwana related terranes (Thuringia, Carnic Alps,
530 Southern France) (Joachimski et al. 2009). Concerning climate, the main difference between
531 Gondwana and Laurussia could rely on the latitudinal position between sites on the
532 subtropical Laurussia and those of North Gondwana that are farther south in a more temperate
533 position. Indeed, emerged parts of North Gondwana would have accentuated seasonality of
534 climate and enhanced continental weathering (Percival et al. 2019; Herman et al. 2013).
535 Therefore, emerged areas within the North Gondwana domain might have provided larger
536 amounts of detrital material than the emerged parts of Laurussia. The decrease of high MS
537 values on the Gondwana shelf began during the *Pa. rhomboidea* highstand of sea level and
538 was probably achieved during the following transgressive pulse of the Enkeberg Event during
539 the early mid-Famennian (Sandberg et al. 2002).

540

541 *5.5. Dynamic paleogeography*

542 Though still debated, Late Devonian plate tectonic models postulate convergence and
543 collisional events between Gondwana and Laurussia heralding both the onset and the
544 development of the Variscan orogeny. Subduction of oceanic crusts between Gondwana-
545 derived continents led successively to the closure from S to N of several oceanic basins
546 (including, Saxo-Thuringian, Rheno-Hercynian oceans...) that previously separated
547 Armorican terranes (e.g., Thuringia, Bohemia) from the southern Laurussian margin (Franke
548 et al. 2017, Golonka 2020) (Fig. 1). This resulted in the formation of large carbonate
549 platforms on distal marine shelves on the Gondwana margins (parts of NW Africa to
550 Montagne Noire). Opposite, on the southern margin Laurussia (Thuringia microcontinent),
551 condensed pelagic limestones were restricted to tectonic or volcanic submarine highs.

552 During the early Famennian, only the narrowing oceanic interspaces of the Rheno-
553 hercynian basin, assumed width was 1000 km during the Frasnian, separated Laurussia from
554 outer-shelves of Gondwana-derived terranes (Franke et al. 2017). The age of the closure of
555 the Rheic Ocean remains debated. After Franke (2019) it closed during the Early Devonian
556 times. Other models maintained the Rheic ocean open between Saxo-Thuringia and Avalonia
557 until the Carboniferous (Eckelmann et al. 2014; Golonka 2020, fig. 4). Nevertheless, all these
558 models consider that the northern Gondwana shelf was much more extensive during the
559 Famennian than those of South Laurussia which were restricted to narrow submarine highs
560 and troughs. In such a setting, the detrital supplies from emerged source areas to carbonate
561 platforms were naturally more homogeneously dispatched in the N-Gondwana shelf than in the
562 Laurussia margin. Opposite, the accumulation of the detrital material in the Laurussia margin,
563 even if locally important, was in fact located in troughs (e.g., Rhenish area) and low MS
564 values are recorded on the rises. Consequently, the N-Gondwana and South Laurussia

1
2 565 margins clearly underwent a different paleogeographic behavior, and thus a different setting
3 566 for detrital accumulation.

4
5 567 The separation between the two margins by the narrowing Rheno-Hercynian Ocean is
6
7 568 effective at least until the beginning of the mid-Famennian, even if some local pelagic
8
9 569 deposits can be found till the early Carboniferous (Franke et al. 2017). From the *Pa.*
10
11
12 570 *marginifera marginifera* Zone onwards to the latest Famennian the effectiveness of the
13
14 571 separation apparently vanished when climate became cooler (Girard et al. 2020). MS values
15
16 572 considerably dropped and became conform to median values throughout the entire region
17
18 573 between the Avalonian margins of Laurussia and N-Gondwana related terranes.
19
20
21 574 Consequently, more uniform conditions and smaller amounts of detrital supply prevailed
22
23 575 throughout. Concomitantly, the conjunction of vicinity of the two margins and similar
24
25 576 climatic conditions is also corroborated by the increasing identity of stenotopic level-bottom
26
27 577 biotas such as phacopid trilobites (Feist 2019) in both areas. Consequently, during this time
28
29 578 interval, we consider that mid-late Famennian deposits with low MS values seems to be
30
31 579 controlled by first an evolving paleogeographic setting, and, at a lesser extent, eustasy, current
32
33 580 activity and climate. This paleogeographic setting results from converging margins prior to
34
35 581 closure, and questions the existence, during mid-late Famennian, of wide oceanic domains.

44 583

45 46 584 Conclusions

47
48
49 585 The MS study of five sections in the N-Gondwana margin shows high and oscillating
50
51 586 values during the early Famennian, and low values during the mid-late Famennian. In the S-
52
53 587 Laurussia margin, MS values remain low through the whole Famennian. Geochemical
54
55 588 investigations, and hysteresis parameters in three N-Gondwana sections indicate that the
56
57 589 diagenetic processes did not significantly overprint the primary signal of MS. This is
58
59
60
61
62
63
64
65

590 emphasized by the degree of burial, thus the temperature during diagenesis (CAI of
591 conodonts) and the presence or absence of red facies, as the MS values remain consistent
592 from one section to other.

593 For the first time, we demonstrate a high correlation between these MS and conodont
594 biofacies, confirming their validity for sea level reconstructions. Taking into account all the
595 above mentioned studies, MS can now be used for paleogeographic reconstructions in the
596 presently dismembered areas of the Variscan Belt.

597 During the early Famennian, the difference in the MS trends and the high values in N-
598 Gondwana compared to S-Laurussia can be explained by two main paleogeographic
599 constraints: i) the Rheic Ocean was not closed; ii) the North-Gondwana margin was wide
600 whilst the South Laurussia margin was fragmented into rises and troughs. During the mid-late
601 Famennian, the uniformization of MS toward low values is interpreted as indicative of rather
602 similar conditions in both margins, linked to plate convergence and vanishing influence of
603 oceanic spaces.

804 **Figure captions**

805 **Figure 1. a)** Early Famennian (-370.3 Ma) paleogeographic map (after Franke et al., 2017 and
806 Golonka, 2020) showing the locations of the studied sections.

807 Abbreviations: SES: Sessacker (Rhenish Slate Mountains, Germany), BHT: Beringhauser

808 Tunnel (Rhenish Slate Mountains, Germany), PZW: Pizzul West (Carnic Alps, Italy), CT:

809 Col des Tribes (Montagne Noire, France), CM: Corona Mizziu (Sardinia, Italy), BU:

810 Buschteich (Thuringia, Germany), ERF: Erfoud (Tafilalt, SE Morocco), DGHS (DuPont GHS

811 Core, Eastern United States, after Over et al. 2019). **b)** Biostratigraphic correlation of the the

812 studied sections.

813

814 **Figure 2.** Magnetic susceptibility curves through the Famennian (Late Devonian) for sections

815 of S-Laurussia and N-Gondwana. Ages based on Girard et al. (2020), and updated after

816 Becker et al. (2020). The curves represent the average of the MS values obtained with 2 to 5

817 measurements with the standard error in grey. Vertical dotted line: average MS values for

818 lithified marine deposits estimated to 5.5×10^{-8} m³/kg (Ellwood et al. 2011a). Data of DGHS

819 (Eastern United States) are after Over et al. (2019) and data of uppermost Frasnian to lower

820 Famennian in Coumiac (CUQ*) and Berinhauser Tunnel (BHT*) after Riquier et al. (2010).

821 Conodont Zones after Spalletta et al. (2017).

822

823 **Figure 3. a)** Magnetic susceptibility curves through the Famennian (Late Devonian) at Col

824 des Tribes (CT, France) in green, Buschteich (BU, Germany) in red and Corona Mizziu (CMI

825 and CM II, Italia) in orange, Sessacker (SES) in black. **b)** Conodont biofacies through time

826 depicted as variations along the first axis of the PCA on conodont genera percentages of CT

827 (in green), BU (in red), CM (dotted line in orange), and (SES) in black. **c)** Simplified

828 transgressive-regressive cycles after Johnson et al. (1985, 1996). Conodont Zones after
1
2 829 Spalletta et al. (2017). Ages based on Girard et al. (2020), modified after Becker et al. (2020).

20 870
21
22 871 **Supplementary Table 8.** Magnetic susceptibility (MS) and low field magnetic susceptibility
23 872 (χ_{LF}), ferromagnetic contribution (χ_{Ferro}), hysteresis parameters (high field magnetic
24 873 susceptibility (χ_{HF})), saturation magnetization (MS), coercitive force (Hc), coercivity of
25 874 remanence (Hcr), highfield remanence and viscosity decay; geochemical data for Corona
26
27 875 Mizziu I (CM I) section.
28
29

30 876
31
32 877 **Supplementary Table 9.** Low field magnetic susceptibility (χ_{LF}), ferromagnetic contribution
33 878 (χ_{Ferro}), hysteresis parameters (high field magnetic susceptibility (χ_{HF})), saturation
34 879 magnetization (MS), coercitive force (Hc), coercivity of remanence (Hcr), highfield
35
36 880 remanence and viscosity decay, geochemical data for the Corona Mizziu II (CM II) section.
37
38
39

40 881
41
42 882 **Supplementary Table 10.** Low field magnetic susceptibility (χ_{LF}), ferromagnetic
43 883 contribution (χ_{Ferro}), hysteresis parameters (high field magnetic susceptibility (χ_{HF})),
44 884 saturation magnetization (MS), coercitive force (Hc), coercivity of remanence (Hcr), highfield
45
46 885 remanence and viscosity decay and geochemical data for the Pizzul West (PZW) section.
47
48

49 886
50
51 887 **Supplementary Table 11.** Mean MS (m³/kg), and conodont genera percentages (pc). Names
52 888 of the samples: CT (Col des Tribes), BU (Buschteich), SES (Sessacker), CM (Corona
53
54 889 Mizziu). Ages are given by the conodont zones after Spalletta et al. (2017) and by the age
55
56 890 model (in My). Proportions of the different genera: pcPa: *Palmatolepis*; pcPo: *Polygnathus*;
57
58 891 pcAn: *Ancyrognathus* and *Ancyrodella*; pcIc: *Icriodus*; pcBi: *Bispathodus*, *Branmehla* and
59
60 892 *Mehlina*; pcSc: *Scaphignathus* and *Alternognathus*, pcSi: *Siphonodella*.
61

893 **Table 1.** Correlations between MS (χ_{LF}), and ferromagnetic contribution (χ_{Ferro}), high field
 894 magnetic susceptibility (χ_{HF}), coercivity of remanence (Hcr), and geochemical data using
 895 linear regression. Number of samples (N), coefficient of correlation (r) and probability (p) are
 896 given. Significant correlations marked in bold ($p < 0.05$).
