HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
Some polycrystalline superalloys synthesized by classical foundry can be very refractory and offer unexpectedly high properties at elevated temperatures. This is for example the case of some cobalt-based alloys strengthened by tantalum carbides or hafnium carbides. Besides, cast alloys based on Ni or Co, and containing other types of MC carbides may be also envisaged for high-temperature applications. In this study this is the titanium carbide phase which is under consideration.

Several Ni-based and Co-based alloys of the (M25Cr-xC-yTi)-type (x=0.25 or 0.50, y=1 or 2, in wt.%) were synthesized by casting using a high-frequency induction furnace under pure argon. Metallographic samples were prepared to allow characterizing their microstructures by electron microscopy and energy dispersive spectrometry. Especially prepared samples were destined to DTA control of the melting range, to oxidation in synthetic air at 1200°C, and to (1200°C, 20MPa) flexural creep tests, in order to start exploring the chemical and mechanical resistances of such alloys at elevated temperatures.

### Thermogravimetry tests at 1200°C in dry synthetic air (parallelpepided samples: about 10 mm length × 8 mm width × 3 mm thickness)

### Centered 3-points flexural creep at 1200°C, for 20 MPa just below the central point (parallelpepided samples: 12 mm length × 2 mm width × 1mm thickness)

Titanium carbides, which are of the MC type as TaC more commonly encountered in superalloys, may be obtained at solidification in chromium-rich cast alloys. However this depends on the base element. In nickel-based alloys, the titanium carbides seem being less stable than chromium carbides since, as this was here anticipated by preliminary thermodynamic calculations, C12C, crystallizes at solidification rather than TiC, and during high-temperature isothermal exposures the rare titanium carbides which precipitated besides the numerous chromium carbides, completely disappear.

This is totally the contrary in chromium-rich cobalt-based alloys: the TiC carbides were successfully obtained and remain stable during long high-temperature exposure. They were obtained as script-like eutectic carbides intermixed with matrix in the interdendritic spaces. Associated to an intrinsic mechanically resistant cobalt-based matrix they allowed the studied cobalt alloys demonstrating interesting creep resistance. The nickel-based alloys, combining – it is true – a much weaker nickel-based matrix, and interdendritic chromium carbides, rapidly deformed and came in touch with the apparatus base after only about 25 hours. In contrast the oxidation kinetics of these Ni-based alloys were much lower than the Co-based alloys the general oxidation behaviour of which is classically much worse than the Ni-based alloys one.
