16 Abstract

17 For several decades, use of nanoparticles (NP) on a global scale has been generating new
18 potential sources of organism disruption. Recent studies have shown that NP can cause
19 modifications on the biochemical macromolecular composition of microalgae and raised questions
20 on the toxicity of plastic particles, which are widespread in the aquatic environment. Polystyrene
21 (PS) particles are among the most widely used plastics in the world. In our experimentation, a
22 combined approach of infrared spectroscopy and molecular biology (real-time PCR) has been
23 applied in order to better apprehend the consequences of interactions between *Chlamydomonas*
24 *reinhardtii*, freshwater microalgae and PS NP. Two references have been used, nitrogen deprivation
25 -a well-documented stressor-, and gold nanoparticles (Au-NP). As regards biochemical

26 composition, our experiments show a differing microalga response, according to the NP to which
27 they have been exposed. Results with infrared spectroscopy and gene expression methods are
28 consistent and illustrate variation among several carbohydrates (galactose...). Furthermore, PS-NP
29 seem to react in the same direction as nitrogen limitation, thereby supporting the hypothesis that PS-
30 NP can induce response mechanisms to environmental changes in microalgae. This study
31 highlighted the interest of combining infrared spectroscopy and gene expression as means of
32 monitoring microalgae response to nanoplastics.

33 Keywords: Nanoplastics, microalgae, infrared spectroscopy, gene expression

34 **Introduction**

35 Nanomaterials are ubiquitous in the environment (Robichaud et al., 2009); especially in
36 aquatic systems. For several decades, nanoparticle (NP) use on a global scale has been generating
37 new sources potentially adverse effects on organisms (Bergami et al., 2017; López-Serrano et al.,
38 2014; Miller and Wickson, 2015). Recent studies have shown that NP can generate modifications of
39 macromolecular microalgae composition. For example, in the presence of titanium nanoparticles,
40 Sadiq et al. (2011) observed a decrease of microalgae *Chlorella* and *Scenedesmus* sp. chlorophyll
41 content. Among the models available for study of the impact of environmental changes on the
42 aquatic systems, microalgae are ideal. The unicellular organisms and primary producers' responses
43 to natural changes (lack in nutrients, ion presence and light fluctuations) are well documented
44 (Irihimovitch and Yehudai-Resheff, 2008; Nama et al., 2015; Szivák et al., 2009). On the other
45 hand, potential stresses caused by interactions with nanoparticles are not fully understood and seem
46 to depend on diverse factors such as size, nature, shape, aggregation... (Tang et al., 2017). However,
47 an increasing number of publications on the impact of this type of particle on the lives of organism
48 have been compiled (von Moos and Slaveykova, 2014). There exist a wide variety of NP types,
49 with metallic particles such as gold accounting for a sizable portion (Déniel et al., 2019). The gold
50 nanoparticles (Au-NP) used in biomedical applications are referenced in the literature as non-toxic

51 elements (Alkilany and Murphy, 2010; Fratoddi et al., 2015). Other nanoparticles such as
52 nanoplastics, of which the presence in aquatic environment is problematical, were detected by Ter
53 Halle et al. (2017). However, their interactions with aquatic organisms have not been extensively
54 described, and only a limited number of commercially available products have been studied
55 (Besseling et al., 2014; Bhattacharya et al., 2010; Casado et al., 2013; Li, 2015; Sjollema et al.,
56 2016). Furthermore, the toxicity of plastic nanoparticles has been called into question, as some
57 articles have indicated a fluctuation of effects according to the surfactant at the particle surface
58 (Bergami et al., 2017; Nolte et al., 2016). To understand how nanoplastics may enhance stress or
59 toxicity in organism, it has become necessary to more clearly specify the responses of microalgae
60 and the different types of NP-microalgae interactions. Different types of interactions have been
61 reported in the literature: shading effect, adsorption, absorption, endocytosis, aggregation, cell-wall
62 disruption, ion release... (Moore, 2006; Navarro et al., 2008; von Moos and Slaveykova, 2014).
63 They generate specific biologic responses leading to morphological, biochemical or molecular
64 changes in microalgae. In order for these responses to be clearly discerned, it is important to use
65 repeatable, reliable, rapid and inexpensive methods.

66 To monitor biochemical composition, infrared microspectroscopy is a rapid and non-
67 destructive analysis technique, which is known to facilitate detection of environmental stress (Dean
68 et al., 2008; Déniel et al., 2020). Given the sensitivity of this technique to functional group
69 conformational changes (C-O, N-H bonds...), it is interesting as a means of analyzing the sub-lethal
70 effects of microalgae. Infrared spectroscopy was previously described as a useful tool to detect
71 protein and carbohydrate variations in cases of nutrient starvation (Driver et al., 2015; Jakob et al.,
72 2007; Stehfest et al., 2005) and, more recently, to follow microalgae under different stress
73 conditions (Déniel et al., 2020). In addition, this technique facilitates monitoring of metabolite
74 spatial distribution variation, as has been shown for *Micrasterias hardyi* after exposure to active
75 pharmaceutical ingredients (Patel et al., 2008). Infrared spectroscopy has also been used to study

76 cellular carbon allocation according to phosphorus quota in *Chlamydomonas reinhardtii* (Dean et
77 al., 2008).

78 Biochemical changes, particularly those linked to the biosynthesis pathway of proteins or enzyme
79 variations, are the result of modifications at the molecular level. To better understand
80 macromolecular microalgae variations, gene expression analysis can be followed by Q-RT-PCR
81 (quantitative Reverse Transcription - Polymerase Chain Reaction). Following microalga-
82 microplastic interactions, this method has been applied in study of the metabolic pathway of
83 carbohydrate biosynthesis in *Chlamydomonas reinhardtii* (Lagarde et al., 2016). Xylose, glucose,
84 galactose and rhamnose are polysaccharides characterized by GC-MS analysis in *C. reinhardtii*
85 (Bafana, 2013). Moreover, some sugars are recognized as participating in stress response, one
86 example being sulphated polysaccharides, in *C. reinhardtii*, which has antioxidant properties
87 (Kamble et al., 2018).

88 Another article identified composition changes in monosaccharides consecutive to salt
89 concentration variation in *Dunaliella salina* (Mishra and Jha, 2009) supporting the hypothesis of
90 variations in polysaccharide content and given its implication in stress response, carotenoid gene
91 expression has been studied (Couso et al., 2012; Wang et al., 2016).

92 This study describes a combined approach of infrared spectroscopy and Q-RT-PCR to
93 monitor and highlights the consequences of interactions between *Chlamydomonas reinhardtii*, a
94 freshwater microalga, and polystyrene nanoparticles. Two other stresses are used as references in
95 these experiments, nitrogen deprivation (N-less), - a stress factor that is well- documented as
96 affecting the growth and biochemical composition of microalgae (Gargouri et al., 2017; Park et al.,
97 2015; Schmollinger et al., 2014; Zarrinmehr et al., 2019), and gold nanoparticles (Au-NP)
98 (Lapresta-Fernández et al., 2012; Pal et al., 2011).

99 **Materials and methods**

100 **Nanoparticle characteristics**

101 The nanoparticles used are 100 nm nanobeads commercialized by Interchim. Au-NP are in
102 an aqueous solution at a concentration of 0.01% with a citrate surfactant. The polystyrene
103 nanoparticles (PS-NP) are stabilized with an anionic surfactant in aqueous solution at 1%
104 concentration. Zeta potential and size of nanoparticles in culture medium are measured with a
105 Zetasizer Nano ZS device (Malvern).

106 **Culture conditions**

107 *Chlamydomonas reinhardtii* (strain 2935, *Chlamydomonas* Resource Center, (Sack et al.,
108 1994)) is cultivated in 250 mL Erlenmeyer containing 70 mL of Tris Acetate Phosphate medium
109 (TAP medium) (Gorman and Levine, 1965) at 20°C. The Erlenmeyer flasks are placed under an
110 irradiance of 122 $\mu\text{mol photons}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$. Lighting is provided by cool white fluorescent tubes
111 (Philips TLD 36 W) and follows a light/dark cycle of 14/10 hours. Cultures are kept in suspension
112 by agitation at 100 rpm (VWR, Model 5000).

113 *C. reinhardtii* ($1\cdot 10^6$ C/mL in the beginning of the experiment) are subjected to various
114 environmental variations for 8 days. Each condition is produced in triplicate with a control group on
115 which no stress is applied. The two types of nanoparticles are interacted separately with microalgae:
116 Au-NP (2 mg/L, either 143 $\mu\text{mol/L}$ or $7.1\cdot 10^5$ NP/microalgae) and PS-NP (2 mg/L, either 274
117 $\mu\text{mol/L}$ or $13.1\cdot 10^6$ NP/microalgae). In congruence with literature on PS-NP interactions, where
118 tested concentrations ranged between 0.1 and 50 mg/L, a concentration of 2 mg/L PS-NP was
119 chosen (Bergami et al., 2017; Casado et al., 2013; Nolte et al., 2016). Nitrogen (N-less) intake is
120 reduced by 15% compared to the control group (a concentration of 6 mM N in medium vs. 7 mM
121 normally). Microalgae growth is measured by cellular counting on Malassez cells.

122 **Infrared spectroscopy**

123 Infrared spectra acquisition is carried out in triplicate on microalgae drops of 10 μL for each
124 tested condition, after one hour of air drying (Dean et al., 2008) of samples on a double-side
125 polished silicon wafer. The transmission mode of the infrared spectroscope (Vertex IR 70v, Bruker)
126 is applied, with an accumulation of 50 scans from 4000 to 500 cm^{-1} and a resolution of 4 cm^{-1} .

127 On raw spectra, preprocessing of the linear baseline (LB) with a standard normal variate
128 (SNV) is applied to normalize each data group to allow relative quantification of functional bonds.
129 SNV removes multiplicative scattering interferences by zero centering and scaling of individual
130 spectra. The whole spectrum is centered on its mean, and whole intensity is adjusted with the
131 standard deviation. Study analysis ranges from 800 to 1780 cm^{-1} . Multivariate analysis of data using
132 PCA (principal component analysis) is carried out successively to preprocessing with the study of
133 loadings.

134 To explore the carbohydrate bands in more detail, peak deconvolution of the 930-1190 cm^{-1}
135 zone is carried out with PeakFit v4.02 software. During this Gaussian-Lorentzian area
136 deconvolution, 6 peaks (980, 1018, 1049, 1078, 1108 and 1152 cm^{-1}) are used to fit the band with
137 half-height width considered as the same for each peak referenced. Minimal R^2 accepted to fit is
138 0.99. After peak deconvolution, area percentage contribution is calculated for each peak of the
139 whole massif band.

140 **Molecular biology: RNA extraction, and quantification-RT-PCR**

141 Ten mL of culture in each condition are filtered (Whatman glass microfiber filters, 47 mm
142 diameter, 1.2 μm pore size). RNA is extracted using a Spectrum Plant Total RNA kit (Sigma-
143 Aldrich, Saint Louis, USA). Sample purity and RNA concentration assay are obtained by deposition
144 of 1 μL on a Nanodrop 2000 (Thermo Scientific).

145 All RNA samples are subsequently standardized to a concentration of 100 $\text{ng}/\mu\text{L}$ to perform a
146 reverse transcriptase according to MMLV kit instructions (Promega, Madison, USA) in presence

147 of 5 μM oligodT_{VN} modified, (Carpin et al. 1998), 25.5 μM random primers (8-10 pb), 2.5 x
148 MMLV Buffer, 0.5 mM dNTP, 25 U RNase inhibitor and 200 U MMLV enzyme. The reaction is
149 carried out in a thermocycler (Applied Biosystems Veriti 96-Well Programmable Thermocycler), in
150 two phases: 5 min at 70 °C and one hour at 42 °C. Quantitative PCR (Q-PCR) is also carried out in
151 two steps, using a StepOne-plus Real-Time thermocycler (Applied Biosystems) with SYBER-Green
152 Q-PCR Master Mix (Promega, Madison, USA).

153 Seven target genes (five involved in polysaccharides biosynthesis and two in carotenoid
154 biosynthesis) are selected in accordance with previous work (Couso et al., 2012; Lagarde et al.,
155 2016; Wang et al., 2016) and primer sequences were designed with Primer3-Plus software
156 (<http://www.bioinformatics.nl/cgi-bin/primer3plus/primer3plus.cgi>). Choice of genes for the sugar
157 biosynthetic pathway was carried out according to those known in the literature and the sequence of
158 which is available in the databases (<https://genome.jgi.doe.gov/portal/>). Efficiency and melting
159 curves for each primer pair (Table 1) were produced on cascade dilutions of a cDNA mixing. The
160 1:8 dilution and the primers with optimal efficiency range of 85%-111% were selected for the
161 second phase of Q-PCR. The Ct (threshold cycle) comparison method (Livak and Schmittgen,
162 2001) was applied to calculate the gene expression level. Housekeeping genes, rps2 and rps14,
163 presenting the best stability among tested conditions, were selected with Best Keeper software
164 (Pfaffl et al., 2004) and used for normalization of the gene expression studied. Gene expression
165 level (EL) was calculated from Ct of each sample: $(EL = ((E_{TG})^{\Delta C_t TG}) / (E_{HG})^{\Delta C_t HG})$, (TG: Target
166 Gene; HG: Housekeeping Gene; $\Delta C_t = C_{tControl} - C_{tSample}$). Amplification program consisted of 15 s at
167 95 °C followed by 35 cycles of one minute to decrease to 60 °C.

168

169

170

171 **Table 1 : List of genes tested and primer sequences: housekeeping gene (rps 2, 8, 14, 19), genes involved in the biosynthesis**
 172 **pathway of sugars (GD, GE, GLD, ME, PG), astaxanthin biosynthesis pathway genes (BKT, CHY)**

173

174 Statistical tests (Shapiro for normality, Levene for homoscedasticity, ANOVA and HSD test
 175 of Tukey if data were normal and homogeneous, otherwise Kruskal-Wallis and Wilcoxon) were
 176 carried out with R software (v 3.4.4) on each gene to control significant differences (at 5%) in
 177 answers among diverse conditions.

178 **Results and discussion**

179 **Nanoparticle characterization**

180 Au-NPs have a size of 190 nm and a zeta potential of -14 mV. PS-NsP have a hydrodynamic
181 diameter of 158 nm and a zeta potential of -50 mV (Supplementary data Figures S1 and S2).

182 **Infrared spectroscopy of microalgae and PCA analysis**

183 After 8 days in interaction with PS and Au-NP and 8 days in control and N-less conditions,
184 mean raw infrared spectra of *C. reinhardtii*, are determined (Figure S3). The spectra display linear
185 baseline preprocessing and standard normal variate (LB+SNV) (Figure 1).

186 First, a peak offset on protein band (N-H) is observed at 1540 cm^{-1} for microalgae infrared
187 spectra under N-less exposure (Figure 1). For the 1110 cm^{-1} peak (elongation vibration, $\nu\text{C-O}$) of
188 carbohydrates, absorbance variation was observed with differentiation of the Control and Au-NP
189 group on the one hand and PS-NP and N-less on the other hand. In our study conditions, PS-NP and
190 N-less conditions could then be considered as stressors. As was the case with salt stress in
191 *Dunaliella salina* (Mishra and Jha, 2009), they generated carbohydrates content variation.

192 However, the PCA derived (Figure 2a) from the spectra of the 4 conditions showed that the N-less
193 group was distinguished from the other three. A new PCA was performed for the three other
194 conditions (Figure 2b), which display more similar spectra. PCA (Figure 2b) clearly separates the
195 sample corresponding to the microalgae in contact with PS-NP from the two other groups.
196 Microalgae in contact with Au-NP exhibit the same behavior as the Control sample. PCA loadings
197 are presented in Figure 3. The principal component (PC1) explains 53% of spectral variation and
198 presents a positive variation at 1109 cm^{-1} , which is attributed to the C-O chemical bond of
199 carbohydrates (Murdock and Wetzel 2009; Coronado, Galán-Mascarós, and Martí-Gastaldo 2009 ;
200 Figure 3a). Protein bands (C=O: 1659 cm^{-1} and N-H: 1547 cm^{-1}) showed a negative variation on
201 PC1. The second component PC2 (40%), which mainly discriminates the PS-NP group from the
202 two others, contains (see Figure 3b) bands at 1672 cm^{-1} (protein chemical bond C=O), 1109 cm^{-1}
203 and 1034 cm^{-1} (carbohydrate chemical bond $\nu\text{C-O}$), 881 cm^{-1} (carbohydrate chemical bond C-H

204 (Liu et al., 2018; Umezawa and Komiyama, 1985)) and 816 cm^{-1} (chemical bond C-O-S, galactose
205 sulfate in C6 (Ananthi et al., 2010; Chopin and Whalen, 1993)). A protein peak shift (1659 cm^{-1} to
206 1672 cm^{-1}) between the two principal component loadings underlined a chemical or physical
207 environment modification (Figure 1 and Figure 3). PC3 is not very relevant insofar as it reflects
208 only 3% of the variations (Figure 3c).

209 The fact that Au-NP and Control conditions do not differ seems to support use of Au-NP as
210 non-toxic standard (Connor et al., 2005). Nature and surface chemistry of particles are potential
211 factors affecting interaction modes (Stone et al., 2010). In this study, although the concentration
212 tested in Au-NP was higher than in previous studies (Dědková et al., 2014; Moreno-Garrido et al.,
213 2015), this did not lead to significant variation in the biochemical composition of microalgae
214 compared to the control. Moreover, Au-NP toxicity has been discussed in the literature and, after
215 size, surfactant nature could be a more important factor of particle toxicity (Moreno-Garrido et al.,
216 2015).

217 The main variations observed with PS-NP were linked to the protein and carbohydrate bands
218 and may have been influenced by the nature or surface chemistry of the nanoparticles. Moreover, it
219 should be noted that the infrared bands related to carbohydrates ($1200\text{-}900\text{ cm}^{-1}$) represent a
220 complex area of the microalgae spectrum (many peaks) on which it was necessary to carry out a
221 detailed study. Carbohydrates are intertwined in the microalgae structure with other components in
222 a complex chemical environment, leading to an overlap of carbohydrates bands in infrared spectra.

223 **Analysis of infrared spectra $1190\text{-}930\text{ cm}^{-1}$ range: carbohydrate bands**

224 A more in-depth analysis of all the carbohydrate bands was carried out by spectral
225 deconvolution of the average spectra of *C. reinhardtii* obtained for each condition using six
226 components (based on spectra shape and half-height width). The spectral deconvolution method
227 provides satisfactory resolution of absorption bands in carbohydrate study according to Buslov et al.

228 (2000) and Palmucci et al. (2011). Figure 4 presents deconvolution and the area percentage of the
229 six peaks describing the bonds of the carbohydrates. First, as in PCA (Figure 2b), very few
230 differences between the distribution of the bands in control and Au-NP conditions (Figure 4 a and
231 b) are observed. This finding once again highlights the use of gold as the standard for inert
232 nanoparticles. With regard to the PS-NP and the N-less conditions, similar variations are observed
233 Figure 4c and d). A decrease is noted in the percentage of area of the 1108 cm^{-1} band corresponding
234 to $\nu(\text{C-O})$ of carbohydrates (Wiercigroch et al., 2017) in the two conditions and a decrease of 1152
235 cm^{-1} (C-O-C glucose conformation, (Nikonenko et al., 2000), with a peak contribution for N-less
236 only. In parallel, Figure 4c and d, show an increase in the contribution of the peak to 1018 cm^{-1}
237 (corresponding to $\nu(\text{C-O})$, (Duygu et al., 2012), which is much greater in N-less condition
238 compared to NP, and relatively similar for the peaks at 1078 cm^{-1} , which according to Wiercigroch
239 et al. (2017), are related to $\nu(\text{C-O})$ and at 1049 cm^{-1} (C-OH, (Hofman and Witanowski, 1959)). The
240 proportions of 980 cm^{-1} peaks ($\beta(\text{C-CH})$, $\beta(\text{C-CO})$) linked to fructose (Wiercigroch et al., 2017))
241 remain relatively stable compared to the control group, meaning that fructose content does not
242 fluctuate in the event of nutrient stress or nanoparticle interaction. Variations of bands
243 corresponding mainly to carbohydrates are observed, but only a few are clearly identified with a
244 specific carbohydrate present in *C. reinhardtii*. With infrared spectroscopy data alone it is
245 consequently difficult to assign a specific carbohydrate type to each band.

246 **Responses of genes linked with carbohydrates**

247 In an attempt to identify the carbohydrates having fluctuated, gene expression monitoring of the
248 carbohydrate biosynthesis pathway was carried out. Variations of gene expression linked with
249 carbohydrates were previously reported under cold stress (5°C) in *C. reinhardtii*, showing
250 overexpression of the sucrose-phosphate-synthase and trehalose-6-phosphate synthase 1 genes
251 implicated in sucrose and trehalose biosynthesis respectively (Valledor et al., 2013). In addition,
252 carbohydrate variations of *C. reinhardtii* were reported under low illumination, with

253 underexpression of hexose kinase (glycolysis) and α -trehalase (glucose dimer cleavage) (Puzanskiy
254 et al., 2018). Moreover, Lagarde et al. (2016) have shown overexpression of two genes linked with
255 biosynthesis pathways: galactose and xylose in the presence of microplastic particles
256 (polypropylene and high-density polyethylene).

257 The gene expression levels of the biosynthetic pathway of four sugars (glucose, xylose,
258 rhamnose and galactose) were evaluated by real time RT-PCR. First, the biosynthesis pathway
259 corresponding to the glucose is monitored via phosphoglucomutase (PG) expression. The gene
260 encoding the UDP-glucuronate decarboxylase enzyme (GD) is implicated in the xylose biosynthesis
261 pathway. The third gene monitored is that of the UDP glucose 4-6 dehydratase (GLD) involved in
262 rhamnose biosynthesis. Finally, with regard to galactose, the transcripts of two genes were
263 measured: UDP glucose 4 epimerase (GE) and GDP mannose 3-5 epimerase (ME). In addition, two
264 other genes, potentially stress markers, encoding enzymes of the astaxanthin biosynthesis pathway,
265 were monitored: β -carotene ketolase (BKT) and β -carotene hydrolase (CHY) (Huang et al., 2012).
266 Figure 5 presents the relative expressions for the genes in the different conditions. Expression of the
267 two genes linked with the astaxanthin biosynthesis pathway was used to follow the response to
268 stress: BKT gene, an enzyme known to catalyze a limited number of steps for astaxanthin synthesis
269 and CHY gene, an enzyme implicated in changeover of β -carotene in astaxanthin (Huang et al.,
270 2012). Under-expression of BKT and CHY gene is observed in *C. reinhardtii* after interaction with
271 PS-NP and N-less. A study on *Haematococcus pluvialis* also showed under-expression of these two
272 genes under light stress (Lee et al., 2018). This result suggests that PS-NP presence can be stressful
273 for *C. reinhardtii*. A gene linked with glucose synthesis (PG) is discriminatory to distinguish
274 particular effect (Au-NP) from plastic effect (PS-NP), since in the first case, overexpression is
275 observed, while in the second case, underexpression occurs (gene expression is 10 times lower than
276 control). Concerning GD genes linked with xylose synthesis, a N-less condition outlines
277 underexpression of 2.5 times. N-less and PS-NP conditions present underexpression compared to
278 control condition for rhamnose and glucose biosynthesis pathway genes. Likewise, underexpression

279 of two genes implicated in the biosynthesis pathway of galactose for PS-NP and N-less conditions
280 is also observed for GE gene linked equally to galactose biosynthesis pathway for the Au-NP
281 condition. In contrast, with glucose the gene linked to its expression is overexpressed in the Au-NP
282 group. It is also possible to differentiate the two types of nanoparticles by their differential
283 expression for mannose epimerase (ME) gene: microalgae in contact with Au-NP did not show
284 modified expression, whereas microalgae in contact with PS-NP presented under-expression of this
285 gene, 8 times less than the control.

286 Composition change in carbohydrates following an environmental change has been explored
287 in a green microalga, *Dunaliella salina*, which is close to our model. It was shown that the
288 exopolysaccharides (EPS) produced in saline stress were composed of monosaccharides: glucose
289 and galactose (aldohexose), fructose (hetrohexose) as well as xylose (pentose) (Mishra and Jha,
290 2009). In our study, N-less condition is differentiated from other conditions by under-expression on
291 the majority of studied genes (PG, GE, GLD and BKT).

292 If we combine infrared data (Figure 2) with gene expression results (Figure 5), some
293 conclusions can be put forward. Wiercigroch et al. (2017) illustrated infrared band spectra
294 differences between hexose and pentose. If we observe gene expression (Figure 5), no variation of
295 linked with xylose, which is a pentose (Wiercigroch et al., 2017), was observed in the presence of
296 nanoparticles. On the contrary, glucose and galactose, which are hexoses, presented gene expression
297 variations in experiments with nanoparticles (GE and PG). In addition, under PS-NP and N-less
298 conditions, certain genes are underexpressed (GLD, ME, PG) in parallel with the decline at 1110
299 cm^{-1} of peak area portion and, for N-less, decline of the 1152 cm^{-1} peak only, linked with glucose.
300 In addition, if we refer to average infrared spectra (Figure 1), a decrease of the 1110 cm^{-1} band is
301 observed in association with a decrease of the bands at 881 and 816 cm^{-1} . The wavenumber at 816
302 is referenced according to Ananthi et al. (2010) and Chopin and Whalen (1993) as C-O-S chemical
303 bound of sulfate on C6 galactose. In parallel, underexpression of mannose epimerase (ME) gene is

304 observed. This result seems to highlight a correlation between molecular composition obtained by
305 infrared and genetic expression of carbohydrates in *C. reinhardtii*.

306 **Conclusion**

307 The presence of nanoparticles in contact with microalgae causes a variation in *C. reinhardtii*
308 biochemical composition. With the sensitive IR technique, the response of microalgae to
309 nanoparticle can be discriminated. Microalgae in contact with AuNP have the same behavior as the
310 Control sample (in IR spectra), thereby supporting the hypothesis that Au-NP can be a standard for
311 inert nanoparticles in ecotoxicology. In presence of PS-NP or N-less, infrared spectroscopy spectra
312 of *C. reinhardtii* showed a modification in protein and carbohydrate bands. In this study, an
313 unmistakable implication of sugars in the PS-NP and *C. reinhardtii* interactions was likewise
314 underlined, using spectral deconvolution. The infrared data are consistent with the gene expression
315 results, which illustrate a variation of several carbohydrate biosynthesis pathways, including the
316 gene related to galactose. As in principal component analysis, differentiation of the response
317 between the two types of particles is highlighted (glucose and rhamnose at gene expression and
318 infrared peak at 1110 cm^{-1}) by gene expression results. Furthermore, microalgae exposed to PS-NP
319 show similarities of response with microalgae under N-less condition (GLD, ME, PG and $1110, 880$
320 and 816 cm^{-1} linked with galactose), thereby supporting the hypothesis that polystyrene
321 nanoparticles can induce microalgae response mechanisms under interactions.

1. Introduction

Essentials Oils (EO) extracts from plants have been the focus of numerous studies due to their potential in the pharmaceutical and food industries. Several works and patents have been developed specifically for the application of EO and their components into the food sector (Ribeiro-Santos et al., 2017; Llana-Ruiz- Cabello et al., 2015; Maisanaba et al., 2017). Globally, their relatively safe status, properties and acceptance by consumers which demand natural compounds to replace synthetic ones have piqued the interest of industries and consumers (Sacchetti et al., 2005; Benkeblia and Lanzotti, 2007; Debiagi et al., 2014). Among those beneficial plants, *Allium* sp. is a genus well-known for its antimicrobial, antiviral, antiprotozoal, antifungal or antioxidant properties (among others). These properties are mainly due to their content of organosulfur compounds (OSC), which are secondary phytochemical metabolites, biosynthesized for defensive purposes against biotic and abiotic stressors. They are mainly formed for the action of the enzyme alliin (stored in vacuoles) on cytoplasmic compounds like alk(en)yl cysteine sulfoxides (ACOs) once the vegetable tissue is hurt (Putnik et al., 2019) (Fig. 1). Otherwise, these compounds are not available in intact cells as they are toxic for the plant (Ramirez et al., 2017).

One of the main components of *Allium* essential oil is propyl-propane-thiosulfonate (PTSO), that corresponds to the molecular formula $C_6H_{14}O_2S_2$ (Fig. 1). This compound has been stabilized and characterized by DMC Research Center SLU (Granada, Spain) to be used for different applications, taking advantage of its beneficial properties. Thus, this product has been reported to show mainly antioxidant and antimicrobial activities, being able to inhibit the growth of Gram (-) and Gram (+) bacteria as well as molds and yeast (Peinado et al., 2012, 2013; Llana-Ruiz-Cabello et al., 2015). Its antibacterial activity *in vitro* in humans has also been demonstrated (Sorlozano-Puerto et al., 2018).

Proallium AP®, a commercial *Allium* sp. extract with a 14.5% PTSO content, has been proposed as a biopreservative in active food packaging for human food commodities mainly due to its antioxidant and antimicrobial activity (Llana-Ruiz-Cabello et al., 2018). The packaging material used in these systems can incorporate components intended to be released into the food from the package, allowing foods to arrive at the consumers with their original or enhanced organoleptic properties, with longer shelf-life and safety (Ribeiro-Santos et al., 2017). Previously, another study carried out by Seydim & Sarikus, (2006) tested the antimicrobial activity of garlic EO in combination with oregano EO in films made with whey protein isolate, and showed antimicrobial activity in a concentration of 4% (w/v). But the incorporation of garlic EO and their components in active food packaging can result in a higher human exposure and consequently, more research is needed to establish the safety concentration. An additional proposed application for PTSO is as sensory additive in animal nutrition, improving the palatability of feed, and also as a zootechnical additive, being an alternative to the use of antibiotics (Peinado et al., 2012), contributing to reduce resistance generated by their excessive use in livestock. Since the ban in the European Union (EU) of the use of antibiotics as growth promoters, the search for new alternative products that ensure similar production levels and food security without generating unwanted effects, including human resistances, has been fostered, being additives of natural origin a good alternative. The regulation (EC) No 1831/2003 of the European Parliament and of the Council of 22 September 2003 sets the parameters of use of the additives used in animal nutrition. Recent studies have shown that some feed additives can help animals to maintain good physiological conditions and improve animal welfare. This has led to an amendment in the abovementioned regulation on 12th June 2019, establishing new functional groups of feed additives to improve

physiological condition of animals. In this regard, other properties demonstrating the potential use of PTSO in animal nutrition sector are the anti-methanogenic effect described during the fermentation process in rumen (Martínez-Fernández et al. 2013) and the immunomodulatory and anti-inflammatory properties (Veza et al., 2019).

However, the successful development of any application of this compound must be accompanied by an extensive toxicological evaluation, that guarantees its safety for the final consumers, both humans and livestock.

In this regard, the toxicological profile of PTSO has been investigated by cytotoxicity assays in human cell lines (Llana-Ruiz-Cabello et al., 2015) as well as its genotoxicity and mutagenicity *in vitro* (Mellado-García et al., 2015) and genotoxicity *in vivo* (Mellado-Garcia et al., 2016b). Furthermore, its acute toxicity *in vivo* has been also evaluated (Llana-Ruiz-Cabello et al., 2015). Notwithstanding, safe doses of use have been not yet established for PTSO. Thus, a repeated dose 90-days oral toxicity study in rodents of PTSO would be necessary to clearly characterize its toxicity, being also a requirement in the authorization application processes of the European Food Safety Authority (EFSA, 2012; 2016a; 2016b; 2017).

The aim of the present study is, therefore, to further explore the toxicity potential of PTSO and, for the first time, to conduct a subchronic dietary toxicity assay of PTSO in rats following internationally recognized test guidelines (Organisation for Economic Co-operation and Development, OECD 408, 2018). Considering these facts, in the present study several parameters have been evaluated, including body weight changes, food and water consumption, feed conversion efficiency, organ weight ratios and biochemistry and hematology parameters. In addition the histopathology of various tissues has been also studied. The results from the complete assessment of this

subchronic study would allow to get an estimation of a non-observed-adverse-effect-level (NOAEL) of exposure to establish safety conditions for human exposure to PTSO.

2. Materials and Methods

2.1. Test item and doses preparation

PTSO was supplied by DMC RC SLU (Granada, Spain) with a 96% of purity. Commercial powder neutral gelatin from pork protein (Jesus Navarro S.A., Alicante, Spain) was employed as the vehicle for the test substance in all groups including the controls.

For the 90-days study, the doses were prepared daily for each animal during the 13 weeks, and on Fridays they were also prepared for the weekend. The dose was mixed in 3 mL of liquid gelatin. The volumes of PTSO (μL) to add to the gelatin depended on the dose selected for each group, and the gelatin could solidify at 4 °C overnight. Homogeneity of the dietary dose formulations and their stability were confirmed to be at least 5 days.

2.2. Animals conditions and husbandry services

The rats were supplied by Charles River laboratories S.L. (Kings, NY, USA), 40 males and 40 females of Sprague-Dawley strain. They were approximately 7 weeks old and were stabilized for an acclimatization period of 7 days during which they were examined by a veterinary surgeon. When the first week of dosage began the rats body weight mean was $320 \text{ g} \pm 11.3$ for males and 227 ± 11.9 for females.

Animals were individually housed in cages type 3H with Souralit 29/12 plus (souralit S.L., Gerona, Spain) aspen wood bedding and food completely available without restriction using standard dry pellet diet for rodents Scientific (Panlab, S.L.U., Cornell de Llobregat, Barcelona, Spain). They were kept in a room with controlled conditions of hygiene behind a barrier system, a range of temperature of $21\pm 2^{\circ}\text{C}$, with a 10-15 air changes per hour, and a relative humidity between 30-70% under 12 h light/dark cycle. Each cage contained an information card which contained study code (19-CAM-11-animal number), sex, dose, group, and individual animal identification. Community tap water (EMACSA, Cordoba Water company, Córdoba, Spain), filtered and autoclaved was available *ad libitum*.

2.3. Study design

The maximum tolerable dose (MTD) for PTSO in rats orally exposed to PTSO (gavage) was previously set at 55 mg/kg by Llana-Ruiz-Cabello et al., (2015) following the OECD 425 (2008) test guideline (oral toxicity study: Up and Down procedure), and it was used as a reference to establish the test doses. Accordingly, this dose was selected as the highest one to be tested, and also descending doses using a 2-fold interval factor according to the guideline OECD 408 (2018) recommendations: 14, 28, 55 mg/kg/day. Rats (10/sex/group) were orally administered the selected doses and the control group received only the vehicle (pork gelatine).

This study was performed at the Central Service of Experimental Animals from the University of Cordoba (SAE, Cordoba, Spain) in which all animals received human care in accordance with the guidelines for the protection of animals used for the science

purposes (Directive, 2010/63 EU, Decision, 2012/707/UE, and RD 53/2013). All procedures have been approved by the Ethical Animal Experimentation Committee of the University of Córdoba and by the Junta de Andalucía (project nº 20/10/2015-348).

2.4. Clinical observations

Each animal was observed twice daily for morbidity and mortality and once daily for clinical signs, such as changes in skin, fur, eyes or mucous membranes; secretions; changes in gait, posture, or handling response; abnormal, clonic, or tonic movements, and stereotypes or bizarre behavior. Ophthalmic examinations were performed on all animals before initiating the study and in the control and in the highest dose group at the end of treatment.

2.5. Body weight, food and water consumption

These three parameters were checked weekly in order to avoid stress. The mean body weight per group and sex were calculated weekly and prior to necropsy from individual animals' data, as well as the food and water consumption. The total food consumed per cage was recorded and the weekly mean intake per rat was calculated. The feed conversion efficiency (FCE) ratio was determined according to Escobar et al., (2015) by the ratio of food intake (g)/ weight gained (g).

2.6. Hematology and Biochemistry

Blood samples were extracted from the heart by an intracardiac injection under light isoflurane anesthesia at week 13. Then, the hematological parameters were

estimated on an automatic hematology analyzer Cell-Dyn 3700 (Abbot, GMI, MI, USA): red blood cell count (RBC), hemoglobin (HGB), hematocrit (HCT), mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), mean corpuscular hemoglobin concentration (MCHC), blood platelet count (PLT), red cell volume distribution (RDW), prothrombin time (PT), cefaline time (CT), white blood cell count (WBC), Neutrophils (NE), Lymphocytes (LY), Monocytes (MO), Eosinophils (EO) and Basophils (BA).

An automatic chemistry analyzer Cobas 6000 (Roche Diagnostics, IN, USA) was used to determinate the following standard biochemistry parameters: glucose (GLUC), blood urea nitrogen (UREA), creatinine (CREAT), bile acids (BILI-T), total cholesterol (CHOL), triglycerides (TRIGL), aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase (ALKP), albumin (ALB), total protein (TOT PROT), sodium (Na⁺), potassium (K⁺) and Calcium (Ca²⁺) ions.

2.7. Necropsy and Organ weight

The animals were fasted for 18 h before the sacrifice and profoundly anaesthetized with isoflurane, then exsanguinated by intracardiac injection. All rats were given a complete pathology examination through the necropsy. The following organs were collected from animals at necropsy and weighed wet immediately after dissection: brain, liver, heart, spleen, kidneys, thymus, adrenal glands, uterus with cervix and ovaries (females) and testes and epididymis (males). In addition, tissue samples of the following organs were taken from the control and the highest dose (55 mg/kg/day) group for histopathological examination under light microscopy: liver, kidney, spleen, heart, brain, pituitary, stomach, intestine, lung, testicle/ovary and

skeletal muscle. Samples were fixed in 10% formalin for 24h at 4°C, and then immediately dehydrated in graded series of ethanol, deep in xylol and embedded in paraffin wax using an automatic processor. Sections of 3-5 µm were mounted. After they had been deparaffinized, the sections were rehydrated, stained with hematoxylin and eosin, and mounted with Cristal/Mount (Paraplat, Oxford Labware, St. Louis, MO.).

2.8. *Statistical analysis*

All statistical analysis were carried out using Graph-Pad Instant software (GraphPadSoftware Inc., La Jolla, USA). Continuous variables, such as body weight, body weight gain, food and water consumption, hematology, clinical chemistry, and organ weight, were summarized using standard measures of central tendency and dispersion, mean and standard deviation (ST. DEV.), and were reported by sex and dosage. One-way analysis of variance (ANOVA) was carried out to test differences in continuous variables. Normality assumption was tested using Kolmogorov-Smirnov's test. If non-normality, comparison was performed with Kruskal Wallis test. In case of significant differences, multiple comparisons were performed using Tukey-Kramer/Dunn's Multiple Comparisons Tests. Differences were considered significant from $P < 0.05$.

3. **Results**

3.1. *Survival and clinical observations*

No unscheduled deaths occurred during the study. Light clinical signs were observed in some animals. Thus, sporadic alopecia was observed in rats 47, 59 and 62; small wounds in the ear of rat 52 and hematoma in the ear of rat 14 satisfactorily

recovered. These signs were not considered to be related to the test item, and were not biologically significant. Ophthalmologic examination revealed no compound-related lesions in the highest dose group of animals. No other clinical observations were noted.

3.2. Body weight, body weight gain, food and water consumption, feed consumption efficiency

Body weight increased along the study period following a usual pattern for this species. The test item did not induce any statistically significant alteration in this parameter (Fig. 2). Similarly, the body weight gain increased along the 13 weeks, with no differences between the control and the exposed groups in both sexes (Fig. 3).

Food and water consumption per week did not show significant differences between control and treated groups, male and female, throughout the duration of the study, following the usual pattern (data not shown). The feed consumption efficiency also did not reveal any remarkable change for animals (Table 1). Thus, the test item did not have a negative impact on these parameters.

3.3. Hematology and blood chemistry

Hematology parameters evaluated in rats exposed to PTSO are provided in Table 2. All variables considered remained unaltered in males. However, in females HCT (%) showed a significant increase ($p < 0.5$) in groups 2 and 3 (14 and 28 mg/Kg/d, respectively) in comparison to group 4 (50 mg/Kg/d), and also the MCH (pg) experienced a significant decrease ($p < 0.5$) in group 2 (14 mg/Kg/d) in comparison to group 3 (28 mg/Kg/d).

The differential White blood cells count did not show any change in any of the exposed groups and neither in males nor females (Table 3).

Table 4 includes the clinical biochemistry values obtained for the parameters analyzed after the oral subchronic exposure of rats to PTSO. Most of them were not modified by the treatment. Only in males, a significant ($p < 0.01$) decrease of Chol (mg/dL) values was observed in the highest dose group (55 mg/Kg/day), and also a significant increase ($p < 0.5$) of TRIGL (mg/dL) in the lowest dose group (14 mg/Kg/day), in comparison to the control group.

In general, as the significant changes observed were minimal, sporadic, not present in all dose groups, neither in both sexes, they were considered incidental and not indicative of toxicity.

3.4. Necropsy, organ weights and histopathology

No gross pathologies were observed during the necropsy in any of the experimental animals. Also, organ weights were not altered by the treatment and only the mean heart weight of males of group 3 (28 mg/Kg/day) showed a slight but significant ($p < 0.5$) decrease in comparison to the control group (Table 5). This was considered to be not related to the test item. Moreover, no significant changes were recorded in the organ weight/body weight ratio (Table 6) neither in the organ weight/brain weight ratio (Table 7).

Regarding to the histopathological study performed, tissues of the rats, both male and female, exposed to the highest dose, did not revealed alterations in comparison to the control group in any of the organs examined by light microscopy (Fig. 4).

4. Discussion

The repeated dose 90-days oral toxicity study in rodents provides information on the possible health hazards likely to arise from repeated exposure over a prolonged period of time covering post-weaning maturation and growth into adulthood of the test animals. The study provides, among others, information on the major toxic effects, identification of target organs and also can provide an estimate of a non-observed-adverse-effect level (NOAEL) of exposure which can be used in selecting dose levels for chronic studies and for establishing safety criteria for human exposure (OECD 408, 2018). Moreover, an oral 90-days subchronic toxicity assay is usually included among the basic set of toxicity tests required in the evaluation of chemical substances with potential applications in the agri-food sector before their authorization. This is the case for example of food (EFSA, 2012a) and feed additives (EFSA, 2017), migrating food contact materials (EFSA, 2016a), or novel food (2016b). All this highlights the relevance of the study performed with PTSO, as this compound has shown beneficial properties with different potential applications previously described.

The general absence of toxic effects observed after the treatment allows to estimate that the NOAEL for PTSO is ≥ 55 mg/Kg/day. Considering a safety factor of 100 usually applied in food additives to derive human safety values from animal data (EFSA, 2012b), a dose of 0.55 mg/Kg/day could be suggested as a safe human exposure ($\sim 38,5$ mg/day for a 70 kg b.w. person). However, this value is underestimated taking into account that a NOAEL could not be established from the assay performed and could be higher than 55 mg/Kg/day.

The results obtained in the present study complete the information available in relation to the toxicity profile of PTSO. Thus, Llana-Ruiz-Cabello et al. (2015)

performed an acute oral toxicity test (Up-and-Down Procedure) following the OECD 425 guideline (2008) and 55 mg/Kg b.w. was established as the maximum tolerated dose (MTD) in rats. However, in that case the exposure was by gavage whereas in the present study it was with the diet, a more realistic human exposure scenario.

Mellado-García et al. (2015) performed a thorough *in vitro* genotoxicity assessment of PTSO including 4 different tests, among them the Ames test and the Micronucleous (MN) assay. This is the basic battery indicated by EFSA (2012) as they cover the three genetic endpoints required: gene mutations and both structural and numerical chromosome aberrations. They also performed the Mouse Lymphoma assay (MLA) and the Comet assay. They concluded that PTSO was not mutagenic in the Ames test, but it was mutagenic in the MLA assay after 24 h of treatment. The parent compound did not induce MN on mammalian cells; however, its metabolites induced positive results. Due to inconclusive results, a follow-up of positive *in vitro* results by *in vivo* testing was performed. The genotoxicity of PTSO in rats following an oral administration of 5.5, 17.4 and 55 mg/kg was evaluated by a combined *in vivo* comet assay and MN test (Mellado-Garcia et al., 2016a) and the results revealed no genotoxicity.

All these results suggest a safety profile of PTSO for food applications at the doses assayed, but in a risk assessment frame it is well known that risk depends not only on the hazard but also in the human exposure level. In this regard, the level of PTSO to use, and therefore the potential exposure, will depend on the specific application considered. For instance, in the active packaging of lettuce, Llana-Ruiz-Cabello et al. (2015) estimated that in the worst-case scenario a human could ingest 6.87 mg PTSO, this means only a 18% of the dose calculated as safe in the present study.

The results obtained agree with those of Mellado et al. (2016b) who evaluated the safety of Proallium AP®, an *Allium*-based commercial product in a 90-days feeding study with rats. PTSO is actually the major organosulfur compound present in Proallium AP® (14.5%). Similarly, neither clinical signs nor any other changes on general, biochemical, hematological or histopathological parameters were detected, and the authors derived a NOAEL higher than 400 mg/Kg/day at the conditions assayed. Both studies show a good correlation as in the present study the test item had a 7-fold higher content of PTSO than Proallium® AP (100 versus 14.5%) and the NOAEL derived for Proallium was 7-fold higher. This suggests that PTSO has an important role on the toxicity of *Allium* extracts. Actually, a MTD of 55 mg/kg in rats for PTSO has been established as previously indicated. And higher doses tested according to the OECD 425 guideline (2000 mg/kg and 175 mg/kg) resulted in the death of the animal and evident hepatotoxicity. On the contrary, a single dose of 55 mg/kg did not induce remarkable damage (Llana-Ruiz-Cabello et al, 2015). Mellado-García et al. (2016a) observed that in rats treated with 55 mg/kg (3 doses at 0, 24 and 45h and euthanized at 48h) an increase in the glycogen storage was noticeable in the liver and also a slight degenerative process in the chief cells of the stomach.

In this regard, at the dose levels assayed, histopathological lesions were absent. This could be explained by the exposure way employed in this study, using gelatin as vehicle and with the feed. In the previous trials, oral gavage with a stomach tube after a fasting period was used following the recommendations of the corresponding OCDE guidelines. The bolus could have a more deleterious effect on the gastrointestinal system as there is a direct contact.

Differences in toxicity between PTSO and Proallium AP® could be explained as the toxicity shown by components of an essential oil can be modulated by the other

constituents by synergistic/antagonistic phenomena (Escobar et al., 2015; Pavlidou et al., 2004). The interest of PTSO in comparison to Proallium® is based on its different chemical properties (higher hydrophilia) and in its higher efficiency on its antioxidant and antimicrobial properties.

Other authors have shown the potential toxicity of aqueous extracts of different medicinal plants, including *Allium sativum*, in Wistar rats. Thus, Sulaiman et al. (2014) administered orally to the animals 10 mg/kg of *A. sativum* extract for 30 days and observed alteration in the activities of marker enzymes: AST increased in liver, kidney and heart, ALT in serum and liver, and ALP activity was reduced in serum, heart, kidney and liver. They concluded that caution was required in using unrefined extracts of these herbs in traditional settings.

There are scarce *in vivo* toxicity data regarding other OSC. Thus, Guyonnet et al. (2000) demonstrated the effects of some of them (DAS, DADS, dipropylsulfide (DPS) and dipropyl disulfide (DPDS)) on the activation of several mutagens in male Wistar rats exposed to 1 mmol/kg by gavage for 4 days. They explained the results based on the induction of cytochrome (CYP) and phase II enzymes activities. This effect, the alteration of CYP activity, was pointed out by other authors as well (Davenport and Wargovich, 2005). Moreover, they observed hepatotoxicity induced by DAS (bile duct obstruction, hyperproliferation and focal points of necrosis) in rats gavaged daily with 200 mg/kg for 1, 4, or 8 weeks. On the contrary, 8 weeks of exposure to lower doses (50 and 100 mg/kg) did not induced liver histopathological damage. This suggest that liver could be the target organ of OSC as both, DAS (Davenport and Wargovich, 2005) and PTSO (Llana-Ruiz-Cabello et al, 2015), have shown liver toxicity when a threshold dose is exceeded. Also, Wu et al. (2001) exposed rats orally to garlic oil (GO, 200 mg/Kg) and 3 allyl compounds, DAS (20 and 80 mg/kg), DADS (80 mg/kg), and diallyl

trisulfide (DATS, 70 mg/kg) 3 times a week for 6 weeks and examined the antioxidation system in rat livers and red blood cells. They found that GO, DADS and DATS significantly induced the glutathione content (GSH) in blood cells but neither GO nor any of its OSC affected the GSH-related antioxidant enzymes. Hepatic GSH was not influenced by garlic components. But DADS and DATS significantly increased the activity of GSH-reductase and GSH-transferase and decreased GSH peroxidase. In the present study the hematological parameters were not influenced by the PTSO exposure and scarce scientific data dealing with PSTO are available to compare.

5. Conclusions

In conclusion, the results obtained confirm the already reported safety profile of PTSO for some food applications at the conditions considered. Thus, PTSO did not promote toxic effects as seen from body weight changes, food and water consumption, feed conversion efficiency, biochemical and blood parameters as well as organ toxicity and histological examinations of main organs that could eventually be affected by its subchronic administration (90 days). NOAEL was estimated to be ≥ 55 mg/Kg/day.

Conflict of Interest

The authors declare that there are no conflicts of interest.

Figure captions

Fig. 1. Biochemical pathways and chemical structures of organosulfur compounds. (Alk(en)yl cysteine sulfoxides (ACOs); Propyl-propane-thiosulfonate (PTSO); Propyl-propane-thiosulfinate (PTS)).

Fig. 2. Mean body weights (g) of A) male and B) female rats orally exposed to 0, 14, 28 and 55 mg/kg b.w./day PTSO and control rats for 90 days.

Fig. 3. Mean body weight gain (%) of A) male and B) female rats orally exposed to 0, 14, 28 and 55 mg/kg b.w./day PTSO and control rats for 90 days.

Fig. 4. Histopathological study of liver, kidney, spleen, heart, brain, pituitary, stomach, intestines, lung, testes, and skeletal muscle of untreated Sprague Dawley rats, control (A), and treated (B) with PTSO (55 mg/Kg/day) for 90 days (bars= 50 μ m). In the liver, normal hepatic cords and normal polyhedral hepatocytes with central nucleus and clear cytoplasm are seen in control and exposed animals. In the kidney, the renal parenchyma with normal glomeruli and renal tubules is shown in control rats (A), as well as in rats treated with the highest dose of PTSO (B). Detail of the apparently normal spleen parenchyma in control and treated rats (A, B). In the heart, normal cardiac fibers were observed in all groups (A, B). In the brain, the motions of the cerebral cortex are normal (A, B). Details of the apparently normal pituitary are observed in control and treated rats (A, B). Detail of the stomach with apparently normal mucous and glandular cells in control and treated rats (A, B). Intestinal villi with abundant apparently normal enterocytes are shown in all groups. Detail of the control

bronchial epithelium, without alterations in the bronchi and alveoli in the untreated rats (A) as well as in the rats treated with the highest dose (B). Male rat testes showed normal seminiferous tubules and interstitial space (A) that is maintained in treated male rats (B). The ovaries of the treated and control female rats (A, B) presented normal follicles in all groups. Detail of the normal striated skeletal muscle of the treated and control rats (A, B).

Table captions

Table 1. Effect of 90 days oral exposure to PTSO on body weight and food consumption in rats. Values represent the mean \pm SD of 10 rats/sex/group. Differences between control and treated groups for male and female rats were evaluated by Kruskal-Wallis test (K.W.) or by ANOVA test (F values).

Table 2. Hematology parameters of male and female rats fed with 0, 14, 28 and 55 mg/kg b.w./day PTSO for 90-days. Values are mean \pm SD for 10 rats/sex/group. The differences between control and treated groups for male and female rats were evaluated by Kruskal-Wallis test (K.W.) or by ANOVA test (F values). The significance levels observed are & in comparison to group 4 (55 mg/Kg/d) when $p < 0.05$, and # in comparison to group 3 (28 mg/Kg/d) when $p < 0.05$.

Table 3. Differential White blood cells count data of male and female rats fed with 0, 14, 28 and 55 mg/kg b.w./day PTSO for 90-days. Values are mean \pm SD for 10 rats/sex/group. The differences between control and treated groups for male and female rats were evaluated by Kruskal-Wallis test (K.W.) or by ANOVA test (F values).

Table 4. Clinical biochemistry of male and female rats fed with 0, 14, 28 and 55 mg/kg b.w./d PTSO for 90-days. Values are mean \pm SD for 10 rats/sex/group. The differences between control and treated groups for male and female rats were evaluated by Kruskal-Wallis test (K.W.) or by ANOVA test (F values). The significance levels observed are * $p < 0.05$ and ** $p < 0.01$ in comparison to control group values.

Table 5. Absolute organ weight of male and female rats fed with 0, 14, 28 and 55 mg/kg b.w./day PTSO for 90-days. Values are mean \pm SD for 10 rats/sex/group. The differences between control and treated groups for male and female rats were evaluated by Kruskal-Wallis test (K.W.) or by ANOVA test (F values). The significance levels observed are *p < 0.05 in comparison to control group values.

Table 6. Relative organ weight/body weight of male and female rats fed with 0, 14, 28 and 55 mg/kg b.w./day PTSO for 90-days. Values are mean \pm SD for 10 rats/sex/group. The differences between control and treated groups for male and female rats were evaluated by Kruskal-Wallis test (K.W.) or by ANOVA test (F values).

Table 7. Relative organ weight/brain weight of male and female rats fed with 0, 14, 28 and 55 mg/kg b.w./day PTSO for 90-days. Values are mean \pm SD for 10 rats/sex/group. The differences between control and treated groups for male and female rats were evaluated by Kruskal-Wallis test (K.W.) or by ANOVA test (F values).
