19 **Keywords:** Mid-Pleistocene Transition - Atlantic deep waters – Foraminifera - Stable
20 isotopes - African aridity – Ti

21

22 **Abstract**

23 A high resolution analysis of benthic foraminifera as well as of aeolian terrigenous proxies
24 extracted from a 37 m-long marine core located off the Mauritanian margin spanning the last
25 ~1.2 Ma, documents the possible link between major continental environmental changes with
26 a shift in the isotopic signature of deep waters around 1.0–0.9 Ma, within the so-called Mid-
27 Pleistocene Transition (MPT) time period. The increase in the oxygen isotopic composition of
28 deep waters, as seen through the benthic foraminifera $\delta^{18}\text{O}$ values, is consistent with the
29 growth of larger ice sheets known to have occurred during this transition. Deep-water mass

30 $\delta^{13}\text{C}$ changes, also estimated from benthic foraminifera, show a strong depletion for the same
31 time interval.

32 This drastic change in $\delta^{13}\text{C}$ values is concomitant with a worldwide 0.3‰ decrease observed
33 in the major deep oceanic waters for the MPT time period. The phase relationship between
34 aeolian terrigenous signal increase and this $\delta^{13}\text{C}$ decrease in our record, as well as in other
35 paleorecords, supports the hypothesis of a global aridification amongst others processes to
36 explain the deep-water masses isotopic signature changes during the MPT. In any case, the
37 isotopic shifts imply major changes in the end-member $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values of deep waters.

38

39 **Introduction**

40 During the Mid-Pleistocene Transition (MPT), which extends from 1.25 to 0.7 Ma
41 (Clark et al., 2006, approximately centered around 0.9 Ma), drastic changes were observed in
42 the glacial isotopic composition of deep-water masses of the Equatorial Atlantic Ocean
43 (enriched $\delta^{18}\text{O}$ values and depleted $\delta^{13}\text{C}$ values) (Flower et al., 2000; Schefuß et al., 2003;
44 Raymo et al., 2004). Similar shifts in isotopic values (i.e., enriched $\delta^{18}\text{O}$ values and depleted
45 $\delta^{13}\text{C}$ values) were observed in cores from different oceanic basins, highlighting the global
46 aspect of such changes (Raymo et al., 1997; deMenocal, 2004; Ravelo et al., 2004; Lisiecki
47 and Raymo, 2005; Hoogakker et al., 2006). Global trends are only apparent in deep-water
48 signatures. Conversely, records of surface conditions vary: cooling is shown in the equatorial
49 Atlantic (Marlow et al., 2000), while stable sea-surface temperatures are observed in the
50 tropical Pacific warm pool (deGaridel-Thoron et al., 2005) at the same time. The global $\delta^{18}\text{O}$
51 benthic enrichment mainly results from the build up of large continental ice sheets at high
52 latitudes. The decrease in $\delta^{13}\text{C}$ benthic values ($>0.3\text{‰}$) between 1.1 and 0.9 Ma has been
53 attributed to a net addition of a ^{12}C -enriched reservoir into the ocean (Raymo et al., 1997).
54 Two main candidates were proposed: (1) marine organic matter exposed on continental
55 shelves as sea level dropped, or (2) carbon input from the terrestrial biosphere reservoir. The
56 first hypothesis suggests an increase in the mean ocean nutrient content, implying changes in
57 the Atlantic- Pacific oceanic $\delta^{13}\text{C}$ gradient. As no such changes are observed in the inter-basin
58 $\delta^{13}\text{C}$ gradient nor in the Redfield nutrients, the first hypothesis has been disregarded. This left
59 the second hypothesis, suggesting, without other robust arguments, a global increase in aridity
60 after 0.9 Ma (Raymo et al., 1997). A global carbon isotope budget, applied to glacial–
61 interglacial climatic shifts (Maslin and Thomas, 2003), estimated the effect of different
62 parameters such as terrestrial biomass volume and carbon isotopic changes (C_3/C_4), together

63 with changes due to exchange of gas hydrates. This study proposed an average shift in the
64 global oceanic $\delta^{13}\text{C}$ values of about 0.3‰ between the last glacial maximum (LGM) and the
65 Holocene, reappraising previous average estimates of ~0.4‰ (Curry et al., 1988; Duplessy et
66 al., 1988). Maslin and Thomas (2003) highlighted here the important consequence of bigger
67 ice sheets on the receding of terrestrial biomass and the impact on the global carbon isotope
68 budget. For the MPT, global models (e.g., Hoogakker et al., 2006) have suggested that such
69 oceanic $\delta^{13}\text{C}$ fluctuations could result from concomitant changes in the burial fluxes of
70 organic and inorganic carbon. On the Atlantic coast of Africa, previous studies on marine
71 records, focusing on the MPT, revealed environmental changes over the continent, linked to
72 atmospheric changes, bringing new pieces of evidence for aridification (Dupont et al., 2001;
73 Schefuß et al., 2003) and wind intensification (Marlow et al., 2000). DeMenocal has even
74 suggested that such changes could have influenced African hominid evolution (deMenocal,
75 2004).

76 In addition to this peculiar isotopic shift occurring during the MPT, isotopic changes
77 are observed in Equatorial Atlantic deep-water masses on orbital time scales (Duplessy et al.,
78 1980; Duplessy and Shackleton, 1985; Curry et al., 1988; Oppo and Lehman, 1993; Raymo et
79 al., 1997; Flower et al., 2000; Curry and Oppo, 2005). In the modern Atlantic Ocean and
80 more generally during interglacial periods, the northward-flowing surface water becomes
81 denser and sinks as the southward-flowing North Atlantic Deep Water (NADW). This deep-
82 water mass is characterized by rather $\delta^{18}\text{O}$ values (~3‰) due to reduced continental ice sheet
83 volume, and by high $\delta^{13}\text{C}$ values (N1‰) resulting from young waters sinking from the
84 surface, after marine productivity has removed nutrients (PO_3 , NO_3) and ^{12}C , enriching it in
85 ^{13}C (Broecker and Peng, 1982; Curry et al., 1988). This carbon isotopic signature can be
86 traced as far south as the equatorial region, at depths of about 2500–3000 mbs (Flower et al.,
87 2000) (Fig. 1). The southern part of the deep Atlantic Ocean hosts Lower Circumpolar Deep
88 Water (LCDW), originating from the Southern Ocean. This watermass is characterized by
89 lower $\delta^{13}\text{C}$ values (between 0.5 and 0‰, after Kroopnick, 1985). Because these southern deep
90 waters have been isolated from the surface for a long time, the continuous oxidation of low-
91 $\delta^{13}\text{C}$ organic matter at depth has lowered its $\delta^{13}\text{C}$ value.

92 During a glacial period, the build-up of huge continental ice sheets influences the
93 dynamics of this deep-water circulation, reducing NADW formation, and delivering it to
94 shallower depths, generating the Upper North Atlantic Deep Water (UNADW). Such change
95 in the deep circulation allows a stronger intrusion of South Oceanic Waters (SOW) at

96 northern latitudes (Fig. 1), for which the aging effect has shifted their carbon isotopic
97 composition to negative values. The mixing between these water masses (SOW and
98 UNADW) led to lower $\delta^{13}\text{C}$ values at equatorial latitudes (Duplessy et al., 1988; Sarnthein et
99 al., 1994; Flower et al., 2000).

100 A schematic pattern of changes in the Atlantic deep-water masses circulation can even
101 be drawn by using their isotopic compositions, as the result of mixing between two end-
102 members, with high $\delta^{13}\text{C}$ ($>0.5\text{‰}$) and low $\delta^{18}\text{O}$ (around 2.5‰) values, attributed to
103 interglacial North Atlantic Deep Waters (NADW), and lower $\delta^{13}\text{C}$ ($<0.5\text{‰}$) and higher $\delta^{18}\text{O}$
104 ($\sim 4.5\text{‰}$), attributed to glacial South Oceanic Waters (SOW) (Duplessy and Shackleton, 1985;
105 Curry et al., 1988; Sarnthein et al., 1994; Flower et al., 2000; Curry and Oppo, 2005) (Fig. 1).
106 Such isotopic oscillations have been observed over tens to hundreds of thousands year time
107 scales (Raymo et al., 1997), but also for millennial-scale events over the last climatic cycle,
108 shifting from warm to cold climatic conditions, associated to abrupt NADW circulation
109 changes (e.g., Vidal et al., 1999; Shackleton et al., 2000).

110 As described previously, glacial–interglacial variations of global oceanic $\delta^{13}\text{C}$ values
111 could also record the expansion and contraction of the terrestrial biosphere (Maslin and
112 Thomas, 2003). However, the consequence of such an effect might have been inadequate for
113 the MPT time period. Indeed, for the LGM–Holocene transition, a 1‰ change in the global
114 $\delta^{18}\text{O}$ sw value has been accompanied by a 0.3‰ change in the global $\delta^{13}\text{C}$ value. Since the
115 $\delta^{18}\text{O}$ difference between successive glacial across the MPT time interval is considerably
116 smaller than across the last deglaciation, it seems fair to assume that the additional carbon
117 input from the larger ice sheets was also smaller than 0.3‰ . This hypothesis is thus not
118 sufficient to explain the entire decrease in benthic $\delta^{13}\text{C}$ values observed for successive glacial
119 periods across the MPT.

120 In order to investigate these deep-water isotopic composition changes and to
121 distinguish the shorter-term fluctuations (e.g. glacial– interglacial deep oceanic circulation
122 changes) from the MPT shift (possibly linked with atmospheric circulation changes), we
123 present here a study of a deep marine core from the tropical Atlantic Ocean, covering the past
124 1.10Ma. Isotopic analyses of stable isotopes ($\delta^{18}\text{O}$ and $\delta^{13}\text{C}$) were made on benthic
125 foraminifera to characterize variations in the isotopic composition of deep-water masses. The
126 core is located along the north western African margin and heavily influenced by atmospheric
127 dust plumes from the Sahara desert. This allows us to study aridity changes over the African

128 continent in parallel with the stable isotope shifts and therefore to test the global aridity
129 hypothesis.

130

131 **Setting and methods**

132 Core MD03-2705 is located in the eastern tropical Atlantic Ocean [18°05.81'N;
133 21°09.19'W; 3085 meters below sea floor (mbsf)]. The area is sensitive enough to record the
134 balance between the NADW and the SOW water masses (Fig. 1). Previous estimates of mean
135 accumulation rate of about 3.4 cm/ka (Jullien et al., 2007; Tisserand et al., 2009) date the
136 oldest part of this 37-m-long core at greater than 1 million years. The core was retrieved from
137 a bathymetric dome, 300 m above the surrounding seafloor, thus preventing possible
138 perturbations of the sediment from gravity and bottom currents (Jullien et al., 2007).

139 Benthic foraminifera have been handpicked under stereomicroscope from dry
140 sediment sieved at 150 µm. The sampling interval was 10 cm and splitting of the dry samples
141 was done when weight exceeded 0.5 g. A maximum of 4 splits were made for sample at 1.022
142 Ma (1.8 g). Total amount of picked individuals per sample ranges from 81 at 0.910 Ma to 521
143 at 0.968 Ma (mean 218). The number of counted specimens per sample has been normalised
144 to sample weight. Data presented in this study are limited to those of the Benthic
145 Foraminiferal Number (BFN) that shows the total number of individuals per gram of dry
146 sediment and *Uvigerina peregrina* abundance changes which are considered as an indicator of
147 surface productivity (Lutze and Coulbourn, 1984, Loubere, 1991).

148 Isotopic analyses were made on monospecific samples of the bathyal epifaunal species
149 of benthic foraminifera *Planulina wuellerstorfi*, and are therefore suitable to record variations
150 in the deep-water isotopic composition. For each sample, 2 to 3 individuals were picked and
151 dissolved in acid via the Micromass Multiprep autosampler system. The resulting carbon
152 dioxide gas was subsequently analysed against the international reference standard NBS 19,
153 using an Optima Micromass mass spectrometer. Measurements were carried out at the
154 Bordeaux 1 University, within the EPOC isotopic laboratory. Triplicate measurements were
155 made for each depth horizon (1 cm) to reduce uncertainties. The analytical precision is better
156 than 0.05‰ for $\delta^{18}\text{O}$ and 0.03‰ for $\delta^{13}\text{C}$. A $+0.64 \text{ mil}^{-1}$ correction factor was applied to
157 *Planulina wuellerstorfi* $\delta^{18}\text{O}$ values, according to previous calibration studies (Shackleton and
158 Opdyke, 1973; Duplessy et al., 1984). No correction is necessary for *Planulina wuellerstorfi*
159 $\delta^{13}\text{C}$ values.

160 Major elements were measured in the bulk sediment using the Bremen XRF-Cortex
161 facility, with a 1-cm step resolution (Jullien et al., 2007). Here, we focus on the titanium (Ti)
162 record as a tracer of terrigenous supply (Richter et al., 2006) derived from preferential aeolian
163 contributions (Itambi et al., 2009). The percentage of calcium carbonate is based on the Ca
164 record, using a previously established calibration (Tisserand et al., 2009), that links XRF-
165 based Ca measurements with the classical volumetric method using Bernard calcimeter
166 (Huelsemann, 1966; Muller and Gatsner, 1971). Biogenic opal is a minor to negligible
167 component of the sediment (less than 10%) in this area (deMenocal et al., 2000). A first-order
168 approximation of the dust content is obtained by assuming that the non-carbonate fraction
169 represents the dust fraction as proposed by Jullien et al. (2007) and Tisserand et al. (2009), as
170 well as by deMenocal et al. (2000) for the neighboring marine core ODP-658.

171 According to this hypothesis, and in a first-step approach, the concentration of
172 terrigenous particles is estimated using the following relationship:

173 Terrigenous content (%) = 100–CaCO₃ content

174 Semi-quantitative quartz content estimates in the clay–mineral fraction have been
175 carried out using X-ray diffraction at the University of Lille. Samples were prepared
176 following the protocol of Bout- Roumazeilles et al. (1999). X-ray diagrams were obtained
177 using a BRUKER D4 Endeavor in association with the Lynxeye fast detector (Cu X-ray tube;
178 35 kV voltage; 30 mA intensity). XRD runs were performed routinely for each sample
179 between 2.49 and 32.49°2θ on air-dried samples. Quartz intensity (in counts per second) was
180 measured on the 4.26 Å peak using the Macintosh MacDiff® 4.2.5 software (Petschick,
181 2000).

182 For paleomagnetic analyses, u-channels were sampled in the deepest part of the core,
183 between 27 mbsf and 29.5 mbsf and below 33 mbsf. The analysis of the natural remanent
184 magnetization (NRM) was conducted using a 755-R 2G-cryogenic magnetometer equipped
185 with high-resolution pick-up coils within the μ-metal shielded room of LSCE (Weeks et al.,
186 1993). Stepwise alternating field demagnetization was conducted with 13 successive steps
187 from 0 to 80 mT. The direction of the characteristic remanent magnetization and the mean
188 angular deviation (MAD) were determined using a PCA analyses (Kirschvink, 1980; Mazaud,
189 2005).

190 Stratigraphy of the upper part of core MD03-2705, covering the last two climatic
191 cycles, has been published in Jullien et al. (2007) and in Tisserand et al. (2009). A new

192 stratigraphy, based on a fifthorder polynomial regression, is proposed for the past 0.22 Ma
193 (Matsuzaki et al., 2011). Stratigraphy of the lower part of the core was developed by tuning
194 the $\delta^{18}\text{O}$ benthic record to the LR04 reference record (Lisiecki and Raymo, 2005), using the
195 Analyserie program (Paillard et al., 1996) (Fig. 2). The $\delta^{18}\text{O}$ benthic record in core MD03
196 2705 is offset by a relatively constant value of -0.5‰ relative to the LR04 record. The
197 constancy of this difference is remarkable, given that Lisiecki and Raymo (2005) used
198 multiple benthic records from different cores to build their stack, while MD03-2705 $\delta^{18}\text{O}$
199 curve originates from a single core.

200 Stratigraphy of the lower part of core MD03-2705 is further constrained using the
201 paleomagnetic record. Three main polarity reversals are identified with a MAD value very
202 rarely exceeding $7\text{--}8^\circ$ (maximum value: 16°): a reverse to normal polarity centered around
203 35.85 mbsf, a normal to reverse polarity around 33.60 mbsf and a reverse to normal polarity
204 at 28.30 mbsf. These three polarity reversals correspond to the lower and upper Jaramillo and
205 to the Matuyama/Bruhnes reversals. They occur during Marine Isotopic Stages (MIS) 31, 27
206 and 19 respectively, consistent with previous studies (Shackleton et al., 1990; Horng et al.,
207 2002). The ages assigned to these horizons in core MD03-2705, when reported on the LR04
208 scale (1.07 Ma, 0.988 and 0.781 Ma, respectively, for 35.85, 33.6 and 28.3 mbsf) (Horng et
209 al., 2002), are consistent within about 5 ka uncertainty with the radiometric ages of the
210 reversals at 1.053 ± 6 Ma, 0.986 ± 5 Ma and 0.779 ± 2 Ma (Singer et al., 1999 and references
211 therein, Singer and Brown, 2002). All of the chrono-stratigraphic information for this core is
212 internally consistent.

213 Unfortunately, the oldest sample extracted from core MD03-2705 (1.1 Ma) is not old
214 enough to cover the whole MPT time interval, starting around 1.25 Ma according to Clark et
215 al. (2006). Our record is therefore missing the background variations that lead up to this
216 transition, and might possibly miss some events which could had have higher amplitude than
217 the ones discussed in this work. Meanwhile, the largest changes recorded during the MPT are
218 usually centered around 0.9 Ma, well within our record.

219

220 **Results**

221 *Continental aridity proxies*

222 The carbonate-free fraction of the core is a mixture of clay minerals and fine silt-sized
223 quartz brought by the winds, along with rare freshwater diatoms and phytoliths. Because of

224 low amounts of biogenic opal in the sediment, the aeolian dust fraction was estimated by
225 difference between the total and the CaCO₃ fraction (see setting and method section). This
226 approximation is supported by the XRF measurements of terrigenous elements such as Ti in
227 the bulk sediment, which show a very good correlation with the percentage
228 of the terrigenous fraction (Fig. 2).

229 The terrigenous percentages may not solely reflect changes in dust inputs as it is also
230 dependant on CaCO₃ productivity and sedimentation, including possible dissolution effects.
231 The carbonate microfossils (foraminifera), however, present no imprint of dissolution.
232 Moreover, in a previous paper focusing on MIS 6, specific counts (on smear slides) of aeolian
233 quartz particles in core MD03-2705, have clearly shown the link between aeolian inputs and
234 terrigenous index (100% -CaCO₃) (Tisserand et al., 2009). Here, the good correlation
235 between the aeolian terrigenous fraction and the quartz content estimates in the clay–mineral
236 fraction during the MPT also supports the validity of the assumption that the percentage of
237 mineral dust primarily reflects an intensification of the aeolian terrigenous supply, which can
238 be interpreted in this particular sedimentary setting as variations in aridity (Rea, 1994), at
239 least for this period.

240 Ti variations, together with the terrigenous particle concentrations and sedimentation
241 rate variations are compared over the past 1.1 Ma in Figure 2. Some rapid increases of the
242 sedimentation rate are found during glacial MIS 28, 12, 6 and 2 periods. During MIS 28
243 (around 1.025 Ma), the sharp increase is clearly linked to an exceptional volcanic event,
244 marked by an ash layer. Both the amount of Ti and the terrigenous content records proxies
245 record one of their highest values within the ash layer (Fig. 2). Otherwise, variations in the
246 sedimentation rates are rather low and steady. A strong similarity between the terrigenous
247 proxies and $\delta^{13}\text{C}$ benthic curve is clear for the earliest part of the record, from 1.1 Ma to 0.7
248 ka while discrepancies appear for the latest part, from 700 ka to present day (Fig. 2). Within
249 the MPT transition, between 1 Ma and 0.9 Ma, glacial periods (from MIS 26 to MIS 22) are
250 characterized by a progressive increase in both terrigenous proxies. Variability decreases in
251 both records to a plateau within MIS 15 and MIS 13, i.e. between 0.60–0.45 Ma.

252

253 *Deep-water masses isotopic signature*

254 We defined time intervals corresponding to full glacial and interglacial periods for the
255 last 1.1 Ma in order to identify the two primary end-member water masses (i.e., similar to

256 NADW and SOW). Climatic transitions (i.e., terminations/deglaciations), during which the
257 water masses mixing readjustment occurs, have been removed in this operation. The selected
258 time periods, and the corresponding depth intervals, are presented in Table 1.

259 An X-Y plot of $\delta^{18}\text{O}$ values and $\delta^{13}\text{C}$ values provides a clear graphical separation of
260 interglacial and glacial periods (Fig. 3). Interglacial periods, concentrated on the upper part of
261 the graph, are characterized by low $\delta^{18}\text{O}$ and high $\delta^{13}\text{C}$ values, while glacial periods, on the
262 lower part of the graph, are identified by high $\delta^{18}\text{O}$ and low $\delta^{13}\text{C}$ values. Interglacial values
263 are scattered around the NADW reference value, in agreement with the modern hydrology off
264 the Mauritanian margin. Glacial periods conversely show a scattering around the SOW
265 reference value.

266 For the glacial values of this scatter plot, some isotopic differences can be observed
267 through time, defined as clusters (Fig. 3) in the following description. For oldest glacials, i.e.
268 from MIS 32 to 28, isotopic values are in between the two end-member values (Fig. 3). The
269 low amplitude $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ variations characterizing MIS 32 to 28 suggest rather small
270 glacial-interglacial deep-water masses variations (Fig. 2). The MPT (from cluster MIS 28–32
271 to cluster MIS 24–20 in Fig. 3) is marked by a clear shift in range of $\delta^{13}\text{C}$ values with lower
272 values during both glacial and interglacial periods compared to the previous intervals, while
273 the total amplitude of the $\delta^{18}\text{O}$ signal is only slightly enriched. The most recent period, from
274 MIS 16 to 2, shows a shift back toward higher $\delta^{13}\text{C}$ values for both glacial and interglacial
275 periods. Only MIS 12, within this recent period, experiences $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ isotopic values
276 comparable to those found within MIS 32 to MIS 28 (Fig. 2). This explains the overlap
277 between these last two clusters (on the X–Y plot, Fig. 3). The $\delta^{13}\text{C}$ signal thus displays a
278 peculiar temporary feature over the MPT interval (from cluster MIS 28–32 to cluster MIS 24–
279 20), with both glacial and interglacial-depleted values (Figs. 2 and 3). Contrastingly, the
280 glacial $\delta^{18}\text{O}$ -values increased during the MPT and progressively reached the recent glacial
281 signature (MIS 16 to 2). Meanwhile the interglacial $\delta^{18}\text{O}$ values remained rather stable (even
282 slightly decreasing) over the MPT interval compared to the increase observed on the more
283 recent periods (MIS 16 to 2), when the $\delta^{18}\text{O}$ amplitude reached its maximum actual range.

284

285 **Discussion**

286 *Continental-deep ocean linkage on the African margin*

287 For the deep-water carbon isotopic composition, a marked depletion is observed in
288 core MD03-2705 between 1.10 and 0.80 Ma, with the lowest $\delta^{13}\text{C}$ values reached during MIS
289 24, 22 and 20 (Fig. 2). This drop in the deep marine $\delta^{13}\text{C}$ values is in complete agreement (in
290 both timing and amplitude) with what was observed in the nearby marine core ODP664
291 (Raymo et al., 1997). In marine record MD03-2705, a strong similarity in shape between the
292 terrigenous content and $\delta^{13}\text{C}$ benthic curve can be observed for the earliest part of the record,
293 from 1.1 Ma to 700 ka, while discrepancies appear for the latest part, from 700 ka to present
294 day (Figs. 2 and 5). For the MPT time interval, between 1.0 and 0.7 Ma, the marked peaks in
295 the $\delta^{13}\text{C}$ benthic record appear to be in phase with increases in the Ti content, the terrigenous
296 percentage and semi-quantitative quartz content records (Fig. 6). Lag-correlation analysis
297 (using MATLAB software) between the $\delta^{13}\text{C}$ benthic and terrigenous content records between
298 1.0 and 0.7 Ma reveals a maximum correlation of 0.55 for a 4000-yr lead of the terrigenous
299 signal (Fig. 4). The relatively weak correlation suggests that, while a clear link exists between
300 continental aridity and the $\delta^{13}\text{C}$ benthic signature, this link is probably not direct (West
301 African terrigenous signal possibly leading global aridification) and that other processes are
302 probably involved in the carbon isotopic changes of deep-water masses.

303 As shown by the $\delta^{18}\text{O}$ benthic record, the MPT corresponds to progressively colder
304 glacial conditions, characterized by the building of larger continental ice sheets. As suggested
305 by paleodata from the equatorial Atlantic Ocean (deMenocal, 1995; Jullien et al., 2007;
306 Mulitza et al., 2008), as well as modelling results (Tjallingii et al., 2008; Kageyama et al.,
307 2009), a strengthening of the atmospheric circulation cells, accompanied by a southward shift
308 in the pattern of the Inter-Tropical Convergence Zone (ITCZ), is expected during these colder
309 periods. The southward shift of the ITCZ would have extended the arid belt further south in
310 Northwest Africa, and is likely to have increase wind stress, as observed during the last two
311 climatic cycles (Jullien et al., 2007; Tisserand et al., 2009; Matsuzaki et al., 2011). Increasing
312 values of dust content are consistent with these changes (Fig. 4). The hypothesis proposed by
313 Raymo et al. (1997) seems to be supported by our Mauritanian margin record. Indeed, an
314 extension of the arid belt associated with stronger winds blowing westward over the African
315 continent might have increased the input from a depleted ^{13}C carbon reservoir into the ocean,
316 contributing to the general lower $\delta^{13}\text{C}$ benthic values.

317 A putative atmospheric circulation change during the MPT, associated with a
318 southward shift in the migration pattern of the ITCZ, may have directly impacted the local
319 oceanic environment, and thus the benthic $\delta^{13}\text{C}$ signature. Today, strong upwelling takes

320 place on the Mauritanian margin, which affects surface $\delta^{13}\text{C}$ values of dissolved inorganic
321 carbon via stronger productivity (Mackensen and Bickert, 1999). Although core MD03-2705
322 is not located directly within the upwelling cells, some filaments of upwelled nutrient-
323 enriched waters could reach our site, during specific periods (Matsuzaki et al., 2011). In the
324 context of sea-level falls during glacial periods, the geographic influence of upwelled waters,
325 due to the westward Ekman deviation of the Canary Current, might have shifted offshore
326 toward the outer shelf and upper slope (Bertrand et al., 1996), moving the productive areas
327 off-shore as well (Martinez et al., 1996). In addition, stronger westward winds could have
328 increased the strength of the upwelling, increasing the phytoplankton productivity. *U.*
329 *peregrina* generally appears more abundant during glacial periods such as MIS 30, 28 and 26
330 when Ti content is also higher (Fig. 6). This is similar to what has been observed for the late
331 quaternary in the South Atlantic Ocean by Schmiedl and Mackensen (1997). This increase in
332 the amount of *U. peregrina* reflects higher oceanic productivity during MIS 30, 28 and 26 that
333 could be associated with a more vigorous upwelling due to stronger winds blowing from the
334 east. The later peak of *U. peregrina* (Fig. 6f) occurring during MIS 28 is most probably
335 related to enhanced fertilization of surface water by volcanic ashes found during this interval
336 (confirmed by magnetic susceptibility) rather than upwelling intensity. Meanwhile, no clear
337 changes are observed while entering into colder glacial periods within the MPT (e.g. MIS 24).
338 The direct influence of lower sea level on the paleoproductivity at the MD 03-2705 core site
339 is therefore uncertain. To further investigate the possible changes and transfer of the carbon
340 isotopic signal from the surface to the deep water, future work should focus on the isotopic
341 and elemental characterization of the thermocline layer. A $\delta^{13}\text{C}$ record of different planktonic
342 foraminifera species of core MD03-2705 is required to test this hypothesis.

343 The contribution of the West African margin aridity alone would obviously be too
344 small to affect the global signature of the whole oceanic deep waters. Meanwhile, other paleo-
345 records help to extent such hypothesis to the rest of the African continent. For the Benguela
346 basin (ODP 1084) along the south tropical Atlantic African coast, intensification of the
347 upwelling cells has been observed during the MPT, and linked with the aridification of the
348 African continent (Marlow et al., 2000). In the Angola basin (ODP 1075), vegetation changes
349 of the African continent have been recorded as early as 1.05 Ma (Dupont et al., 2001). For a
350 neighbouring core, a record of African C4 plant abundance, derived from compound-specific
351 carbon isotope analysis of wind-transported terrigenous plant waxes, confirms some changes
352 in the atmospheric moisture content during the MPT (Fig. 6) (Scheffuß et al., 2003). The

353 abundance of C4 plants, found predominantly in tropical savannahs and semi-deserts, seems
354 to be directly linked with the sea surface temperature record and the atmospheric moisture
355 content. The establishment and persistence of C4 grassland around 0.9 Ma has been explained
356 by a large-scale aridification of the African continent during this time period (Schefuß et al.,
357 2003). Despite uncertainties linked to different age scales, increases in C4 percentage in
358 marine core ODP1077 in the Angola basin seem to be in phase with wind-strengthening
359 proxies (Ti and Quartz counts) in core MD03-2705 off the Mauritanian margin (Fig. 6). The
360 hypothesis of a southward shift of the ITCZ, leading to aridification and erosion of previously
361 moist areas, is in agreement with the absence of any typical arid markers within the clay
362 mineral association in our record. Indeed African arid sources provide fibrous clay minerals
363 as palygorskite or sepiolite (Bout-Roumazelles et al., 2007; Jullien et al., 2007) that are not
364 particularly abundant over the MPT.

365

366 *The carbon isotopic MPT depletion—a response to an increase in global aridity?*

367 As discussed previously, an expansion of the mean global ice volume could have
368 occurred for each successive glacial interval within the MPT time interval, dragging a
369 perennial polar front southward. This latitudinal shift might have forced the southward
370 migration of NADW convection centers, reducing the convection efficiency, as is observed
371 for recent glacial periods. The subsequent change in the latitudinal distribution of deep-water
372 masses would have impacted the $\delta^{13}\text{C}$ benthic record in core MD03-2705, assuming that the
373 deep-water masses are characterized by a unique isotopic signature (high $\delta^{13}\text{C}$ and low $\delta^{18}\text{O}$
374 for NADW, and low $\delta^{13}\text{C}$ and high $\delta^{18}\text{O}$ for SOW). The reduction of NADW formation
375 during each successive glacial interval within the MPT might have allowed the northward
376 penetration of the SOW from 1.0 to 0.8 Ma, producing noticeable $\delta^{13}\text{C}$ depletion, along with a
377 $\delta^{18}\text{O}$ enrichment in the MD03-2705 benthic isotopic record. While such shift is clearly
378 observed in the glacial benthic $\delta^{13}\text{C}$ values from MIS 30 to MIS 24 (Fig. 2), only a slight
379 amplitude change appears in the glacial benthic $\delta^{18}\text{O}$ values for the same time interval. The
380 strongest $\delta^{18}\text{O}$ -enriched value occurs during MIS 22 and MIS 16 (Fig. 2), while the $\delta^{13}\text{C}$
381 benthic value does not present low values during MIS 16, for example. Such discrepancies
382 appear clearly in the X–Y isotopic plot (Fig. 3), in which the post-MPT glacial cluster (MIS
383 24–20) lays far apart from the two end-members mixing line. As long as the most drastic
384 amplitude changes between each MPT glacial periods are not in phase in both isotopic records
385 of the same core, the validity of the hypothesis involving modification in the deep-water

386 masses distribution along the successive MPT glacial interval is doubtful. Meanwhile, such
387 discussion stands for glacial periods only, the role of circulation changes across glacial-
388 interglacial transitions staying undisputed. From our data, we argue that the depletion in the
389 $\delta^{13}\text{C}$ benthic record of core MD03-2705, observed for the successive MPT glacial interval,
390 could partly be the consequence of a global atmospheric change and its impact on the
391 terrestrial carbon budget. However, more high-latitude benthic records covering the MPT
392 time interval are needed for confirmation.

393 The ‘aridity hypothesis’ proposed by Raymo et al. (1997) still needs to be tested for
394 other continents. Indeed, the decrease in carbon isotope values has been observed on a global
395 scale, in each deep ocean basin. For the past 0.80 Ma, a clear link can be observed between
396 global aridification as suggested by atmospheric dust content recovered from the Dome C ice
397 core record (EPICA community members, 2004) and our $\delta^{13}\text{C}$ benthic record. For each glacial
398 period of increased dust content in the Antarctic ice, a depletion in the $\delta^{13}\text{C}$ benthic record is
399 observed in core MD03-2705 (Fig. 5). Meanwhile, no such global record of atmospheric dust
400 exists for the period prior to 0.8 Ma. Some paleo-records of the East Asian Monsoon extend
401 back one million years. These records are extracted from two red-clay and loess palaeosol
402 sequences observed on the Chinese Loess Plateau (Sun et al., 2006), and are plotted in
403 Figures 5 and 6 along with MD03-2705 records. In the continental Asian records, magnetic
404 susceptibility is believed to represent amplitude and frequency of the eastern Asian summer
405 monsoon. The mean grain size of the Chinese loess, which principally reflects the wind
406 intensity, has been interpreted as a proxy for the intensity of monsoon circulation and aridity
407 in sources area of dust (Xiao et al., 1992). Over the MPT, an increase in the mean grain size is
408 observed for glacial periods MIS 22 and 24, in phase with aridity proxies from the Angola
409 basin (ODP1077) or with wind-strength proxies in the Mauritanian margin (MD03-2705)
410 (Fig. 6). Within the different timescale uncertainties linked to each of these palaeoclimatic
411 records, eastern Asian Monsoon proxies suggest an enhanced winter monsoon activity
412 (coarser grain size) during the MPT, while the summer monsoon is weak (Fig. 5). Such a
413 configuration might have enhanced the aridity over the Asian continent, leading to the same
414 impact over the ocean, i.e. an input from a ^{13}C depleted carbon reservoir into the ocean. The
415 eastern Asian continental aridity (which mainly impacts the Pacific deep waters) reveals the
416 same response when compared to the African continent aridity (which mainly impacts the
417 Atlantic deep waters), and both might have thus triggered similar consequences on the mean
418 deep-water carbon isotopic composition.

419

420 **Conclusions**

421 Multiproxy analysis of a marine core off the Mauritanian margin has allowed for
422 reconstruction of variations in atmospheric and oceanic dynamics during the last 1.1 Ma. Ti
423 and Quartz contents show past variations in African continental aridity, in agreement with the
424 aeolian terrigenous particle concentration. Within the MPT, an increase of these proxies
425 during consecutive glacial periods (MIS 26, 24 and 22) suggests enhanced aridity over the
426 African continent. These results are consistent with evidence for aridification throughout the
427 African continent, found in the Benguela basin (Marlow et al., 2000) or in the Angola basin
428 (Scheffuß et al., 2003). These terrestrial environmental changes correspond to shifts in the
429 deep ocean carbon isotopic composition, with benthic $\delta^{13}\text{C}$ minima during the same glacial
430 periods. The proposed link calls for a larger input from the continental ^{13}C depleted carbon
431 reservoir into the ocean as the result of the extension of C4 vegetation in the arid latitudinal
432 band in Northwest Africa (due to a southern shift of the ITCZ), and facilitated by stronger
433 winds. While the contribution of the West African increased aridity is probably too small to
434 imprint the global deep-water carbon isotopic signature (as also indicated by the phase lag
435 relationship between our terrigenous and $\delta^{13}\text{C}$ records), it is likely indicative of a global
436 aridification phenomenon that may have taken place during the MPT.

437 Similar shifts in the benthic $\delta^{13}\text{C}$ have been observed in deep marine cores from
438 different oceans, during the MPT, highlighting the global aspect of such changes. While the
439 $\delta^{18}\text{O}$ benthic enrichment expresses the building of bigger continental ice sheets over the high
440 latitudes continents (moving from a '41 ka' climatic cycle world to the '100 ka world'), the
441 $\delta^{13}\text{C}$ benthic depletion has been hypothetically linked with global aridity changes (Raymo et
442 al., 1997). On a global scale, we compare our African record with the continental loess record
443 from Asia. For the same time interval, the Asian continent displayed an increased winter
444 monsoon while the summer monsoon remained weak. Such a configuration is likely to have
445 resulted in increased wind strength and aridity over the Asian continent. These two records
446 therefore support Raymo et al.'s (1997) hypothesis of a worldwide input of carbon from the
447 terrestrial biosphere reservoir into the ocean in order to account for the global deep-water
448 carbon isotopic composition change during the MTP.

449 In the future, global circulation model runs could help to define the role of
450 atmospheric dynamics during the MPT, and more precisely, test the hypothesis of a shifting
451 ITCZ associated with the cold glacial stages of the MPT (Kageyama et al., 2009).

629

631
 632 Figure 1. Cross sectional maps of the Atlantic ocean. Location of cores MD03-2705 (this
 633 study), ODP 664 (Raymo et al., 1997) and ODP1077 (Dupont et al., 2001; Schefuß et al.,
 634 2003) and carbon isotopic values ($\delta^{13}C$) of water masses.

635

636

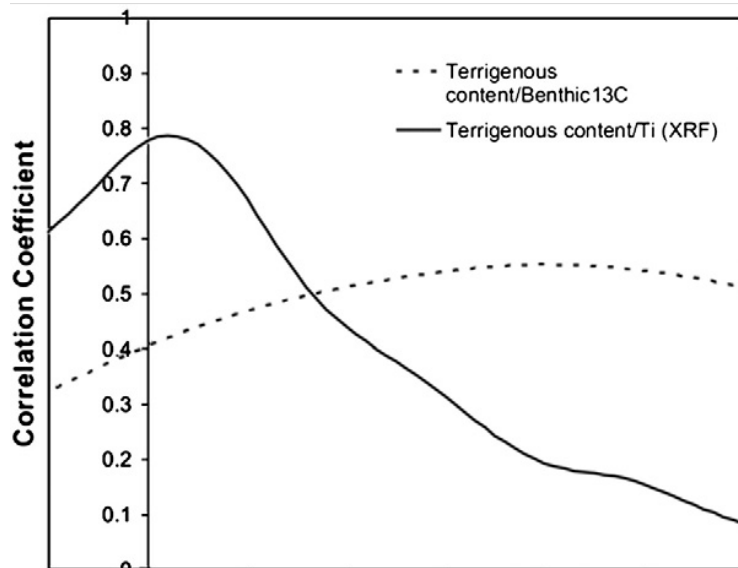

637 Figure 2. (a) Ti qualitative content (XRF) in core MD03-2705; (b) Terrigenous content
 638 approximation in core MD03-2705; (c) Benthic $\delta^{13}\text{C}$ record in core MD03-2705; (d)
 639 sedimentation rate in core MD03-2705; (e) Benthic $\delta^{18}\text{O}$ record in core MD03-2705. (f)
 640 Benthic $\delta^{18}\text{O}$ record from LR04 stack (Lisiecki and Raymo, 2005). Main paleomagnetic
 641 horizons are marked (B/M: Bruhnes-Matuyama, Jup: upper Jaramillo, Jlow: lower Jaramillo).

642

643

644 Figure 3. Isotopic composition of deep-water masses. Crosses and stars (red and pink)
 645 represent interglacial periods. Diamonds and circles (blue and green) represent glacial
 646 periods. We have distinguished between recent glacial periods, from MIS 2–16 (clear blue
 647 circles), oldest glacial periods (blue diamonds: MIS 28–32, and plain green circles: MIS 20–
 648 24), as well as recent interglacial intervals, from MIS 3–17 (crosses) and oldest interglacials
 649 (red bold stars: MIS 29–33 and pink stars: MIS 19–23) as discussed in text. Black arrows
 650 represent evolution from older time periods to younger ones. Black triangles present the
 651 modern isotopic composition of NADW and of a southern water mass which isotopic
 652 composition could be associated to a ‘SOW-like’ end-member.

653

654 Figure 4. Correlation as a function of lag (years) for the interval 700-1100 kyrs between the
 655 terrigenous content and the benthic $\delta^{13}\text{C}$ records (dash line) and between the terrigenous
 656 content and Titanium (Ti) measurement with the XRF core scanner records (plain line).
 657 Maximum correlation (0.55) are achieved for a 4000-year lead of terrigenous content vs
 658 benthic $\delta^{13}\text{C}$. Maximum correlation (0.79) indicate a quasi-in phase relationship between
 659 terrigenous content and Titanium (Ti) measurement with the XRF core scanner.

660

661

662 Figure 5. (a) Dust content in Dome C ice Core (Antarctica) (Epica community members,
 663 2004); (b) Magnetic susceptibility of East Asian Loess (Summer monsoon proxy) (Sun et al.,
 664 2006); (c) Mean grain size composition of East Asian Loess (Winter monsoon proxy) (Sun et
 665 al., 2006); (d) Ti qualitative content in core MD03-2705 (aridity proxy); (e) Sedimentation rate
 666 in core MD03-2705; (f) $\delta^{13}\text{C}$ benthic record from core MD03-2705; (g) Benthic $\delta^{13}\text{C}$ record
 667 for core MD03-2705.

668

669

670 Figure 6. Zoom on the MPT:(a) C4 plant percentage of n-C31 alkanes (%) from the Angola
 671 basin (ODP 1077) (Scheffuß et al., 2003)(b) Mean grain size composition of East Asian Loess
 672 (Winter monsoon proxy) (Sun et al., 2006)(c) Ti qualitative content in core MD03-2705
 673 (aridity proxy);(d) Quartz content in core MD03-2705;(e) $\delta^{13}\text{C}$ benthic record from core
 674 MD03-2705;(f) Benthic foraminiferal analysis in core MD03-2705. BFN (black line) and
 675 *Uvigerina peregrina* (grey area), indicating higher paleoproductivity for high values.(g)
 676 Benthic $\delta^{18}\text{O}$ record for record core MD03-2705.The vertical grey band highlights the
 677 volcanic ash layer found in core MD03-2705.

678

679 Table 1

680 Glacial and interglacial intervals, together with their mean isotopic values.

M.L.S.	Depth (cmbst)	Age (cal.) ka B.P.	$\delta^{18}\text{O}$ mean value (‰)	$\delta^{13}\text{C}$ mean value (‰)
1	0 - 28	0 - 10.07	2.480	0.961
