1 **ABSTRACT**

2 **Aims:** To develop an automated deep-learning-based whole heart segmentation of ECG-gated
3 computed tomography data.

4 **Methods:** After 21 exclusions, CT acquired before transcatheter aortic valve implantation in
5 71 patients were reviewed and randomly split in a training (n=55 patients), validation (n=8
6 patients), and a test set (n=8 patients). A fully automatic deep-learning method combining two
7 convolutional neural networks performed segmentation of 10 cardiovascular structures, which
8 was compared with the manually segmented reference by the Dice index. Correlations and
9 agreement between myocardial volumes and mass were assessed.

10 **Results:** The algorithm demonstrated high accuracy (Dice score=0.920; interquartile range:
11 0.906-0.925), and a low computing time (13.4 sec, range 11.9-14.9). Correlations and
12 agreement of volumes and mass were satisfactory for most structures. Six of ten structures
13 were well segmented.

14 **Conclusion:** Deep-learning-based method allowed automated WHS from ECG-gated CT data
15 with a high accuracy. Challenges remain to improve right-sided structures segmentation and
16 achieve daily clinical application.

1 INTRODUCTION

2 Tridimensional (3D) cardiac imaging has emerged as a cornerstone in the evaluation
3 and the management of patients in contemporary cardiology. As the number of procedures
4 dedicated to the treatment of a variety of arrhythmias or structural heart diseases is
5 exponentially growing [1-7], 3D cardiac imaging, providing a precise anatomic description of
6 cardiothoracic structures, now plays a crucial role in patients selection and procedural
7 planning[8-11]. Manually obtaining an accurate anatomic description of the heart and
8 surrounding structures may be a tedious task, and may suffer from reproducibility issues[12],
9 which highlights the challenges posed by whole heart segmentation (WHS).

10 Recently, artificial intelligence (AI) has also established itself as an appealing tool in
11 the analysis of multiple functional and anatomic parameters from imaging data[13-16].
12 Allowing user-free processes and high reproducibility, it appears promising for procedural
13 planning, when a description of each cardiac chamber and structure is required. Several works
14 evaluating WHS from computed tomography (CT) imaging have already been performed[17-
15 21]. However, some of these studies were based on multi-atlas segmentation, which seems to
16 be less accurate and more time consuming than deep-learning-based methods [20].
17 Furthermore, owing to the computing power required for the algorithms, to date none of the
18 previously published work integrated the automatic segmentation process in a readily useable
19 and standalone software, which may impede the use of these methods in daily practice,
20 despite the good results reported in these studies.

21 In the present work, we developed and validated a deep-learning-based WHS
22 segmentation process from a dedicated CT database, which was fully integrated in a routinely
23 used procedural planning software.

24

25 METHODS

1 **Data acquisition**

2 Imaging data used in the present work were ECG-gated CT performed during the pre-
3 procedural work-up of patients undergoing transcatheter aortic valve implantation (TAVI) at
4 our institution. CT of consecutive TAVI recipients between May and September 2019 were
5 analyzed. Exclusion criteria were image quality not allowing precise manual segmentation of
6 the structures of interest, either because of artifacts or poor image contrast, which was
7 assessed by the expert physician performing manual segmentation, and patients with prior
8 surgical aortic valve replacement or TAVI. All patients gave written informed consent for the
9 procedures and anonymous collection of their data, which were prospectively gathered in an
10 electronic database as part of a national registry[3]. The present study was not pre-specified,
11 observational and retrospective. Thus, the institutional review board waived specific consent
12 for this study.

13

14 **CT acquisition protocol**

15 All patients underwent a cardiac CT scan for the procedural planning of TAVI
16 according to established consensus[8]. CT scan was performed on a third generation dual-
17 source CT scanner (SOMATOM Force, Siemens Healthcare, Forchheim, Germany). No
18 systematic intravenous beta-blocker was used before CT scan. A prospective ECG-triggered
19 high-pitch CT angiography extending from the carotid to the femoral arteries was performed
20 during a single breath-hold. ECG gating was set on end-systole (30% interval of the cardiac
21 cycle) and activated to trigger the acquisition on cardiac volume only. Acquisition parameters
22 were: collimation 192×0.6 mm, gantry rotation time 250 ms, fixed tube voltage 100 kV,
23 current-time product ranging from 342-604 mAs, spiral pitch factor 3.2. A bolus of 90 mL of
24 iobiditridol (Xenetix 300, Guerbet, Roissy, France) was injected at 4 mL/s, followed by a 40-
25 mL saline chaser bolus. An automated bolus tracking system was used to synchronize the

1 arrival of the contrast material with the initiation of the scan. Cardiac dataset was
2 reconstructed using a 181 mm FOV, a 512x512 matrix, a Bv40 kernel and iterative
3 reconstruction technique (Admire level 3, Siemens).

4

5 **CT manual segmentation protocol**

6 For each CT, an expert interventional cardiologist with a cardiac imaging degree and
7 extensive experience in the field of cardiac CT and TAVR performed a manual segmentation
8 of the heart and surroundings large vessels using the Endosize© software (Therenva, Rennes,
9 France) a CE- and FDA-marked medical device for planning and sizing of endovascular
10 procedures[22]. The following ten structures were segmented: pulmonary veins (PV), left
11 atrium (LA), left ventricular cavity (LVC), left ventricular myocardium (LVM), aorta (Ao),
12 coronary sinus (CS), superior vena cava (SVC), right atrium (RA), right ventricular cavity
13 (RVC), pulmonary artery (PA). The segmentation method of the different elements has been
14 previously described[20,23-25]. LA and RA segmentation included the appendage. For the
15 left ventricular myocardium, considering the end-systolic phase acquired, the frequent LV
16 hypertrophy among TAVI recipients, and the procedural planning perspective of our work, we
17 decided to include the mains papillary muscles, i.e. exclude them from the cavity. The
18 different cavities were delineated by identifying the endocardial border[21]. LVM mass was
19 calculated as the left ventricular myocardial volume derived by the delineation of its
20 endocardial and epicardial borders and multiplied with the specific gravity of myocardial
21 tissue (assuming a tissue density of 1.05 g/ml)[26]. These segmentations were considered as
22 the reference ground-truth for our deep-learning model.

23

24 **CT automatic segmentation protocol**

1 The automatic deep-learning-based WHS segmentation process was divided into two
2 distinct stages: a localization step, which automatically selects the aortic valve to generate the
3 region of interest (ROI) in the CT volume, and the segmentation step.

4 In the present study, the localization step was performed by using a regression Convolutional
5 Neural Network (CNN[27]) based on the SqueezeNet architecture. In contrast with
6 classification approaches, during which CNNs detect the presence or absence of anatomical
7 target structures in each of the orthogonal viewing planes independently and then combine
8 them to obtain the coordinates of each landmark, here the distance (in mm) between the
9 current slice and the slice belonging to the anatomical structure is used. After parsing the
10 entire volume, distances can be converted to parabolic curves using polynomial regression,
11 where the minimum is searched for each axis. The center of the aortic valve (defined as the
12 intersections of the three commissures) was defined as the anatomical landmark to be found.

13 3D images were converted into three sets of 2D images for the axial, sagittal and coronal axis,
14 respectively, and preprocessed with cropping and padding operations. For each axis, a
15 regression CNN was trained with the 2D image slice as input. Specifically, the VGG-16 CNN
16 architecture[28] was adapted to output quantitative values by modifying the softmax loss
17 layer with a Euclidean loss layer. All other weights were initialized from pre-training on the
18 ImageNet database (accessed at <http://www.image-net.org>). The three networks were trained
19 separately and did not share weights. Convergence was obtained after 100 epochs. Following
20 this approach, the exact position of the aortic valve was estimated. After this automatic
21 detection of the aortic valve, in the segmentation step, 3D data were resized to a 320x320x320
22 ROI and resampled to 0.7x0.7x1 mm by voxel to include all structures of interest. These
23 preprocessed volumes were then used as the input dataset of the Dense V-Net 3D
24 segmentation CNN[29]. Briefly, the volume is cropped into voxels batches and a succession
25 of convolutional 3D 3x3x3 kernels, dense connections, and batches normalizations are

1 applied to extract 3D spatial information from each batch. The resultant feature maps are then
2 down-sampled by 2 and the operation is repeated 3 times. At the end, the feature maps are up-
3 sampled to the original resolution and a softmax layer gives the result class for each voxel.
4 Adam optimizer was preferred for training with an initial learning rate of 0.001, along with a
5 loss combining the dice and cross-entropy coefficients. The output of the network is directly a
6 3D mask with one label for each structure. The network was trained for 300 epochs during 6
7 days on a Nvidia RTX 2070 GPU. The Niftynet open-source framework (<https://niftynet.io/>)
8 was used for the training and the validation of the network. The complete workflow of the
9 segmentation process is illustrated in the **Central Illustration**.

10

11 **CT automatic segmentation testing**

12 The dataset was randomly split in a training set (n=55 patients, 17 600 slices), a validation set
13 (n=8 patients, 2560 slices), and a test set (n=8 patients, 2560 slices). For testing purposes, the
14 segmentation method was integrated in the Endosize® software (Therenva, Rennes, France).
15 The automatic segmentations in the test set were obtained directly from this routinely used
16 software using a standard 2GHz workstation with 2GB of RAM to evaluate the clinical
17 applicability of our method.

18 WHS obtained using the deep-learning approach were compared with the manually
19 segmented reference from the test set. The image-based performance metric was the Dice
20 index[30]. Dice similarity score quantifies the voxel-wise degree of similarity between the
21 model predicted segmentation mask and the ground truth, and ranges from 0 (no similarity) to
22 1 (identical). Mathematically, it can be expressed as follows:

$$23 \text{ Dice similarity coefficient} = \frac{(2 \cdot \text{true Positive})}{(2 \cdot \text{True Positive} + \text{False Positive} + \text{False Negative})}$$

24

25 **Statistical analysis**

1 Continuous variables are presented as mean \pm standard deviation or median (interquartile
2 [IQR] or full range) depending on their distribution, which was assessed using the Shapiro-
3 Wilk test. Categorical variables were summarized as numbers (percentages). Dice scores were
4 summarized as medians and quartiles. Comparisons between groups were performed with the
5 use of the Kruskal-Wallis and the Fisher exact test for continuous and categorical variables,
6 respectively. Levels of agreement between the automatic and manual segmentation were
7 assessed on the test set with the Bland–Altman difference against mean plot. Pearson
8 correlation coefficients of volumes between the manual reference and automatic prediction
9 were also evaluated. Volumes measured by the automatic segmentation were compared with
10 the manual segmentation results using the Wilcoxon’s signed rank test. Statistical analyses
11 were conducted using the Statistical Package for Social Sciences version 25 (SPSS Inc., IBM,
12 Armonk, New York).

13

14 **RESULTS**

15 **Population**

16 Between May 15 and September 4 2019, 107 consecutive patients underwent TAVI
17 at our institution. Among them, nine had a history of aortic valve replacement whereas 21 had
18 poor-image quality on their pre-procedural CT, and were excluded (**Supplemental figure 1**).
19 Moreover, the CT of six patients were successfully manually-segmented but presented
20 technical issues (mainly important motion artifacts in five patients), which precluded their
21 analysis by the deep-learning-based algorithm. Therefore, these patients were excluded from
22 the study population leaving 71 patients for analysis. Baseline characteristics of included
23 patients are described in **Table 1**. Patients from the training and validation sets were
24 comparable to patients from the test set at the exception of a lower body surface area in the

1 test set. The 3D imaging dataset consisted of 2.064 billion voxels, i.e. 32.768 million voxels
2 per volume.

3

4 **Manual and automatic deep-learning-based segmentations**

5 Manual segmentations of the ten labels took a median of 90 min/patient (range: 57 min
6 to 153 min). The performance and results of a manual segmentation are illustrated in **Figure**
7 **1**.

8 The aortic valve position was detected in less than 2s in a standard workstation thanks
9 to the multi-resolution search scheme for each axis. Automatic segmentations of the ten labels
10 took a median of 13.4 sec (range: 11.9 sec to 14.9 sec) on a standard 2GHz computer with
11 2GB of RAM in the test set.

12

13 **Validation of the automatic deep-learning-based segmentation**

14 The combined overall Dice index for the 10 labels was 0.920 (IQR: 0.906-0.925). The
15 median Dice scores for Ao, CS, LA, LVC, LVM, PA, PV, RA, RVC, SVC were 0.915 (IQR:
16 0.902-0.930), 0.604 (IQR: 0.516-0.652), 0.939 (IQR: 0.933-0.941), 0.852 (IQR: 0.793-0.867),
17 0.927 (IQR: 0.923-0.940), 0.878 (IQR:0.865-0.888), 0.657 (IQR: 0.594-0.712), 0.877 (IQR:
18 0.816-0.901), 0.819 (IQR:0.763-0.862), and 0.627 (0.408-0.659), respectively (**Table 2**,
19 **Figure 2**). Bland-Altman and linear regression plots are shown (**Figure 3**), with the mean
20 difference and limits of agreement between the manual reference and automatic prediction for
21 Ao, CS, LA, LVC, LVM, PA, PV, RA, RVC, SVC being -0.41ml (95% confidence interval
22 [CI]: -20.6 to 19.7), -0.40ml (95%CI: -1.56 to 0.76), -1.07ml (95%CI: -10.4 to 8.2), -6.63ml
23 (96%CI: -16.2 to 2.9), -1.76g (95%CI: -9.5 to 6.0), 0.53ml (95%CI:-9.0 to 10.1), -4.67 ml
24 (95%CI: -9.68 to 0.35), -0.76 ml (95%CI: -14.6 to 13.1), -8.17ml (95%CI: -18.0 to 1.6), and
25 2.51 ml (95%CI: -9.9 to 14.9), respectively. **Table 3** summarizes manual and automatic

1 volumes and mass measurements. The automatic segmentation predictions correlated poorly
2 with the manual reference for SVC ($r=0.49$, $p=0.27$), marginally better for CS ($r=0.77$,
3 $p=0.02$), and significantly better for all other structures. Correlation coefficients were 0.97
4 ($p<0.001$) for Ao, 0.98 ($p<0.001$) for LA, 0.99 ($p<0.001$) for LVC, 0.99 ($p<0.001$) for LVM,
5 0.96 ($p<0.001$) for PA, 0.90 ($p=0.002$) for PV, 0.95 ($p<0.001$) for RA, and 0.98 ($p<0.001$) for
6 RVC (**Figure 3**).

7

8 **DISCUSSION**

9 In the present study, we proposed a deep-learning-based method allowing fast and
10 automated WHS from ECG-gated CT data of TAVI candidates. The chief findings of the
11 present study are as follows: 1) the proposed deep-learning-based model displayed an overall
12 high level of accuracy with a Dice score of 0.92. 2) There were discrepancies in the model's
13 accuracy according to the considered structure. Especially automatic segmentation of CS, PV
14 and SVC were less accurate. 3) The automatic segmentation and manually obtained reference
15 of volumes and mass correlated and agreed well for most structures. 4) The computing time of
16 the model, fully integrated in a standalone routinely used software, was very limited (median:
17 13.4s) which represents a first step towards a potential implementation in routine practice.

18 WHS remains a challenging task for which emerging deep-learning methods appear as
19 innovative and appealing tools, especially from a computational cost standpoint, compared
20 with previously described methods[12,17,20]. Zhuang et al. reported the results of a
21 worldwide challenge of multimodality WHS[20]. In this work, twelve algorithms from twelve
22 different teams were evaluated for the automatic segmentation of seven cardiac structures
23 (Ao, LA, LVC, LVM, PA, RA, and RVC) from CT and magnetic resonance imaging data. For
24 the CT dataset, composed of 60 cardiac CT volumes with only 20 for training, the best Dice
25 score was 0.908 ± 0.086 and was obtained with a mean 104s computing time on an Intel i7-

1 4820K 32GB CPU with a Nvidia GTX TITAN X 12GB GPU. Similarly to the proposed
2 model in the present work, the best algorithm in this challenge used two separate CNNs to
3 first localize the ROI in the volume and then perform the pixel-wise segmentation using a
4 volumetric kernels equipped 3D CNN. Another interesting contribution to the field recently
5 came from Baskaran et al. who trained, validated and tested in a 70:20:10 split dataset of 166
6 CT, a U-Net-inspired, deep-learning model[21]. The authors identified five cardiac structures:
7 LA, LVC, LVM, RA, RV. They reported an overall Dice score of 0.925 (IQR: 0.887 to 0.948)
8 for the identification of these structures by their model with Dice score for LA, LVC, LVM,
9 RA, RV being 0.934, 0.938, 0.920, 0.915, and 0.927, respectively. They demonstrated a good
10 correlation and agreement between volumes and mass predicted by the model compared with
11 their manual ground-truth in a test set encompassing 17 patients with 1477 images. The mean
12 computing time was 13.13 s/patient but the authors did not report the characteristics of the
13 workstation they used for this work. In the present study, we attempted to increase the number
14 of substructures segmented by adding surroundings vessels (Ao, CS, PA, PV, and SVC)
15 considering their potential usefulness for the procedural planning of structural interventions.
16 Our overall Dice score of 0.920 (IQR: 0.906-0.925) is comparable with values reported in
17 these previously published state-of-the-art works. Nonetheless, we demonstrated significant
18 discrepancies according to the segmented structures, i.e. the model was not sufficiently
19 accurate for small structures such as CS, PV and SVC, and was marginally less accurate for
20 right-sided structures and the LVC. Several reasons may explain these observations. First, we
21 used CT data obtained during the pre-procedural work-up of TAVI recipients, for which
22 acquisition parameters intend to optimize the contrast in the aorta and peripheral vascular
23 structures. This may explain the sub-optimal results obtained for right-sided structures.
24 Similarly, mixing of the non-contrasted blood from the inferior vena cava and the contrast-
25 saturated blood from the SVC results in an inhomogeneous enhancement of the RA and beam

1 hardening artifacts, which contribute to a decreased visualization of surrounding structures
2 (CS, SVC, RVC). Second, our TAVI recipients population was older and likely sicker than
3 the population of Baskaran et al, which was in average 20 years younger. Interestingly,
4 Baskaran et al. reported worse prediction for the LVC in patients older than 65 years[21]. As
5 we wanted to evaluate the feasibility of automatic WHS in routine practice, in contrast with
6 this previous study, we did not exclude patients with elevated heart rate or atrial fibrillation.
7 As expected among TAVI candidates, more than one-fourth of our population suffered from
8 atrial fibrillation, which negatively affects CT images quality and is a known contributor to
9 sub-optimal results of deep-learning-based WHS[20]. Furthermore, one-fifth of our
10 population harbored chronic pulmonary diseases, which may also affect image quality,
11 especially among patients who cannot sufficiently stand apnea. Despite these limitations, we
12 believe that the population of the present study accurately represents current structural heart
13 interventions candidates therefore allowing a precise evaluation of the potential clinical
14 impact of our model. Third, regarding LVC, we elected to include the papillary muscles into
15 the LVM label in contrast with previous studies[20,21] and usual echocardiography
16 guidelines[23], yet in line with magnetic resonance imaging measurements guidelines[24].
17 The interventional perspective we have set our work in motivated this choice. Indeed,
18 accurate knowledge of any obstacle operators could meet when maneuvering or deploying a
19 device into a cardiac chamber may be crucial to the procedural success. Thus, it makes sense
20 to consider the main papillary muscles as myocardium to provide an appropriate description
21 of the LVM shape and mass. From a segmentation standpoint, it likely complicated the
22 automatic delineation of the LVC border, which was far less predictable than when papillary
23 muscles are included in the LVC. In keeping with this point, CT data of the present study
24 were acquired in systole, in patients with varying degrees of cardiac remodeling induced by
25 their aortic stenosis, which may have resulted in different patterns of left ventricular

1 hypertrophy, heterogeneously affecting the global geometry of LVC. These elements might
2 have significantly participated in degrading the results of the automatic WHS explaining the
3 lower Dice score values observed for LVC in the present study. However, on the contrary, a
4 segmentation based on image density as the present one may be easier when the papillary
5 muscles are not considered as a part of the ventricular cavity. Moreover, the systolic
6 acquisition resulted in a lower LVC volume involving a reduced number of voxels. Therefore,
7 any small difference between the manual and deep-learning-based segmentation has larger
8 consequences upon the Dice score measurement than those expected from the measurement of
9 LVC in a diastolic phase. This size consideration also apply for other small structures such as
10 CS or PV. Fourth, regarding the PV, they usually exhibit a large degree of anatomical
11 variation from one patient to another[31], which may explain the sub-optimal performance of
12 our model to identify these structures.

13 Nevertheless, we reported excellent correlations between manually obtained and deep-
14 learning predicted volumes for most structures. Although, statistically significant absolute
15 differences in volume measurement for the LVC, PV and RVC were observed, the mean
16 differences of measurement for all structures were low and would likely be clinically
17 irrelevant. It is noticeable that the small size of our test set makes it vulnerable to the presence
18 of outliers. However, the width of the 95% CI of the limits of agreement in the present study
19 are in the range of those reported by Baskaran et al., which were themselves comparable or
20 markedly lower than previously-reported limits of agreement in deep-learning studies[21].

21 Clinical applicability of these deep-learning-based segmentation methods is crucial to
22 whether they are to ultimately achieve widespread use. To the best of our knowledge, no
23 recently published papers have mentioned the integration of such work in a readily useable
24 system. Indeed, to provide optimal results, most of the published algorithms require powerful
25 computing hardwares[20], which may not represent the majority of workstations available in

1 the current daily medical environment. Before the advent of deep learning approaches,
2 computation times were never below 10min. Using a dedicated hardware, Baskaran et al.
3 reported an impressive processing time of 13s/patient[21]. Furthermore the mean computing
4 time of the ten algorithms from the work by Zhuang et al. was also rather low at 312s (range:
5 0.22s to 21min, 104s for the most accurate model), with the use of dedicated workstations
6 with such powerful GPUs[20]. The median computing time of our algorithm was only 13.4s
7 on a routinely used workstation, i.e. not equipped with a powerful hardware dedicated to
8 research purposes. This point is of paramount importance for future clinical integration of the
9 method. The current quickness of the algorithm also suggests that further work may easily
10 achieve a refinement of the accuracy-computing time tradeoff, which would maximize the
11 former while keeping the latter in a range compatible with a minimal disruption of clinical
12 workflows. This good trade-off was achieved thanks to our two-stage segmentation process,
13 which had the benefit to keep relevant structures into a limited region of interest. With the
14 prior aortic valve localization, a high resolution can be kept for precise 3D segmentation
15 while restraining overall computation time into an acceptable range. The choice of the Dense
16 V-Net architecture was also driven by this objective, while other segmentation network
17 architectures (e.g. V-Net architecture) are recognized to be more precise but much more time
18 consuming.

19

20 **Limitations**

21 A number of this study's limitations have been discussed above. First, CT were
22 acquired during the pre-procedural work-up of TAVI recipients using a dedicated protocol in
23 accordance with an international expert consensus[8]. Whether the feasibility and
24 performance of our algorithm, especially for the identification of right-sided structures,
25 significantly differ according to the CT acquisition protocol or the underlying pathology will

1 be addressed by our future works on a larger, more diverse database. In keeping with this
2 point, this analysis was performed at a systolic phase in accordance with current guidelines
3 for the measurement of aortic annulus. Future works will also have to determine the
4 performances of our algorithm at a diastolic phase. Second, the training and validation sets of
5 63 patients encompassed a largely sufficient number of images to train a medical image deep-
6 learning system to reach high accuracy[32]. However, this choice of keeping a large amount
7 of data for model training limited the test set to 8 patients, which makes it vulnerable to
8 outliers and likely resulted in larger 95% CI for the limits of agreement between the automatic
9 and manual segmentations. Third, the manual segmentation was performed by a single expert.
10 Fourth, a significant proportion of patients were excluded from this “pilot” study because of
11 image quality, which precluded either manual or automatic segmentation, potentially raising
12 generalizability issues. Finally, the localization step uses the intersection of the three aortic
13 commissures to detect the center of the aortic valve, which may represent a limitation in case
14 of bicuspid aortic valves. However, it should be emphasized that the localization step of the
15 present algorithm is somewhat coarse, essentially used to crop an area of interest within the
16 entire volume. Thus, it is unlikely that this aspect of our algorithm played a significant role in
17 the results. Overall, this work is only the first step towards clinical application of our model.
18 Aside from improving the accuracy-computing time tradeoff, further identification of
19 structures such as cardiac valves remains a challenging task and an unmet need, which should
20 be overcome to increase our model applicability in this transcatheter therapies era.

21

22 **CONCLUSION**

23 We developed a deep-learning-based segmentation method, which was fully integrated in a
24 routinely used software supporting its potential clinical application. The method allowed fast,
25 automated WHS from ECG-gated CT data with an overall high accuracy on a voxel level, and

1 demonstrated excellent correlations and adequate agreements compared with manual
2 measurements for most segmented structures. However, further work is needed to improve
3 right-sided and small structures segmentation, as well as to include other structures of interest
4 (e.g. valves).
