Abstract

16 The abyssal ocean is broadly characterized by northward flow of the densest waters and
18 southward flow of lighter waters above. Understanding what controls the strength and structure
20 of these inter-hemispheric flows, referred to as the abyssal overturning circulation, is key to
22 quantifying the ocean's ability to store carbon and heat on timescales exceeding one century.
24 Here we show that, north of 32°S, the depth distribution of the seafloor compels dense southern-
origin waters to flow north below ~ 4 km depth and to return south predominantly deeper than
2.5 km. Unless ventilated from the north, the overlying mid-depths (1-2.5 km) host
comparatively weak mean meridional flow. Backed by a new analysis of historical radiocarbon
measurements, the findings imply that the geometry of the Pacific, Indian and Atlantic basins
places a major external constraint on the overturning structure.

26

Main text

28 Dense waters originating from the surface at high latitudes make up the overwhelming majority
30 of the ocean volume. Once formed through heat loss and salt gain, they sink to depth and spread
32 across the globe, carrying surface information into the slow-paced abyss and contributing to the
long memory of the ocean¹. But the memory time and climate buffering effect of the deep ocean
ultimately depend upon the rate at which these dense waters are removed from deep seas and
returned to the surface. Physical controls on the volume and return pathways of dense waters are
34 therefore key to the ocean's carbon and heat storage capacity and its role in centennial to multi-
millennial climate variability^{2,3}.

36 The cycle of production, modification and consumption of dense water masses is often
conceptualized as a meridional overturning circulation composed of two dynamically distinct
38 limbs^{4,5} (Fig. 1a): an abyssal, northward limb that carries the densest Antarctic-sourced waters
(Antarctic Bottom Water: AABW) until they upwell into lighter waters of the Indian, Pacific and
40 Atlantic basins; and a shallower, southward limb that carries these lighter deep waters to the
Southern Ocean. Because it involves a gradual decrease in the density of AABW, the abyssal
42 branch is considered to be essentially a diabatic circulation. In contrast, the southward flow of
overlying deep waters is thought to be predominantly adiabatic, that is, density-preserving^{6,7}. This
44 dynamical divide is consistent with the two regimes apparent in the deep ocean density
distribution (Fig. 1a): north of the Antarctic Circumpolar Current and away from polar sinking,
46 flat density surfaces above ~ 2.5 km depth appear compatible with an adiabatic arrangement of
water masses, whereas the northward descent of abyssal density surfaces signals transformation
48 of AABW as it travels north. The transition between diabatic and adiabatic regimes, and the
transition from northward to southward mass transport, have been linked to the depth profile of
50 basin-averaged mixing rates, and to surface wind forcing over the Southern Ocean³⁻⁸. Here we
show that these two transitions are tied to the depth distribution of seafloor and are separate from
52 each other.

The deep ocean communicates with the surface in two high-latitude regions (Fig. 1a): the North
54 Atlantic, where deep waters are formed and exported southward to ventilate the 27.7-28.14 kg m⁻³
density range^{9,10}; and the Southern Ocean, where rising density surfaces allow deep waters to
56 upwell primarily adiabatically^{6,7,11,12} until they are converted into denser AABW or lighter

intermediate and mode waters⁵. Note that we use neutral density¹³, denoted γ , as a globally consistent density variable and subtract $1,000 \text{ kg m}^{-3}$ from all density values. Away from these regions, dense waters are isolated from surface exchanges: their density transformation and upwelling rely on deep diabatic processes. We henceforth focus on such processes and restrict the analysis to ocean waters deeper than 1 km between 32°S and 48°N.

62 Geometry. At depths of 1 to 2.5 km, ocean topography is dominated by relatively steep continental slopes and accounts for less than 8 % of the total seabed area (Fig. 2a,b). Deeper, the emergence of flatter ridges decaying onto abyssal plains markedly increases the seafloor area per unit depth, which quadruples between 2.5 and 4.3 km depth. Depth layers therefore have unequal access to the seafloor: the 1/4 of the water volume which resides below 3.5 km occupies 3/4 of the seabed. This inequality is reinforced when considering the seafloor coverage of density layers — that is, layers defined by a fixed density interval —, because their thickness generally increases with depth in the deep ocean (Figs. 1 and 2c,d). By analogy with surface outcrop areas, the seafloor area intersected by a given density layer is termed incrop area. The relatively narrow 28–28.25 kg m^{-3} density range takes up over 80 % of the ocean floor between 32°S and 48°N, the lion's share going to $\sim 28.11 \text{ kg m}^{-3}$ waters (Fig. 2c,d; see also Extended Data Fig. 1).

These simple geometric considerations have important implications for the consumption rate and upwelling pathways of dense waters. Deep ocean sources of density transformation have long been recognized to be concentrated near the seafloor^{14–20}, where boundary-catalysed turbulence and geothermal heating combine to erode the near-bottom stratification and progressively lighten bottom seawaters. The resulting near-bottom confinement of density loss suggests that deep water masses benefiting from a large seafloor coverage are more likely to be efficiently consumed than those isolated from the bottom. Consistent with the preferential lightening of bottom boundary waters, incrop areas tend to increase along the northward path of AABW and to slowly migrate towards smaller densities (Fig. 1b), indicative of a successive removal of incropping density layers and resultant homogenization of AABW²¹. The conjunction between the regime of sloping density surfaces and the presence of significant incrop areas (Figs. 1b and 3b; Extended Data Figs. 2–4) is further suggestion of the dominant role of boundary transformation. Hence, the concentration of seafloor area around the 4–5.5 km and 28.11 kg m^{-3} levels may strongly influence the structure of cross-density transports and the associated meridional flows.

88 Water mass transformation. To formally relate overturning flows to incrop areas, we first set out the link between cross-density transport and the vertical profile of diffusive density fluxes. Consider the volume $V(\gamma)$ of waters denser than γ , bounded by the seafloor, the density surface $A(\gamma)$ and latitudes $y_s < y_n$ (Fig. 4). We define the total geothermal and mixing-driven density fluxes entering V from below and from above as $G(\gamma)$ and $F(\gamma)$, respectively. For the volume V to remain unchanged, advection across A must balance local geothermal and mixing-driven density tendencies, such that^{21–23}

$$T = \partial_\gamma(F + G), \quad (1)$$

where $T(\gamma)$ denotes the mass transport through $A(\gamma)$ and is termed the dianeutral transport. Equation (1) states that the transport across a given density layer is proportional to the net geothermal and mixing-induced density change within that layer. Geothermal heating causes only

100 lightening, balanced by dianeutral upwelling ($T > 0$, towards lower density). In contrast, mixing
may be a density source or sink, requiring downwelling or upwelling, respectively.

102 Dianeutral transports are thus controlled by the γ -profile of the total density flux entering
successively denser water volumes, $(F + G)(\gamma)$. In turn, we can relate basin-scale dianeutral
104 transports to meridional, along-density flows by realizing that T must equal the zonally-integrated
meridional mass flux into V . Denoting by the streamfunction ψ_s (ψ_n) the net southward mass
transport through the y_s (y_n) bounding latitude section of V (Fig. 4), we have by continuity

$$106 \quad T = \psi_n - \psi_s. \quad (2)$$

In the deep Indian and Pacific oceans, choosing y_n at the closed northern end of each basin yields
108 simply $T = -\psi_s$. This entails in particular that the density surface of peak dianeutral upwelling T
north of y_s defines the boundary between northward and southward flow at y_s (Figs. 3d and 4). In
110 the abyssal Atlantic, dianeutral upwelling may balance inflow from the south and north, so that
the meridional flow reversal may lie at a denser level than the peak upwelling rate. Nonetheless,
112 we find the two levels to match in this basin as well when choosing $y_n = 48^\circ\text{N}$ (Fig. 4, Extended
Data Fig. 4 and Methods).

114 **Mixing scenarios.** Fig. 5 shows the profile of the mixing-driven density flux F as well as the
associated 32°S - 48°N dianeutral transports under two idealized scenarios (Methods): (s1) uniform
116 local density fluxes throughout the ocean interior; (s2) bottom-enhanced local density fluxes,
with uniform bottom magnitude. The bottom-intensification of (s2) density fluxes is specified as
118 an exponential decay from the seafloor with a 500 m e-folding scale, a structure representative of
turbulence observations in the abyssal Brazil Basin²⁴. Flux magnitudes are chosen so that both
120 peak upwelling rates equal $25 \times 10^6 \text{ m}^3 \text{ s}^{-1}$, a mid-range estimate of maximum abyssal
upwelling^{9,10,5} constrained by velocity measurements at circulation nodes²⁵⁻²⁹. Shadings show the
122 added contribution of a uniform mixing rate of $10^{-5} \text{ m}^2 \text{ s}^{-1}$, a typical level of mixing away from the
direct influence of boundaries^{14,30-33}.

124 Scenario (s1) corresponds to a diabatic bottom boundary overlain by an adiabatic ocean interior:
convergence of local density fluxes occurs only in the unstratified bottom boundary layer, where
126 the density flux weakens to satisfy a no-flux boundary condition — the constraint that turbulent
mixing cannot flux density across the seafloor^{19,21,34,35}. The implied density transformation and
128 dianeutral circulation are thus qualitatively identical to those that would be generated by a
uniform geothermal density sink along the ocean bottom. The scenario results in diabatic
130 upwelling peaking at $\gamma = 28.11 \text{ kg m}^{-3}$ and mostly confined to below the 28 kg m^{-3} density surface,
matching the incrop area distribution (Figs. 2c, 5c and 6). Indeed, since a uniform density flux
132 homogeneously lightens waters covering the ocean floor, scenario (s1) implies that density layers
upwell in proportion to their access to the seafloor (Extended Data Fig. 5). Consequently,
134 diabatic upwelling is restricted to the depth and density range of significant incrop areas, and the
boundary between northward and southward meridional transport is the density surface of
136 maximum incrop area (Fig. 6). In particular, most of the southern-origin dense waters must then
flow back to the Antarctic Circumpolar Current deeper than 2.5 km.

138 Because geothermal heat fluxes exhibit relatively weak spatial variations away from ridge crests
and contribute only bottom density losses, their impact on circulation is well described by the
140 uniform-flux idealization (s1)^{23,21}. In contrast, deep ocean mixing is observed to be dominated by

142 patchy, topographically-enhanced turbulence^{15-17,19,36-38,32,33}. Such turbulence is generally
143 associated with a bottom-enhanced local density flux, whereby lightening of densest waters
144 occurs at the expense of densification immediately above. Scenario (s2) explores the impact of an
145 idealized, geographically homogenous bottom-intensification of density fluxes. Under this
146 scenario, density loss (gain) generally dominates for density layers that have a larger (smaller)
147 incrop area than their underlying neighbour: the change in incrop area with height determines the
148 diapycnal transport (Extended Data Fig. 5). Upwelling is consequently found within waters
149 denser than 28.11 kg m^{-3} , peaking just under this level, whereas density gain and downwelling
150 characterize lighter waters (Fig. 5c). Hence, despite their structural difference (Fig. 5a,b), the
151 simple scenarios (s1) and (s2) share two essential features: the induced upwelling peaks near the
152 density level of maximum seafloor coverage, and decreases rapidly at lighter densities.

152 The complex spatial patterns of deep ocean turbulence could override these features. Multiple
153 lines of evidence indicate otherwise. First, examination of a range of bottom-intensified mixing
154 scenarios analogous to (s2), where the magnitude of local density-flux profiles is not uniform but
155 instead depends on bottom roughness, slope, stratification or internal wave generation rates
156 (Methods), consistently shows upwelling peaking at or below the peak incrop surface and
157 dwindling rapidly above (Extended Data Fig. 6). Second, consideration of local density fluxes
158 that decay above the bottom according to non-exponential and region-dependent profiles alters
159 the distribution of density gain in the interior but preserves the near-bottom location of density
160 loss, leading to a coupling between incrop and upwelling profiles similar to that inherent in the
161 scenarios (s1) and (s2). Third, turbulence remote from boundaries, fed by interactions among
162 internal waves and associated with weakly varying mixing rates of order $10^{-5} \text{ m}^2 \text{ s}^{-1}$ (refs. 14,30-
163 33), drives only weak upwelling deeper than 2.5 km (Fig. 5c, shadings). From 2.5 to 1 km depth,
164 the upwelling induced by a uniform $O(10^{-5} \text{ m}^2 \text{ s}^{-1})$ diffusivity remains modest and fairly constant,
165 demanding little net meridional flow.

166 **Radiocarbon evidence.** Fourth, analysis of historical radiocarbon measurements^{39,40} confirms the
167 tight connection between incrop areas and the overturning structure (Fig. 3c; Extended Data Figs.
168 2-4). By mapping radiocarbon content ($\Delta^{14}\text{C}$) along density surfaces (Methods), we find that: (i)
169 the maximum incrop area accurately predicts the transition surface between northward and
170 southward flow identified in each basin's $\Delta^{14}\text{C}$ distribution; (ii) the height at which the incrop
171 area falls to 10 % of its peak approximates the lower boundary of the relatively thick $\Delta^{14}\text{C}$
172 minimum (age maximum) observed at mid-depth in the Pacific and Indian oceans.

173 Because of its size and connectedness, the Pacific basin shows the clearest signature of seafloor
174 areas on the radiocarbon distribution (Fig. 3). The strongest vertical $\Delta^{14}\text{C}$ gradient at 32°S occurs
175 at the density of the basin's peak incrop area, $\gamma = 28.11 \text{ kg m}^{-3}$, where the inflow of relatively
176 young waters underlies their southward return after a centuries-long journey in the abyssal
177 Pacific. Water mass transformation estimates (Fig. 5 and Extended Data Fig. 6) further indicate
178 that most of this southward return flow takes place below the 28 kg m^{-3} density surface, the
179 transitional level above which seafloor availability becomes scarce (Figs. 2 and 3a,b). The
180 minimum $\Delta^{14}\text{C}$ centred around 2.3 km ($\gamma = 27.95 \text{ kg m}^{-3}$) must then reflect weak upwelling of
181 bottom waters to that depth. This inference is corroborated by the correspondence between the
182 structure of the $\Delta^{14}\text{C}$ minimum and the depth or density distribution of seafloor areas (Fig. 3 and
183 Extended Data Figs. 2 and 3): oldest density layers appear to be those largely isolated from the
184 ocean bottom and, thereby, from renewal via abyssal upwelling.

186 The Atlantic and Indian oceans host more complex AABW pathways due to their
188 compartmentalisation into many subbasins. There, the leading role of inter-basin passages in
190 transforming the northward-flowing AABW is clearly demonstrated by the bottom density field
192 (Extended Data Fig. 1). Indeed, substantial density drops from subbasin to subbasin largely
194 reflect concentrated mixing within connecting AABW throughflows^{16,29,36}. Such concentrated
196 density transformation suggests that the access to constrictive passages could be as strong a
determinant of diabatic upwelling rates as is the access to large seafloor areas. However,
radiocarbon distributions show that abyssal circulation chokepoints do not host the peak
dianeutral transports that define the meridional flow reversal (Methods and Extended Data Figs. 3
and 4). Instead, deep straits and sills appear to reinforce the influence of incrop areas on the
overall overturning structure: by contributing prominently to the homogenization of AABW, they
favour the concentration of incrop areas to a narrow density range and the pivotal upwelling of
end-basin waters³⁶ (Methods).

198 Hence, water mass transformation scenarios and modern radiocarbon distributions together show
200 that diabatic upwelling peaks near the density layer that has the largest seafloor coverage and
202 decreases rapidly at lighter densities. The robustness of this structure owes to two principal facts:
204 (i) boundary mixing and geothermal heating restrict density loss to the bottom boundary; and (ii)
206 density layers have strongly unequal access to the seafloor. Fact (ii) is firstly a consequence of
208 the concentration of seafloor at depths greater than 2.5 km (Figs. 2 and 3a,b; Extended Data Figs.
210 2-4). It is further reinforced by fact (i), which underpins the progressive focusing of AABW into
its lighter classes that monopolize the floor of northern basins^{21,36}, and which favours the
northward spreading of abyssal density surfaces⁸ (Fig. 1b). Boundary-dominated transformation
and the depth distribution of seafloor thus collude to shape an incrop area profile which peaks
deeper than 4 km and decays to small values near 2.5 km depth. This collusion accentuates the
segregation of water masses situated below and above the 2.5 km geopotential, and suggests that
the main patterns of incrop area and upwelling diagnosed from the modern hydrography must
hold across a broad range of ocean states.

212 Implications of these patterns for the functioning of the meridional overturning north of 32°S can
214 be summarized as follows (Figs. 2 and 6): (i) strong upwelling (or downwelling) rates define a
216 diabatic deep ocean regime at depths greater than 2.5 km, where most of the seabed lies; (ii) an
218 overlying adiabatic regime, within 1-2.5 km depth, hosts non-negligible mixing but
220 comparatively limited dianeutral transports; (iii) northward-flowing dense waters reside below
222 the density layer with greatest access to the seabed, thus largely below 4 km depth, where
seafloor availability is maximal; (iv) the majority of dense southern-origin waters returns
southward within the diabatic regime, below 2.5 km depth. The first two conclusions rely
essentially on the knowledge of the ocean bathymetry and could potentially be recast for a
different depth distribution of seafloor. The latter two further assume a southern origin of the
densest global-scale water mass.

224 Conclusion (iv) entails that the circulation of dense Antarctic-origin waters in the Pacific and
226 Indian basins is more compressed in the vertical than has been inferred in most inverse box
228 models^{9,10,5}, despite limited consistency among these inverse solutions (see discussions of Pacific
and Indian abyssal pathways in the Methods). The depth profile of the southward return flow at
32°S implied by idealized water mass transformation scenarios is also variable (Fig. 5c and
Extended Data Fig. 6), reflecting the lack of constraints on the global mixing distribution. These

230 uncertainties and discrepancies call for further work to refine and reconcile different estimates of
232 the abyssal overturning structure. Examining the silicic acid ($\text{Si}(\text{OH})_4$) distributions⁴¹ of the
234 Pacific and Indian oceans, we find additional support for a relatively deep southward return flow
236 (Extended Data Fig. 7). In the northern part of the two basins, where deep $\text{Si}(\text{OH})_4$ production is
238 thought to be more intense and largely placed at the sediment-water interface⁴²⁻⁴⁵, vertical maxima
240 of $\text{Si}(\text{OH})_4$ lie immediately above the depth range of large seafloor areas⁴⁶. This concurs with
relatively strong circulation and short residence times limiting $\text{Si}(\text{OH})_4$ accumulation within this
depth range. Further south, the maxima shift towards larger densities falling within the diabatic
regime, consistent with southward mean flow promoting the export of $\text{Si}(\text{OH})_4$ there. This latter
feature is not visible in the eastern Indian ocean, but the radiocarbon structure of this subbasin
clearly substantiates a geometric confinement of its abyssal overturning to depths greater than 3.7
km (Extended Data Fig. 3 and Methods).

242 The seafloor area distribution, generally absent from conceptual models or quantitative theories
244 of the overturning, thus exerts major constraints on the volumes, pathways and interplay of dense
246 water masses. In particular, within basins receiving only a southern influx of ventilated dense
248 waters, the abyssal concentration of seafloor implies a partial disconnect between a relatively
250 well-ventilated abyss and more stagnant mid-depth waters. Accordingly, we propose that present-
252 day Pacific and Indian waters straddling the mid-depth radiocarbon minimum do not embody
returning AABW but rather lie in a shadow zone of the overturning (Figs. 3d and 6),
characterized by its isolation from surface and bottom boundary influences, and traversed by
relatively weak mean meridional flow. The larger volume and longer residence time of shadow
zone waters relative to the underlying diabatic abyss make them a stronger candidate for lasting
property storage. Yet an active northern surface source of deep water, as occurs in today's
Atlantic and could have occurred in the Pacific^{47,48}, may disrupt the mid-depth stores, and reduce
the volume and influence of the dense southern-origin waters.

Figure legends

378 **Figure 1: Density surfaces, seafloor areas and the ocean's overturning.** Climatologies^{41,49} of
380 (a) neutral density and (b) zonally-summed incrop areas (units of m^2 per latitude degree and per
380 kg m^{-3}) as a function of latitude and pseudo-depth. The pseudo-depth of density surfaces is found
382 by filling each latitude band from the bottom up with ocean grid cells ordered from dense to light.
382 Grey arrows in a give a simplified view of overturning flows. Flows oriented along (across)
384 density surfaces correspond to adiabatic (diabatic) transports. This study focuses on the latitude
range 32°S - 48°N enclosed in white lines.

Figure 2: Depth and density distributions of seafloor area over 32°S - 48°N . a,c, Seafloor area
386 per unit (a) depth or (c) density. The mean density of geopotential surfaces and the mean depth of
density surfaces are indicated on the left y-axis of a and c, respectively. b,d, Bottom-up
388 cumulative seafloor area as a function of (b) depth or (d) density. Lower and upper white lines
depict respectively the northward-southward and diabatic-adiabatic transition levels tied to the
390 seafloor distribution, as proposed in this study. Spreading ridges and abyssal plains dominate
topography deeper than 2.5 km; steep continental slopes dominate at smaller depths. Northward-
392 flowing AABW dominates waters deeper than 4.3 km (denser than 28.11 kg m^{-3}); its southward
return as relatively dense Pacific Deep Water (PDW), Indian Deep Water (IDW) or North
394 Atlantic Deep Water (NADW) occurs predominantly at depths greater than 2.5 km (densities
greater than 28 kg m^{-3}).

396 **Figure 3: Pacific seafloor and radiocarbon distributions.** a, Zonally-summed seafloor areas as
a function of latitude and depth. b, Zonally-summed incrop areas as a function of latitude and
398 pseudo-depth. c, Along-density zonal mean radiocarbon content ($\Delta^{14}\text{C}$) as a function of latitude
and pseudo-depth. d, Schematic regime transitions, as in Fig. 2b,d. The pseudo-depth of density
400 surfaces is defined as in Fig. 1. Lower and upper white curves depict respectively the local
northward-southward and diabatic-adiabatic transition levels inferred from the incrop area
402 distribution. Specifically, at each latitude y_s , we calculate the γ -profile of summed incrop areas
north of y_s . The northward-southward transition then corresponds to the density of the profile
404 peak, while the diabatic-adiabatic transition is defined as the smallest density at which the incrop
profile decreases to 10 % of its peak. This figure includes the light blue region shown in the inset
406 map in a, which hosts the main Pacific abyssal overturning (Methods). The full Pacific and
southeastern Pacific are shown in Extended Data Fig. 2.

408 **Figure 4: Sketch of a volume V of waters denser than γ , bounded by the density surface
 $A(\gamma)$ and latitudes y_s and y_n .** Density fluxes F and G entering V and the diapycnal mass transport
410 T leaving V are also sketched. The streamfunctions $\psi_s(\gamma)$ and $\psi_n(\gamma)$ are defined as the net

412 southward mass transport below $A(\gamma)$ at y_s and y_n , respectively. As an illustrative example, we
413 show (dotted line) the surface of (grey arrow) peak dianeutral upwelling. Mass conservation
414 requires that this density surface corresponds to meridional flow reversal at y_s (see velocity
415 arrows on the left) if: (i) the along-density transport at y_n is zero, as is the case of the Pacific and
416 Indian basins given y_n at their northern end; or (ii) the along-density transport at y_n is both
southward and weak below the peak upwelling level, as we infer to be the case of the western
Atlantic given $y_n = 48^\circ\text{N}$ (Methods).

418 **Figure 5: Density fluxes and dianeutral transports within 32°S-48°N.** Density profiles of (a)
419 the total density flux F , (b) the density flux averaged over density surfaces and (c) total
420 dianeutral transports T under (orange) scenario (s1) and (blue) scenario (s2). Shadings denote the
added contribution to fluxes and transports of a uniform mixing rate of $10^{-5} \text{ m}^2 \text{ s}^{-1}$.

422 **Figure 6: Schematic abyssal overturning circulation north of 32°S.** The average depth of
423 density surfaces is shown as a function of (lower axis) bottom neutral density and (upper axis)
424 cumulative seafloor area. The surface of maximum incrop area ($\gamma = 28.11 \text{ kg m}^{-3}$), corresponding
425 to meridional flow reversal, and the surface marking the approximate transition between diabatic
426 and adiabatic flow regimes ($\gamma = 28 \text{ kg m}^{-3}$), are contoured in white. Straight and wiggly red
427 arrows depict mixing-driven and geothermal buoyancy ($-\gamma$) fluxes, respectively. To simplify the
428 illustration, mixing-driven fluxes are taken to be uniform in the vertical, as in scenario (s1).
429 Density loss and diabatic upwelling are confined to near-bottom waters, which climb across
430 density surfaces and along topography at a rate commensurate with the incrop area. Through
431 mass conservation, this cross-density, along-bottom circulation maintains an along-density,
432 interior circulation which supplies (returns) dense waters from (to) the Antarctic Circumpolar
433 Current. Note that in the Atlantic these along-density flows may have an additional supply
434 component from the subpolar North Atlantic. In the Indo-Pacific, a weakly-ventilated shadow
zone lies above the abyssal overturning circulation in the approximate 1-2.5 km depth range.

436

Methods

438 **Dianeutral transports.** Water mass transformation estimates presented in Fig. 5 and Extended
439 Data Fig. 6 use the global neutral density field of the WOCE hydrographic climatology⁴¹. In
440 scenarios (s1), (s2) and the scenarios of Extended Data Fig. 6, the specified three-dimensional
441 map of neutral density fluxes allows us to calculate the total density flux F through each density
442 surface $A(\gamma)$. The density derivative of F then yields the dianeutral transport T as per equation (1).
443 The contribution of a fixed diffusivity illustrated by shadings in Fig. 5 is obtained through the
444 same procedure. Uncertainty in the obtained transport profiles reflects mostly the incomplete
445 spatial coverage of the hydrographic observations that underlie the WOCE climatology and the
446 limited horizontal and vertical resolution of the climatology. In spite of these limitations,
447 substantial errors in the basin-scale structure of density fluxes and dianeutral transports discussed
448 here are not expected²¹.

450 Sources of near-bottom turbulence, such as the breaking of internal waves⁵⁰ or the generation of
451 submesoscale instabilities^{51,52}, depend on local flow, topography and stratification conditions. In
452 particular, topographic roughness, topography scales and bottom stratification enter scalings for
the rates of bottom internal wave generation^{53,54}. In addition, the presence of steep slopes or

454 small-scale topographic features may catalyse near-bottom turbulence^{51,52,55-57}. To explore the
455 influence of these parameters, in Extended Data Fig. 6 we examine variations of the bottom-
456 intensified mixing scenario (s2) by setting the magnitude of local density-flux profiles
457 proportional to the: large-scale topographic slope squared; large-scale topographic roughness;
458 small-scale topographic roughness⁵⁸; horizontal wavenumber of small-scale topography⁵⁸; bottom
459 buoyancy frequency; squared bottom buoyancy frequency; internal tide generation rate^{59,60}; lee
460 wave generation rate⁶¹. Roughness is defined as the variance of bathymetric height. Large-scale
461 slopes and roughness are obtained by fitting planes over half-degree grid squares to the 1/30°-
462 resolution etopo2v2 bathymetry product⁴⁹. Small-scale abyssal hills are not resolved by this
463 product. To account for these we use the small-scale roughness and wavenumber parameters
464 estimated by ref. 58. In all eight cases, the average magnitude of the fluxes is adjusted to obtain a
465 maximum upwelling rate of $25 \times 10^6 \text{ m}^3 \text{ s}^{-1}$. Only the structure of transports thus warrants
466 interpretation. Extended Data Fig. 6 shows that, irrespective of the scenario, dianeutral upwelling
is maximum at or below $\gamma = 28.11 \text{ kg m}^{-3}$, is weak or negative at $\gamma = 28 \text{ kg m}^{-3}$, and remains
modest across the overlying regime of small incrop areas.

468 **Radiocarbon maps.** Radiocarbon content ($\Delta^{14}\text{C}$, expressed in per mil) corresponds to the
469 deviation of the measured $^{14}\text{C}/^{12}\text{C}$ ratio relative to an atmospheric reference ratio, correcting for
470 isotopic fractionation⁶². At leading order, the evolution of $\Delta^{14}\text{C}$ in the deep ocean is governed by
471 advective-diffusive processes and radioactive decay of about -10 ‰ every 83 years^{63,64}. Mixing
472 affects the deep $\Delta^{14}\text{C}$ distribution through both its impact on circulation and the direct diffusive
473 redistribution of radiocarbon^{64,65}. The latter effect dominates in particular when significant
474 divergence of diffusive ^{14}C fluxes coexists with weak divergence of diffusive density fluxes:
475 mixing along density surfaces — an important process controlling the $\Delta^{14}\text{C}$ distribution⁶⁶ — or
476 depth-independent density fluxes are cases in point.

We consider all $\Delta^{14}\text{C}$ values assembled in the GLODAPv2 data product^{39,40} and pair these with γ
478 values derived from corresponding hydrographic casts. The 2 ‰ of $\Delta^{14}\text{C}$ measurements (891 out
479 of 36,541 measurements) for which concurrent hydrographic parameters are not available are
480 assigned the γ value of the corresponding position in the WOCE climatology. Next, each $\Delta^{14}\text{C}$
481 cast is vertically interpolated onto a fixed series of 140 γ surfaces using a piecewise cubic
482 Hermite interpolating polynomial. We then map $\Delta^{14}\text{C}$ along each γ surface independently. Grid
483 point values are obtained as a weighted average of neighbouring measurements, the selection and
484 weighting of which rely on the distance look-up table described at
<http://www.marine.csiro.au/~dunn/cars2009/DLU/>. Specifically, weights are defined as^{67,68} $(1 -$
485 $(r/1,200 \text{ km})^3)^3$, with r the shortest path from the mapped grid point to surrounding data points at
486 the grid point depth, bypassing topographic obstacles. Only data points whose distance r to the
487 mapped grid point is less than 1,200 km are retained in each weighted average. The resulting
488 global three-dimensional (longitude,latitude, γ) radiocarbon field is then plotted as a zonal
489 average in Fig. 3 and Extended Data Figs. 2-4 using the pseudo-depth reprojection described in
490 the caption of Fig. 1. In Extended Data Fig. 8, we show an example map of $\Delta^{14}\text{C}$ at $\gamma = 28.045 \text{ kg}$
491 m^{-3} , together with the underlying observations.

Uncertainty in the constructed maps originates from: the individual $\Delta^{14}\text{C}$ measurement error,
494 estimated as $\pm 4 \text{ ‰}$ (ref. 69); errors in concurrent neutral density values; the limited spatio-
495 temporal coverage of $\Delta^{14}\text{C}$ measurements; and limitations of the mapping procedure. Given the
496 sparse observational coverage, uncertainties relate primarily to the sampling density, which is

498 lowest in the southeastern Pacific, the western Indian and the eastern Atlantic oceans (Extended
Data Fig. 8b). The search radius of 1,200 km allows the vast majority of the ocean to be mapped,
500 but smooths out smaller scale structures that may be present in the data. Note also that the
presented radiocarbon maps do not correct for the bomb-produced ^{14}C , nor for any source of
502 temporal variability of $\Delta^{14}\text{C}$. Because we focus on the northern abyssal ocean whose ventilation
timescales typically exceed centuries, the influence of bomb ^{14}C should not significantly affect
504 the qualitative structure discussed here⁶¹. In particular, the surfaces of meridional flow reversal
identified in radiocarbon distributions are corroborated by other hydrographic fields such as
506 stratification, oxygen or silicic acid (see Extended Data Fig. 7). In contrast, these features are
blurred in the bomb-corrected GLODAP climatology product⁷⁰, whose accuracy may be reduced
508 in the abyss⁶⁶. The neutrally-averaged radiocarbon climatology constructed for the present study
is available for download at https://www.nodc.noaa.gov/ocads/oceans/DC14_climate.html.

Pacific ocean abyssal pathways. The density profile of summed incrop areas over the Pacific
510 exhibits two different peaks (Extended Data Fig. 9a,d): a dominant peak at $\gamma = 28.11 \text{ kg m}^{-3}$ and a
secondary peak at $\gamma = 28.03 \text{ kg m}^{-3}$. The latter peak originates from the subbasins situated east of
512 the East Pacific Rise (Extended Data Fig. 1). These subbasins receive an inflow of Circumpolar
Deep Water^{71,72}, which is older than the AABW entering the southwestern Pacific but younger
514 than southward-flowing deep waters (Extended Data Fig. 2c,f). Given that abyssal upwelling in
the Pacific is inferred to be mostly confined to below the crest of the East Pacific Rise, we posit
516 that all or part of the Circumpolar Deep Water inflow feeds a secondary overturning cell
restricted to the southeastern Pacific and the 28-28.06 kg m^{-3} density range (Extended Data Fig. 2).
518 North of 32°S this overturning cell is presumed to be separate from the main Pacific abyssal cell
fed by AABW.

520 Our analysis suggests that the bulk of the Pacific AABW waters returns to 32°S deeper than 2.5
km. This result accords with early analyses of transport across zonal hydrographic sections of the
522 North Pacific⁷³⁻⁷⁵ and the South Pacific^{71,76} but contrasts with more recent inverse estimates of
overturning transports at 32°S^{10,72,77-81}. Although the latter estimates all imply a shallower return
524 flow at this latitude, they exhibit significant spread, most place the meridional flow reversal well
above the 28.11 kg m^{-3} density surface, and many conflict with a high-resolution inverse study of
526 the eastern South Pacific circulation⁸². The uncertainties carried by the inverse solutions at this
location thus appear too large to permit validation or invalidation of the present results. Further
528 work is required to reconcile herein proposed regime transitions with large-scale property
budgets and to narrow down ranges for the strength and structure of the deep southward return
530 flow.

Indian ocean abyssal pathways. Extended Data Fig. 3 documents the relationships between the
532 distributions of seafloor areas, incrop areas and radiocarbon content in the Indian basin. The latter
hosts multiple subbasins with different ventilation histories. For improved interpretation,
534 subbasins with overlapping latitude ranges are therefore shown in separate panels. Two separate
AABW routes ventilate the abyssal Indian ocean⁸³ (Extended Data Fig. 1): an east-route through
536 the Perth, Wharton and Cocos basins, with some connection to the Central Indian basin
(Extended Data Fig. 3a-f); and a west-route through the Madagascar, Mascarene and Somali
538 basins, and into the Arabian basin (Extended Data Fig. 3g-l).

Inflow of young, dense AABW in the eastern Indian ocean is clearly seen in its radiocarbon
540 distribution. Yet an unambiguous ^{14}C -signature of the level of meridional flow reversal at 32°S is

not distinguishable, in part due to the small ventilated volume of the subbasin. Indeed, a distinct transition towards much older waters near 3.7 km depth, approximately coinciding with the weak incrop level (the inferred diabatic-adiabatic transition), suggests that the seafloor distribution constrains the upwelling and southward return of young Antarctic-sourced waters to depths greater than 3.7 km. Such a compressed AABW overturning in the eastern Indian ocean is consistent with: (i) weak AABW throughflow to the Central Indian basin, whose abyssal radiocarbon activities are much lower than those of eastern Indian bottom waters; (ii) the steep topographic barriers bounding the subbasin, which limit diapycnal upwelling; (iii) the location of the silicic acid maximum within the northern half of the subbasin, above that overturning (Extended Data Fig. 7f). Additional deep water overturning in the 28.1-28.17 kg m⁻³ density range driven by water mass transformation in the Central Indian basin is expected to be weak due to the low mixing rates^{85,33} and low radiocarbon concentrations observed north of 30°S in this density range (Extended Data Fig. 3i,l). We thus interpret the apparent Si(OH)₄ tongue near 28.12 kg m⁻³ north of 15°S (Extended Data Fig. 7f) as due to local production, diffusion and/or horizontal recirculation, rather than net meridional flow⁸⁴.

The western Indian ocean has a more gradual decrease of its area, due to the presence of weakly-sloping ridges. As a result, significant seafloor and incrop areas extend higher up in the water column, to about 2.5 km depth. The predicted northward-southward and diabatic-adiabatic transitions lie near 4 km (28.13 kg m⁻³) and 2.7 km (28.04 kg m⁻³) depth, respectively. These compare well with the observed $\Delta^{14}\text{C}$ and Si(OH)₄ distributions (Extended Data Figs. 3c and 7c). Nonetheless, sampling limitations (Extended Data Fig. 8b), lateral redistribution by mixing along density surfaces, and the inflow of relatively young waters of North Atlantic origin into deep layers of the basin⁵ hinder clearer identification of the overturning structure in the radiocarbon data. The Arabian basin has no water denser than 28.13 kg m⁻³, so that its contribution to the overturning appears restricted to the transformation of lighter deep waters.

The inferred structure of the deep Indian ocean overturning contrasts with results of steady geostrophic box inversions^{10,77,79,81,86-89}, which suggest a shallower return of dense southern waters. However, published inverse estimates of the Indian overturning differ widely in structure and strength⁸⁵. Complexity of the flow and topography of the basin likely plays a role in this scatter^{80,87,89}. In particular, the limited number of abyssal density layers considered in the inverse box models disallows resolution of the compressed AABW overturning identified in the eastern Indian ocean: most inversions carry one layer denser than 28.15 kg m⁻³ in this subbasin, and predict either net northward⁸¹ or southward⁸⁹ flow in the layer at 32°S. Further, the presence of multiple peaks in the total incrop area profile of the Indian ocean (Extended Data Fig. 9c,f), related to its topographic partitioning, suggests that the basin's overturning streamfunction may exhibit several abyssal peaks. Coexistence of several abyssal overturning cells traversing relatively small depth, density and other property contrasts could possibly explain the limited consistency of hydrographic inversions and their mismatch with water mass transformation estimates^{85,90}.

Atlantic ocean abyssal pathways. Antarctic Bottom Water (AABW) enters the Atlantic ocean west of the Mid-Atlantic Ridge⁸³ (Extended Data Figs. 1 and 4a-c). As opposed to the situation in the Pacific ocean, it carries a low radiocarbon signature relative to the overlying ¹⁴C-rich North Atlantic Deep Water (NADW). At 32°S, the boundary between northward-flowing AABW and southward-flowing NADW coincides with the strongest vertical $\Delta^{14}\text{C}$ gradient, observed at $\gamma =$

28.14 kg m⁻³. This density surface is also the peak incrop surface across the western Atlantic, consistent with control by incrop areas of the level of meridional flow reversal. Transport analyses^{9,10} and the climatological density field further indicate weak southward influx of waters denser than 28.14 kg m⁻³ at 48°N, substantiating a match between the levels of meridional flow reversal, peak incrop area and maximum dianeutral upwelling. We infer that the pivotal upwelling across the 28.14 kg m⁻³ surface occurs mainly between 30°N and 45°N near 4.5 km depth, where the weak abyssal stratification and large seafloor availability combine to maximize incrops (Extended Data Fig. 4b). Additionally, weak seafloor and incrop areas shallower than 3 km imply that the dianeutral upwelling of bottom waters and their southward return are concentrated at depths greater than 3 km.

The abyssal eastern Atlantic (Extended Data Fig. 4d-f) is primarily fed from its western counterpart through the Chain (1°S), Romanche (1°N) and Vema (11°N) fracture zones, with additional NADW inflow from the northern end of the basin^{83,91} (Extended Data Fig. 1). The $\Delta^{14}\text{C}$ levels at the outflow of the three fracture zones approach -115‰ , which is closer to western Atlantic NADW levels ($\sim -100\text{‰}$) than AABW levels ($\sim -150\text{‰}$). This suggests that the outflows are dominated by NADW, not AABW, in accord with local observational surveys^{92-95,28} and silicic acid distributions (Extended Data Fig. 7g,h). Consequently, the eastern Atlantic contributes primarily to the transformation and upwelling of NADW. Because the estimated AABW throughflow to the eastern basins^{94,95} is only a fraction of the 32°S Atlantic AABW input^{96,27}, we conclude that dianeutral upwelling within the western Atlantic controls the present-day boundary between northward-flowing AABW and southward-flowing NADW. The seafloor and tracer distributions of the eastern Atlantic nonetheless indicate that, there as in the western Atlantic, dianeutral upwelling and AABW influence are most significant below the 3 km geopotential.

Radiocarbon evidence from the Atlantic and Indian basins thus bears out the relationship between the abyssal overturning structure and the depth and density distributions of the ocean floor. Major topographic obstacles and constrictions at subbasin boundaries either (i) catalyse the transformation of AABW or (ii) restrict its access to certain subbasins, but do not override this relationship. In situation (i), flow constrictions contribute to the creation of a more homogeneous bottom water mass, focusing incrop areas into a narrow density range and favouring rapid upwelling at the peak incrop layer downstream. Such inter-basin passages lie below the boundary between northward AABW transport and southward deep water transport. In situation (ii), topographic barriers limit the role of more isolated subbasins in the transformation and upwelling of lighter deep waters. The additional deep boundary transformation occurring en route to and within these subbasins (namely the eastern Atlantic, the Arabian basin and the Central Indian basin) concerns mostly waters lighter than AABW and denser than 28.05 kg m⁻³ (Extended Data Fig. 9).

Code availability. Code for the generation and usage of the distance look-up table is available at <http://www.marine.csiro.au/~dunn/cars2009/DLU/>. Analysis scripts are available from casimir.delavergne@gmail.com on request.

Data availability. The global bathymetry product can be downloaded at <https://www.ngdc.noaa.gov/mgg/global/etopo2.html>. The WOCE hydrographic climatology is available at <http://icdc.cen.uni-hamburg.de/1/daten/ocean/woce-climatology.html>. GLODAPv2 radiocarbon data can be retrieved from <https://www.nodc.noaa.gov/ocads/data/0162565.xml>. The

constructed radiocarbon climatology is made available by the authors at
630 https://www.nodc.noaa.gov/ocads/oceans/DC14_climate.html.

Extended data legends

736 **Extended Data Figure 1: Bottom density contrasts and basin masks.** **a**, Shaded bottom
738 neutral density field, with the 4 km bathymetric contour overlaid in black. **b**, Basin masks
employed for Extended Data Figs. 2-4. The dianeutral circulation, which is essentially confined
740 to the near-bottom, can largely be tracked from the bottom density distribution. The four main
northward paths of AABW are identified in the western Indian, eastern Indian, western Pacific
742 and western Atlantic oceans. The southeastern Pacific, east of the East Pacific Rise, hosts inflow
of Circumpolar Deep Water^{71,72} (see Extended Data Fig. 2). Large bottom density differences
744 across connected, AABW-ventilated subbasins largely reflect the efficient consumption of the
densest through- and over-flowing waters at deep straits and sills. The Chain (CFZ), Romanche
(RFZ) and Vema (VFZ) fracture zones linking the abyssal eastern and western Atlantic are
746 indicated.

**Extended Data Figure 2: Seafloor and radiocarbon distributions of the full Pacific and the
748 southeastern Pacific.** The full Pacific (shown in **a-c**) comprises the main Pacific (shown in Fig.
3) and the southeastern Pacific (shown in **d-f**) domains defined in Extended Data Fig. 1b. **a,d**,
750 Zonally-summed seafloor areas as a function of latitude and depth. **b,e**, Zonally-summed incrop
areas as a function of latitude and pseudo-depth. **c,f**, Along-density zonal mean radiocarbon
752 content ($\Delta^{14}\text{C}$) as a function of latitude and pseudo-depth. White curves depict the local
northward-southward and diabatic-adiabatic transition levels inferred from the incrop area
754 distribution, as in Fig. 3. The cluster of large incrop areas within $28\text{-}28.06\text{ kg m}^{-3}$ south of 20°N
seen in **b** originates in the southeastern Pacific, which hosts a secondary circulation branch^{71,72}
756 separate from the main abyssal overturning cell (Methods).

Extended Data Figure 3: Indian seafloor and radiocarbon distributions. **a,d,g,j**, Zonally-
758 summed seafloor areas as a function of latitude and depth. **b,e,h,k**, Zonally-summed incrop areas
as a function of latitude and pseudo-depth. **c,f,i,l**, Along-density zonal mean radiocarbon content
760 ($\Delta^{14}\text{C}$) as a function of latitude and pseudo-depth. Notice the different colorscales from Fig. 3.
White curves depict the local northward-southward and diabatic-adiabatic transition levels
762 inferred from the incrop area distribution, as in Fig. 3. In the (**g-i**) Central Indian Basin, whose
abyss is not fed from the south but instead through gaps in the Ninety East Ridge, white curves
764 correspond to the peak and weak incrop density surfaces based on the total subbasin incrop
profile. Subbasin masks are shown in Extended Data Fig. 1b.

Extended Data Figure 4: Atlantic seafloor and radiocarbon distributions. **a,d**, Zonally-
766 summed seafloor areas as a function of latitude and depth. **b,e**, Zonally-summed incrop areas as a
function of latitude and pseudo-depth. **c,f**, Along-density zonal mean radiocarbon content ($\Delta^{14}\text{C}$)
768 as a function of latitude and pseudo-depth. Notice the different colorscales from Fig. 3. In the (**a-
770 c**) western Atlantic, white curves depict the local northward-southward and diabatic-adiabatic
transition levels inferred from the incrop area distribution, as in Fig. 3. In the (**d-f**) eastern
772 Atlantic, whose abyss is not fed from the south but instead through ridge gaps in the vicinity of

774 the equator, white curves correspond to peak and weak incrop density surfaces based on the total
subbasin incrop profile. Subbasin masks are shown in Extended Data Fig. 1b.

776 **Extended Data Figure 5: Simplified sketch of the density transformation associated with**
777 **scenarios (s1) and (s2).** **a**, Scenario (s1): case of a uniform geothermal density sink or,
778 equivalently, of a mixing-driven density flux that is uniform in the interior. Density loss occurs in
779 a thin bottom boundary layer. The net density loss within a density layer, and therefore the
780 dianeutral transport across it, is proportional to the layer's incrop area. **b**, Scenario (s2): case of
781 bottom-enhanced turbulence where density loss in a thin bottom layer is compensated by an equal
782 and opposite density gain above that layer. Density loss and density gain layers are sketched with
783 equal thicknesses to illustrate this compensation: a density layer undergoes net density loss if the
784 red area dominates over the blue area, and conversely. As an approximate rule, a density layer
785 loses density in proportion to its incrop area but gains density in proportion to the incrop area of
786 its underlying neighbour. Consequently, the larger the increase (decrease) of incrop area with
height, the larger the net density loss (gain) of a density layer, and therefore the larger the net
upwelling (downwelling) transport across it.

788 **Extended Data Figure 6: Bottom-intensified mixing scenarios.** 32°S-48°N density profiles of
789 (**a,d**) the total density flux, (**b,e**) the density flux averaged over density surfaces and (**c,f**) total
790 dianeutral transports, under various scenarios for the local intensity of bottom-intensified mixing.
791 Specifically, we set the magnitude of local density-flux profiles proportional to (see also labels
792 and Methods): (**a-c**, orange and red) characteristics of the large-scale topography; (**a-c**, dark and
793 pale blue) characteristics of small-scale abyssal hills; (**d-f**, orange and red) bottom energy fluxes
794 into internal waves; (**d-f**, dark and pale blue) powers of the bottom buoyancy frequency. Absolute
795 values of density fluxes are chosen such that the peak upwelling rate is $25 \times 10^6 \text{ m}^3 \text{ s}^{-1}$ under all
796 scenarios. Only the structure — as opposed to the magnitude — of dianeutral transports thus
warrants interpretation.

798 **Extended Data Figure 7: Silicic acid distributions.** Along-density zonal mean silicic acid
799 concentration⁴¹ in the (**a**) main Pacific, (**b**) southeastern Pacific, (**c**) western Indian, (**d**) Arabian,
800 (**e**) central Indian, (**f**) eastern Indian, (**g**) western Atlantic and (**h**) eastern Atlantic domains.
Domains are defined in Extended Data Fig. 1b.

802 **Extended Data Figure 8: Example radiocarbon map and underlying data.** $\Delta^{14}\text{C}$ (**a**) mapped
803 and (**b**) measured on the 28.045 kg m^{-3} neutral density surface. Dark grey patches in **a** are
804 portions of the density surface that are unmapped due to insufficient data density. Similar maps
have been constructed for 140 density surfaces spanning the world ocean's neutral density range¹³.

806 **Extended Data Figure 9: Subbasin profiles of incrop area.** Total incrop area as a function of
807 (**a-c**) density and (**d-f**) pseudo-depth at 32°S, shown for labelled subdomains of the (**a,d**) Pacific,
808 (**b,e**) Atlantic and (**c,f**) Indian oceans. The abyssal Arabian and central Indian subbasins exchange
with the Southern Ocean via the western and eastern Indian oceans, respectively. We therefore
809 use the 32°S pseudo-depth of the western and eastern Indian oceans for the (orange) Arabian and
810 (pale blue) central Indian profiles in **f**, respectively. Subbasin masks are shown in Extended Data
811 Fig. 1b.
