Abstract

In this work, the effect of the partial replacement of cement by alternatives derived from waste glass and silica fume on the hygrothermal behavior of concrete was investigated. For this purpose, concretes containing 20% and 30% of glass powder (GP) have been tested. In addition, two concretes containing the same replacement ratios of GP and 5% of silica fume (SF) were also manufactured. The mixtures were characterized in terms of workability, compressive strength, microstructure and hygrothermal properties. The results show that the use of 20% and 30% of GP improves the consistency of the concrete in the fresh state by 41% and 55%, respectively. In the hardened state, the use of GP engenders an increase in porosity and slightly affects the pore size distribution. However, the SF reduces the critical diameter and creates a range of micropores. Despite the decrease of compressive strength with increasing GP ratio, the concrete exhibits satisfactory performance for structural application at both 28 days (36–41 MPa) and 91 days (40–45 MPa). The cement substitution by 30% of GP and 5% of SF highlights a decrease in thermal conductivity and the specific heat of about 17% and 2.3%, respectively. The water vapor permeabilities of the concrete used ranged from 2.07e-12 to 4.74e-12 kg/m.s.Pa.

Keywords

Glass waste; Silica fume; Microstructure; Hygrothermal properties; Concrete.

1. Introduction

With about 100 billion cubic meters per year, concrete is the most widely used building material in the world (Gencel et al., 2021; Miller et al., 2016). It is responsible for 5.2% of global greenhouse gas emissions mainly due to the manufacturing process of cement, which requires a very high firing temperature to form the clinker (WBCSDIEA, 2009). This is in contradiction with the sustainable development requirements, which are becoming more and more stringent. Therefore, on the path to ensuring environmental sustainability, it is crucial to consider ways to further reduce the carbon impact of this material.

40 Among the proposed solutions, the use of mineral additions, such as silica fume, blast furnace slag and
41 fly ash, to replace the cement in concrete is a promising method to minimize the environmental impact
42 of the cement industry (Berenguer et al., 2020; Feldman, 1981; Manmohan, D. and Metha, 1981;
43 Sellevold et al., 1982; Shen et al., 2020; Zemri and Bachir Bouiadjra, 2020). Beyond environmental
44 aspects, in several works (Antoni et al., 2015; Bani Ardalan et al., 2017), it has been argued that the
45 use of mineral additions improves the consistency of concrete and its mechanical properties and
46 enhances its durability. Moreover, from a hygrothermal point of view, recent studies underlined that
47 incorporating fly ash (Bentz and Peltz, 2011; Demirboğa, 2007) and silica fume (Gökçe et al., 2019) as
48 partial cement replacement in concrete resulted in the reduce of its thermal conductivities and increase
49 of its specific heats and mass transfer parameters such as sorption isotherms and water vapor
50 permeability (Issaadi et al., 2015). While recognizing that the use of silica fume constitutes a
51 widespread application, research on other additions resulting from waste recovery as a substitute for
52 cement remains a challenge for construction engineers. More recently, the incorporation of glass waste
53 in concrete has been widely used because of the economic and environmental issues (Bouchikhi et al.,
54 2019; Chandra Paul et al., 2018; Du et al., 2021; Mohajerani et al., 2017; Oliveira et al., 2015; Xiao et
55 al., 2021; Yang et al., 2019). The motivations are the physical and chemical properties of glass
56 powder, which are relatively similar to those of the additional cement materials (Tan and Du, 2013).
57 Although glass powder can be used as an additional cement material, a lack of data in the literature is
58 one of the principal obstacles preventing it from reaching the same commercial success as other
59 mineral additions.

60 Over the past two decades and in order to preserve natural resources, the use of glass waste as fine or
61 coarse aggregate in concrete has been widely studied in the literature (Aliabdo et al., 2016; Chandra
62 Paul et al., 2018; Federico and Chidiac, 2009; Gerges et al., 2018; Mohajerani et al., 2017; Penacho et
63 al., 2014; Rashad, 2015, 2014). When the glass is used as an aggregate, its high alkali content
64 generates an alkali-silica reaction (ASR) that causes damaging stresses and cracks in the concrete
65 (Shayan and Xu, 2004). Based on research conducted by (Gerges et al., 2018), it was concluded that
66 the incorporation of fine aggregates at percentages below 30% improves the long-term compressive
67 strength. On the other hand, the addition of these aggregates exhibits a rather negative effect beyond
68 30%, where it reduces the mechanical properties of the concrete. In fact, the lessening of the
69 mechanical properties for a high amount of glass could be attributed to the angular nature of glass
70 particles (Bisht and Ramana, 2018), which affects the quality of the Interfacial Transition Zone “ITZ”
71 between the aggregate and cementitious matrix.

72 In addition, several researchers highlighted that reducing the glass size as much as possible reduces the
73 ASR reaction and concrete damage and increases the pozzolanic reactions, which enhances the
74 mechanical properties of the concrete (Serpa et al., 2013; Shayan and Xu, 2004; Zidol et al., 2017).
75 The use of less than 30% of glass powder as cement replacement in concrete, in particular, glass
76 powder particles below 75 microns, reduces the ASR and concrete expansion (Idir et al., 2011, 2010;

77 Shao et al., 2000; Shayan and Xu, 2004; Taha and Nounu, 2008; Zidol, 2009). Furthermore, it has
78 been shown that the finer the glass powder obtained from grinding glass bottles further develops the
79 pozzolanic properties, reduce the alkali–silica reaction (ASR) (Khmiri et al., 2013; Samtur, 1974;
80 Shayan and Xu, 2006; Vaitkevičius et al., 2014), enhances mechanical performance and can be used as
81 a cement substitute for construction (Idir et al., 2011; Shayan and Xu, 2006, 2004; Zidol, 2009).

82 In addition to the advantages offered by the use of fine glass waste with regard to the properties in the
83 hardened state, the partial replacement of cement by glass powder improves the properties in the fresh
84 state, so it can be used to make high-strength concrete without using other superplasticizers (Meyer et
85 al., 2001). From a sustainability point of view, De Castro and De Brito (2013) have found that the use
86 of glass powder as a replacement for cement does not significantly alter the durability-related
87 properties of concrete. Besides the mechanical and fresh properties, which have been sufficiently
88 discussed in the literature, recent works (Chand et al., 2021; Du et al., 2021; Yang et al., 2019) has
89 attempted to evaluate the thermal conductivity and durability of concrete containing glass powder.

90 In spite of the growing attention paid to the valorization of waste glass in concrete, the hygrothermal
91 properties of these materials are rarely studied in the existing literature. Recently, Yang et al., (2019)
92 studied the effect of waste glass as a total sand replacement on the thermal conductivity and
93 compressive strength of concrete exposed to fire. The thermal conductivity and density of the mortars
94 decreased slightly as the particle size of the glass aggregates decreased. Furthermore, the use of glass
95 improves the compressive strength after fire exposure. Du et al., (2021) evaluated the thermal
96 conductivity of cement paste containing up to 25% of glass waste fine aggregate. The results
97 highlighted that the greater the amount of glass, the lower the thermal conductivity of the mixtures. At
98 25% of glass, a diminution of 24% of the thermal conductivity was noticed compared to the reference
99 paste without glass replacement. Experimental investigations showed a good behavior of concrete with
100 glass powder towards the thermal conductivity (Guo et al., 2020) and water permeability (Hussain,
101 1994; Rahman, 2015; Zidol, A., Pavoine, A. and Tagnit-Hamou, 2012; Zidol et al., 2017).

102 A promising way to address the requirements of the RE2020 environmental regulation in terms of
103 greenhouse gas emission reduction and sustainable construction in the building sector is the use of
104 solid waste glass and silica fume as partial replacement of cement. Use of silica fume can be expected
105 to avoid problems associated to the low mechanical strength at short term. To be precise, the glass
106 powder and silica fume incorporated in concrete is both beneficial to environmental protection and
107 economic development while keeping/improving the mechanical and hygrothermal performance of the
108 material. To the best of our knowledge, researches dealing with the partial replacement of cement by
109 glass powder and silica fume have been limited to the mechanical and durability properties.

110 The objective of this work is to investigate the impact of the microstructural properties of concretes
111 with glass powder and silica fume on their intrinsic properties; it concerns the mechanical properties in
112 addition to the thermal and hydric properties. The hydric aspect directly intervenes on the durability of
113 materials, since water, in its various forms, is the main vector of transport of aggressive species such

114 as sulfates and chlorides. It is also the seat of chemical reaction of carbonation phenomenon.
115 Moreover, in the perspective of an application of its materials in construction and renovation, it is
116 important to know the thermal properties, to reach the regulation requirements. An experimental
117 investigation has been carried out which considers all these aspects.

118 For this purpose, heat and mass transfer parameters such as water vapor permeability, sorption
119 isotherms, thermal conductivity and specific heat were evaluated. In addition, aiming to understand the
120 phenomena that govern hygrothermal transfer, this experimental investigation was complemented by a
121 microstructure characterization of the material by means of water and mercury porosimetry, scanning
122 electron microscopy in environmental mode (E-SEM) and thermogravimetric analysis. The results
123 obtained will be useful when predicting the hygrothermal behavior of building envelopes based on
124 these concretes. This study is part of the environmental transition and sustainable construction. They
125 will also allow the identification of possible risks of disorders related to excessive humidity and help
126 predict the durability of building materials and structures (steel corrosion).

127 **2. Experimental program**

128 The experimental investigation was undertaken with the aim of concretizing the link between the
129 consistency, mechanical and hygrothermal properties and the substitution of a fraction of cement,
130 which is responsible for significant greenhouse gas emissions, by other non-biodegradable greenhouse
131 alternatives, that is, glass powder, which constitutes large amounts of waste.

132 In a first step, a characterization of the binder constituents was performed through particle size
133 analysis, scanning electron microscopy (SEM) and reactivity analysis of the powders used. After that,
134 concretes with Portland cement (CEMI), glass powder (GP) and silica fume (SF) were mixed. Several
135 replacement ratios of cement by GP and SF were addressed. A microstructural characterization of the
136 tested concretes was undertaken using water and mercury porosimetry, SEM and thermogravimetry
137 analyses (TGA). In addition to that, the workability and mechanical strength of these concretes were
138 assessed and compared to a control concrete with CEMI (Ref).

139 Finally, the hygrothermal characterization of the concretes used were performed and analyzed in
140 relation to their microstructural properties. The experimental investigations cover the study of the
141 thermal conductivity, specific heat, vapor permeability and sorption isotherms.

142 **2.1. Materials**

143 The cement type used is CEMI 52.5N in compliance with the European standard EN 197-1 (2012).
144 Silica fume in compliance with the European standard EN 13263-1 (2005) and glass powder were
145 used as mass substituents of the CEMI. The glass powder was recovered from glass waste of different
146 colours, provided by the waste disposal plant of La Rochelle agglomeration (France). The procedure
147 used for preparing the glass powder was first to clean the collected waste glass from any impurities by
148 immersion in water for 7 days. During this period, the water was changed every day. After cleaning,
149 the crushing was repeated until achieving a glass powder diameter $< 50 \mu\text{m}$ as shown in Fig. 1.

For this study, five concrete mixtures were proposed as shown in Table 1. All mixtures have a water to binder ratio (W/B) of 0.45, with 350 kg/m^3 of binder. Firstly, a control concrete based only on CEMI was manufactured (called Ref).

Then, four concretes containing glass powder (GP) as a partial mass replacement of CEMI were used: (i) 20% of glass powder (called 20G-I); (ii) 30% of glass powder (30G-I), these two ratios being based on the literature (Zidol et al., 2017). Secondly, two other concretes with partial mass replacement of cement with glass powder and mineral addition of silica fume SF were produced: (iii) 20% of glass powder and 5% of silica fumes (20GSF-I) and (iv) 30% of glass powder and 5% of silica fumes (30GSF-I), where SF was added in order to refine the microstructure which could prove the durability and hygrothermal performances of the concretes. In fact, (Perraton et al., 1988) suggest that it is preferable to substitute between 5 and 10% of the cement mass with silica fume; beyond 8%, the substitution is useless and the material performance decreases. A SikaCem[®] superplasticizer was added to all the mixtures of 2 l/m^3 in order to obtain a better consistency. Finally, sand (0/4 mm) and gravel (4/12.5 mm) were used for all the concrete studied. We noted that the mix design of concretes and mass substitutions used were based on the previous studies in the literature in order to compare it with our results (Bouchikhi et al., 2019; Islam et al., 2017; Matos and Sousa-Coutinho, 2012; Zidol et al., 2017). The formulations of concretes with GP and SF are calculated from the approach previously used by (Khokhar et al., 2010) considering the densities of all the raw materials and keeping the same W/B ratio and paste volume for all the concretes used.

Table 1: Mix design of concretes studied (kg/m³).

| Formulations | Density (kg/m ³) | Ref | 20G-I | 30G-I | 20GSF-I | 30GSF-I |
|----------------------|---------------------------------|-------|-------|-------|---------|---------|
| Sand 0/3.15 | 2490 | 639 | 639 | 639 | 639 | 639 |
| Gravel 3.15/12.5 | 2310 | 1070 | 1070 | 1070 | 1070 | 1070 |
| Cement | 3170 | 350 | 282.9 | 258.2 | 271.2 | 248.4 |
| Glass powder | 2180 | 0 | 56.6 | 77.5 | 54.2 | 74.5 |
| Silica fume | 2710 | 0 | 0 | 0 | 13.6 | 12.4 |
| Water | 1000 | 157.5 | 152.8 | 151.0 | 152.6 | 150.9 |
| W/B | - | 0.45 | 0.45 | 0.45 | 0.45 | 0.45 |
| Clinker ratio (%) | - | 95 | 77 | 70 | 74 | 67 |

172 2.2. Tests and protocols

173 2.2.1 Raw material analysis

174 Particle size analysis of each binder used was carried out using a dry method with the CILAS 1090
 175 particle-size-analyser[®] device in compliance with NF EN 933-1 (2012), which can detect particle sizes
 176 from 0.1 μm to 2 mm. The specific surface measured by BET method based in Brunauer, Emmett et
 177 Teller theory and in compliance with standard EN ISO 18757 (2006) of raw materials were performed.
 178 The heat flow was measured using a TAM air-insulated calorimeter[®], containing eight separate
 179 measuring cells in compliance with ASTM C1702 (2017). The glass vial was sealed and placed in the
 180 calorimeter, and the heat flow was measured for about 25 h. During the test, isothermal conditions of
 181 20°C ± 0.02°C were maintained in the measuring cells. Isothermal calorimetry was performed to
 182 investigate the pozzolanic reaction of the GP and SF on cement hydration at an early age.

183 2.2.2. Workability

184 The Abrams cone slump test is most commonly used to determine the fresh concrete workability. This
 185 test is carried out in compliance with the recommendations in NF EN 12350-2 (2012). In this test,
 186 workability is characterized by the slump of a concrete cone under its own weight. The standard NF
 187 EN 206 (2016) defines five consistency classes according to the measured slump: firm, plastic, very
 188 plastic, fluid and very fluid.

189 2.2.3. Water and mercury porosimetry

190 Water porosity tests were carried out in compliance with the recommendations of AFPC-AFREM
 191 (2007) The porosity (Φ) can be obtained by Eq. (1):

$$192 \quad \Phi = \frac{M_{air} - M_{dry}}{M_{air} - M_{water}} \times 100\% \quad (1)$$

193 where M_{air} and M_{water} are the weight mass of the saturated sample weighed in air and in water
 194 respectively. M_{dry} is the dry mass of the tested sample. For each concrete, the average water porosity
 195 and its standard deviation from three measurements were measured at 91 days.

196 In order to study the effect of the glass powder and silica fume on the pore size distribution and the

197 transfer parameters of the concretes tested, mercury intrusion porosimetry was performed on a sample
198 size of 3 cm³ at 3 months of curing. It was carried out using an Autopore V 9600 from Micromeritics®
199 in compliance with the standard ASTM D4404–84 (1998). Its injection pressure was higher than 400
200 MPa.

201 **2.2.4. Compressive strength**

202 The compressive strength at 28 and 91 days was measured on three different cylindrical specimens
203 measuring 11 cm in diameter and 22 cm in height in compliance with the European standard EN
204 12390-3 (2019). The specimens were demoulded after 24 hours of manufacturing and stored in a
205 humid chamber at 50% RH and a temperature of 22°C. These conditions (air-curing), widely used in
206 the literature (Younsi et al., 2011), better simulate the reality than water-curing and avoid the material
207 leaching in water.

208 **2.2.5. Scanning electron microscopy (SEM)**

209 SEM imaging was carried out by using an environmental FEI Quanta 200 ESEM FEG, equipped with
210 a FEG Field Effect GUN electron emitter, and Large Field Detector (LFD) of Secondary Electrons
211 (SE). The device was operated at 20 kV and 1.5 mbar in water vapor pressure. The advantage of this
212 technique is that no sample preparation is required before the test, which can affect its morphology,
213 and to preserve it from damage (Cherif et al., 2020; Conforto et al., 2015).

214 **2.2.6. Thermogravimetric analysis TGA**

215 Thermogravimetry is an analytical technique that involves measuring the mass variation of a sample as
216 a function of temperature. In our case, this technique was used to monitor the solid phase formations
217 of the concretes and the possible pozzolanic reaction (Ca(OH)₂, calcite, etc.). The device used was the
218 SETARAM® type SETSYS Evolution 16/18. It consists of a sealed chamber to control the atmosphere
219 of the sample by injection of argon gas, an oven to manage the temperature, a weighing module
220 (microbalance), a thermocouple to measure the temperature, and a computer to control and record
221 data. During the test, the temperature should be increased from the ambient to a temperature of
222 1000°C with a constant velocity of 10°C/min. The latter are widely used in the literature and
223 recommended by (AFPC-AFREM, 2007; Santos et al., 2020).

224 **2.2.7. Specific heat**

225 The specific heat was measured by using the calorimeter Calvet BT 2.15® device in compliance with
226 the standard NF EN 821-3 (2005). The advantage of this device is that the 3D Calvet sensor
227 completely surrounds the sample, such that all the heat emitted is measured.

228 The calorimeter consists of a reference cell containing a thermally inert product and a measuring cell
229 in which the test sample is placed. Cells are fitted with a socket and a three-dimensional flow meter.
230 They are specially used for solids or powdered materials with low vapor pressure with an internal
231 pressure of up to 500 kPa. The amount of heat exchanged by the sample is measured by the 3D flow
232 meter, which allows the specific heat to be deduced. The heat change follows three sequences: (i)
233 constant temperature of -10°C for 12 hours, (ii) a ramp from -10°C to 45°C with a velocity of

234 0.1°C/min, and (iii) constant temperature of 45°C for 3 hours. The samples analyzed followed the
235 same protocol of post-fabrication preservation and pre-conditioning prior to the test: preservation in a
236 wet room for 24 hours after manufacture (RH = 50% and T = 22°C) for 28 days of curing, after which
237 they are dried in an oven at 40°C until equilibrium.

238 **2.2.8. Thermal conductivity**

239 The thermal conductivity was measured, under stationary conditions, for a controlled temperature of
240 the samples at 23°C), using the λ -Meter EP 500e[®] device based on the guarded hot plate method in
241 compliance with the European standards (EN 12664, 2001; EN 12667, 2001). The test involves
242 placing a sample of 15x15x5 cm between a cold and hot plate, i.e. the sample is subjected to a given
243 temperature gradient. A guard ring around the measuring area ensures the unidirectional transfer
244 through the sample thickness. Then, the thermal conductivity is calculated from the electrical power
245 supplied using Eq. (2).

$$246 \quad \lambda = \frac{Q.e}{\Delta T.A} \quad (2)$$

247 where e (m) is the sample thickness; A (m²) is the area of the sample; ΔT (K) is the temperature
248 gradient between the two plates and Q (W) the electric power.

249 **2.2.9. Sorption isotherm**

250 The sorption–desorption isotherms present the capacity of the material to capture or retain water with
251 relative humidity variation (RH) for a constant temperature in compliance with ISO 12571 (2000).

252 The method used to determine the sorption–desorption curves is the gravimetric method using the
253 ProUmid[®] device. It is based on the regular monitoring of the gain or loss of the sample mass as a
254 function of the RH ranges. For each range, weighing is performed until equilibrium is reached.

255 **2.2.10. Water vapor permeability**

256 The coefficient of water vapor permeability is determined by the Cup method in compliance with the
257 European standard ISO 12572 (2001). The test is carried out using the Gravitest[®] device, which is
258 composed of 6 cups in a controlled climatic chamber and a high balance precision (10⁻⁴ g) for the mass
259 monitoring. Indeed, a gradient vapor pressure is applied, under isothermal conditions, between the
260 interior of the cup and the climatic chamber, i.e., between the two faces of the tested sample. The flow
261 ratio was evaluated by regularly weighing each cup including the material. In order to determine the
262 equilibrium water vapor transmission ratio and the water vapor permeability, regular de-weighing of
263 the cup and sample were automatically carried out.

264 **3. Results and discussion**

265 **3.1. Raw material characterization**

Table 2: Physical properties of cement, silica fume and glass powder used.

| | CEMI 52.5 N | Silica fume | Glass powder |
|---|-------------|-------------|--------------|
| d_{10} (μm) | 3.2 | 2 | 11 |
| d_{50} (μm) | 12 | 8.5 | 19 |
| d_{90} (μm) | 28 | 18 | 34 |
| d_{max} (μm) | 60 | 36 | 50 |
| Density (kg/m^3) | 3170 | 2180 | 2710 |
| BET specific surface area (m^2/g) | 6.43 | 22.07 | 5.65 |

267 The results are given in Fig. 2. The diameters d_{10} , d_{50} and d_{90} , density and BET specific surface area
 268 BET of the powders used are illustrated in Table 2. The silica fume (SF) was also designed with a
 269 density of $2180 \text{ kg}/\text{m}^3$ and a maximum particle size (d_{max}) of $36 \mu\text{m}$. The glass powder (GP) presents a
 270 density of $2710 \text{ kg}/\text{m}^3$ and d_{50} of $19 \mu\text{m}$. The particle size distribution of the cement was continuous,
 271 being finer than GP and coarser than SF.

272
 273

Fig. 2: Particle-size distribution of cement, glass powder and silica fume.

274 The SEM images in Fig. 3 show the morphology and size particles of the CEMI, GP and SF.
 275 Obviously, the CEMI and SF consist of multi-size and multi-phase powder particles, irregularly
 276 shaped for the CEMI, contrary to the SF powder. In addition, the SF contains finer particles of the
 277 order of 50 nm stacked on large particles as shown in Fig. 3-b. The particle sizes range from $1 \mu\text{m}$ to
 278 $60 \mu\text{m}$ for the CEMI and SF as shown in Fig. 2. The GP has multi-size and irregular shaped particles,
 279 ranging from $8 \mu\text{m}$ to $50 \mu\text{m}$ as shown in Table 2. The elemental analysis by weight percentage of the
 280 binders, performed by energy dispersive X-ray micro-analysis (EDX) coupled to SEM at a spot, is
 281 shown in Table 3. It allows the chemical elements of the materials used to be identified and quantified.
 282 The results show that the glass powder and silica fume are rich in silica. The latter are responsible for

283 the pozzolanic reaction of both the binders and the formation of more C-S-H, to the detriment of
 284 portlandite (Urhan, 1987a, 1987b), which participates to improve the material durability.

285
 286 Fig. 3: SEM images of CEMI (a), silica fume (b) and glass powder (c).

287 Table 3: Elemental composition of the binders used (% wt).

| | C | O | Na | Mg | Al | Si | S | K | Ca | Fe |
|--------------|-------|-------|-----|------|------|-------|-----|------|-------|------|
| CEMI | 47.06 | 20.55 | 0 | 0.31 | 3.06 | 5.01 | 0.4 | 0.41 | 22.42 | 0.78 |
| Silica fume | 32.74 | 43.92 | 0 | 0 | 1 | 22.34 | 0 | 0 | 0 | 0 |
| Glass powder | 8.67 | 43.36 | 7.7 | 1.19 | 4.17 | 28.83 | 0 | 0.53 | 5.55 | 0 |

288 The rate of hydration represented in the heat emission curve of the materials studied with 0%,
 289 20%, and 30% GP replacements within the first 25 h after contact between the water and
 290 cementitious materials contact, normalized to the total binder weight in the mixture, are shown in
 291 Fig. 4. It is clear that the maximum heat flow was reduced as the cement replacement with GP and
 292 SF increased. Fig. 4 show that the maximum value of the second exothermic peak of 20G-I, 30G-
 293 I, 20GSF-I and 30GSF-I were 14.6%, 22%, 29.2% and 31.7% lower, respectively, compared to
 294 REF. The reduction in the rate of heat evolution was due to the dilution of the cement (reduction
 295 in overall volume of the cementitious materials) and, consequently, the hydration products. The
 296 pozzolanic reaction of GP generates less heat than cement because the reaction is similar to that of
 297 C_2S . The results of this study are consistent with previous findings (Dyer and Dhir, 2001) and
 298 allows to better discuss the obtained results for the mechanical and hygrothermal characterization.

Fig. 4: Hydration process of binders used.

3.2. Workability

Fig. 5 shows the slump values for the studied concretes measured at the time of elaborating. The results obtained showed that the slump of the tested concretes varies between 129 and 200 mm. Moreover, for concretes only with GP (20 G-I) and (30 G-I), the addition of GP led to an improvement of up to 55%, thus changing the concrete's consistency from very plastic (for the control concrete Ref) to fluid for concretes with GP. The lower fineness of GP led to higher workability because of its smaller specific surface area BET and low water demand for hydration. This result seems to be in good agreement with those found previously by (Raju et al., 2020), which underlined that the use of glass powder increased the workability of concrete due to the fineness of the GP (BET area of 5.65 m²/g) which is lower than that of CEM I used (of 6.43 m²/g). Therefore, the substitution of cement by GP decreases the water demand for hydration i.e., increases the amount of free water and the workability of the concretes. Furthermore, the workability increases with the amount of GP used (20% GP and 30% GP). For concretes with GP (20% and 30%) and silica fume (5%), workability also decreased compared to the control concrete (Ref), despite the presence of silica fume which is supposed to absorb water and increase water demand in the mix due to its fineness (of 22.07 m²/g and $d_{max} = 36\mu m$). This is due to the presence of GP in large quantity (compared to SF) and with a much lower fineness which decreased the water demand for hydration and increased the workability compared to Ref with only CEMI. Finally, the increase in workability of G-I concretes remains lower than that of GSF-I due to the presence of silica fume. This is in agreement with the literature (Bueno et al., 2020; Chand et al., 2021). That is why we do not insist on the comparison between the slumps of

321 materials to discuss their properties. Further investigation on concretes with the same fineness of the
322 blinder and the same workability could be useful to monitor their feasibility.

323 Furthermore, the improvements obtained make the workability of the concrete easier while reducing
324 the costs related to the vibration and pouring time and offer the possibility of using these concretes in
325 heavily scrapped elements. The incorporation of glass powder and SF as substitutes for cement has, in
326 addition to the above-mentioned benefits, the advantage of reducing the quantity of the admixture
327 while remaining within the range of fluid concretes. This equates to a reduction in the overall cost per
328 m³ of concrete.

329
330 Fig. 5: Workability of the studied concretes.

331 3.3. Porosity

332 The results of the water and mercury porosities of concretes at the age of 91 days are shown in Fig. 6.
333 Firstly, the porosity of the control concrete based on CEMI (Ref) is of about 13%, which is in
334 agreement with literature (Issaadi et al., 2017). Furthermore, substitutions of 20% and 30% of cement
335 by glass powder (20G-I and 30G-I) slightly affect the porosity of the concrete. A slight increase of 7.9
336 and 16.7% was noted in the average porosity of 20G-I and 30G-I, respectively compared to Ref, which
337 corroborates well the findings reported in the literature by (Bouchikhi et al., 2019). This could be due
338 to the fineness of glass powder used which is lower than that of CEM I substituted, especially since
339 the water porosity continues to increase, compared to Ref, with the amount of GP used (20% and 30%
340 of GP). In contrast to what was found for concrete containing only glass powder, the porosity of
341 concretes with 5% of SF decreased according to (Kuzielová et al., 2017). The percentage of
342 diminution was about 19.4 and 20.5% for 20% and 30% of GP, respectively. The decrease is due, on
343 the one hand, to the fineness of SF that is higher than CEMI and GP used, and in the other hand, to the
344 pozzolanic reaction of the mineral addition (SF) with portlandite. In fact, that refines the porosity of

345 concrete as shown in the literature (Gallé, 2001; Urhan, 1987a). Finally, the difference between water
 346 and mercury reflects that water porosimetry can detect a wider range of pores compared to the MIP.

347
 348

Fig. 6: Water and mercury porosities of studied concretes.

349 Fig. 7 shows the pore size distribution of concretes obtained by MIP. The pore distributions of Ref,
 350 20G-I and 30G-I are generally monomodal. For 20G-I and 30G-I, we notice the formation of new
 351 ranges of micropores (finer than $0.01 \mu\text{m}$) and macropores (finer than $100 \mu\text{m}$), which confirms the
 352 porosity increase for 20G-I and 30G-I compared to the control concrete (Ref). However, the
 353 incorporation of 5% of SF highlighted a second range of pores and slowly reduced the critical pore
 354 diameter. The decrease confirms the porosity refinement of concretes with glass powder and SF. In
 355 general, we note that 30% of glass powder increases the diameter of large pores mainly for 30GSF-I
 356 compared to 20GSF-I, with new ranges of pores lower than $0.04 \mu\text{m}$ and higher than $0.2 \mu\text{m}$. These
 357 results are in agreement with those for the porosity shown above (Fig. 6).

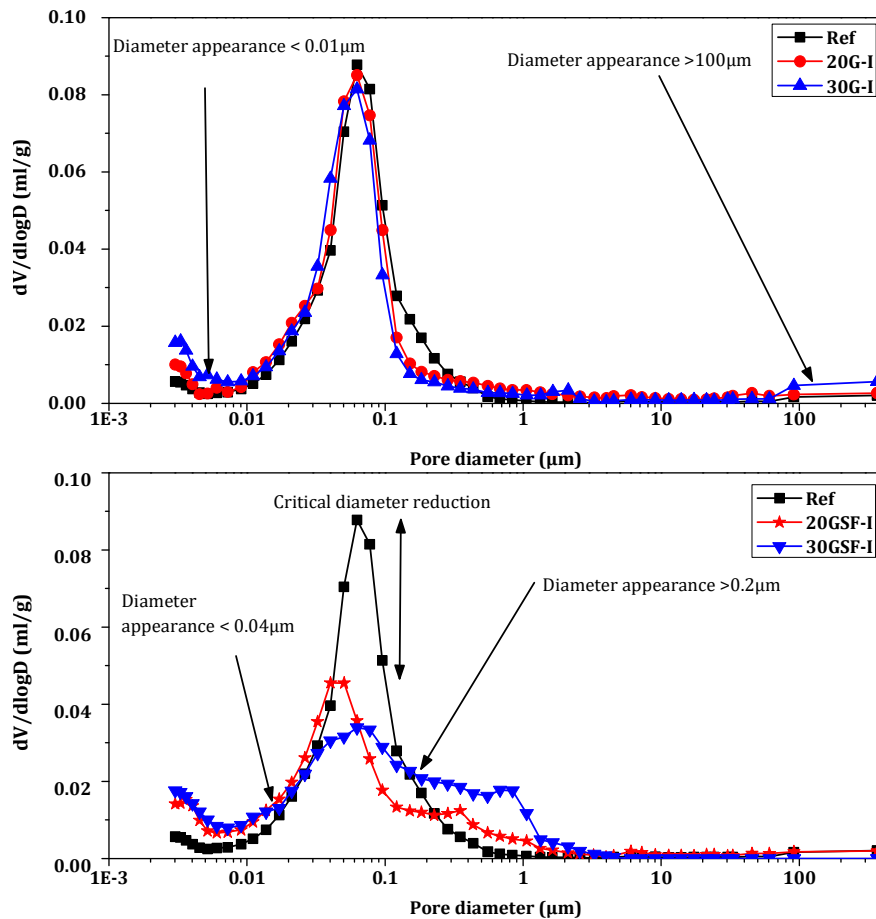

Fig. 7: Pore-size distribution of concretes studied.

367
368
369
370
371
372
373
374
375
376

Fig. 8 shows the compressive strength of the concretes used at the age of 28 and 91 days. The compressive strength for all concretes containing GP is lower than that of the control concrete (Ref), but remains sufficient for structural application (in the range of 36–41 MPa). This is due to a dilution effect which is the immediate consequence of the substitution of a more reactive powder (cement) with a less reactive powder (GP) in the short term (Zidol et al., 2017). Furthermore, the low cementing efficiency of the GP could be due to the low fineness of the GP compared to cement CEMI used (Guo et al., 2020). For Ordinary Portland Cement CEMI, a significant part of the total hydration is done in the short term (28 days) compared to materials with GP. The latter are known for pozzolanic reactions in the long term (more than 91 days).

The control concrete (Ref) reaches its maximal compressive strength of about 57 MPa at 28 days and remains relatively constant with time. However, the compressive strength of the concretes with glass powder continues to increase between 28 and 91 days (+ 5 MPa for 20G-I and 30G-I, and + 10 MPa for 20GSF-I and 30GSF-I). The increase is due to the pozzolanic reaction between portlandite, GP and SF in order to form C-S-H (Idir et al., 2011; Urhan, 1987a, 1987b). This observation is supported by the decrease of the $\text{Ca}(\text{OH})_2$ formed after the addition of GP. Further discussions are given in the following sections.

377 In general, concretes with GP or GP and SF have a satisfactory compressive strength for the structural
 378 application. Therefore, GP can be incorporated up to 20% and 30% as a partial replacement of cement
 379 in concrete, with a potential benefit in reducing the carbon footprint of these materials.

380

381

Fig. 8: Compressive strength of the concretes used.

382

383

384

385

386

387

388

389

Fig. 9 summarizes the research in the literature studying the effect of GP incorporation in concrete on its compressive strengths at 28 days. The database on compressive strength comprises 10 experimental investigations in the literature (Dyer and Dhir, 2001; Idir et al., 2011; Islam et al., 2017; Khmiri et al., 2013; Matos and Sousa-Coutinho, 2012; Ozkan and Yuksel, 2008; Shayan and Xu, 2006, 2004; Taha and Nounu, 2009; Zidol et al., 2017), with which, in general, our results are in agreement. Furthermore, the mechanical behavior of the concrete in the present study showed a declining trend with the GP replacement ratio. Finally, some exceptions may be observed in some studies where the replacement level was 10%, resulting in the highest resistance of the hardened mixtures.

390
 391 Fig.9: Effect of GP replacement ratio on the 28day compressive strength of mortar and
 392 concrete.

393 3.5. Scanning electron microscopy images (SEM)

394 SEM images and the corresponding elemental distributions (EDX spectra) given by EDX from
 395 EDAX/Gemini (a semi-conductor lithium-doped silicon detector Si:Li) of 30G-I and 30GSF-I are
 396 shown in Fig. 10. These analyses show the formation of C-S-H gel and much more in concretes
 397 containing SF. In addition, it can be seen on the same images that 30GSF-I (concrete with GP and SF
 398 rich in silica as shown in the EDX spectra) has a small volume of voids in the cement matrix
 399 compared to 30G-I. Therefore, the SEM images are in accordance with the porosity and pore size
 400 distribution results. The SEM observations and EDX analyses show a shortage of portlandite for the
 401 30G-I and 30GSF-I concrete. This decrease is explained by the formation of C-S-H obtained by the
 402 pozzolanic reaction between silica and portlandite as shown above (Idir et al., 2011). In fact, this
 403 explanation is reinforced by thermogravimetric analyses (TGA) in the section below. In addition, a
 404 high formation of C-S-H is observed in 30GS-I concrete compared to 30G-I concrete. This explains
 405 the decrease in porosity for concrete containing SF compared to concrete without mineral addition.

Fig. 10: SEM images and EDX analyses of 30G-I, and 30GSF-I.

3.6. Thermogravimetric analysis (TGA)

TG and derivative TG curves of the concretes studied are presented in Fig. 11. For each dTG curve, the three main phases are mentioned. The first phase at 30°C–145°C corresponds to the free water released from the sample (Issaadi et al., 2015; Loukili et al., 1999). We note a loss of physically bound water of around 3% for Ref, 20G-I, and 30G-I, and 2% of concretes with SF substitution, which requires more water from the pozzolanic reaction (Amar et al., 2017). The second part reflects the release of the chemically bound water from the portlandite. Water loss of 3% for Ref, 2% for 20G-I and 30G-I and about 1% for the other concretes tested was noted. The later concretes have low portlandite content that is consumed by the pozzolanic reaction of GP and SF (Idir et al., 2011; Shi et al., 2005). The third phase corresponds to the CaCO_3 decarbonation at 750°C, where we note a high CaCO_3 decarbonation for Ref compared to the other concretes, which confirms the high amount of portlandite in Ref without mineral additions or pozzolanic reaction (Amar et al., 2017). The TGA

420 results are in accordance with the SEM images showing the amount of portlandite in the concretes
 421 used with and without SF.

422
 423 Fig. 11: TG and dTG curves of the studied concretes (solid line: TG; dash line: dTG).

424 3.7. Specific heat

425 Figs. 12 and 13 show the specific heat of the concretes obtained by the Calvet® calorimeter. In general,
 426 the difference between Ref (highest specific heat obtained) and 30G-I (lowest specific heat) is about
 427 2.3%. The cement mass substitution with 20% and 30% GP decreases the specific heat by about 1.4%
 428 for 20GP-I and 2.3% for 30GP-I compared to the control concrete Ref with only CEMI. Despite the
 429 porosity changes due to the incorporation of 5% of SF, 20GSF-I and 30GSF-I present a very low
 430 increase in the specific heat compared to 20G-I and 30G-I, respectively. For a higher amount of SF

431 (15%), previous studies showed more effect of SF on the specific heat of concretes (Fu and Chung,
 432 1997; Xu and Chung, 2000). Finally, for all the concretes used, an increase of 13.7% in the specific
 433 heat was noted between -5°C and 40°C (Fig.11).

434
 435

Fig. 12: Specific heat of the studied concretes.

436
 437

Fig. 13: Specific heat of the concretes used at 23°C .

438 3.8. Thermal conductivity

439 Fig. 14 shows the thermal conductivity versus porosity of the tested concretes. Firstly, the cement
 440 replacement by 20% and 30% of GP decreases the thermal conductivity of the concretes by 3.7% and
 441 8.9%, respectively. The thermal conductivity reduction is due to the porosity increase for concretes

442 with GP as shown in Fig. 6. However, the incorporation of SF in concretes decreased their thermal
 443 conductivities of about 10% for 20GSF-I and 17% of 30GSF-I, as have been already highlighted by
 444 (Fu and Chung, 1997; Xu and Chung, 2000). This is due to the finer particles of SF compared to
 445 CEMI and GP whose decrease the total porosities of concrete with SF and changed their pore-size
 446 distribution, showing a second range of pore diameters and the appearance of micro and macro pores
 447 (see Fig. 7).

448
 449 Fig.14: Thermal conductivity of studied concrete.

450 Fig. 15 shows the thermal conductivity results of the concretes used as a function of their densities.
 451 Also, it shows the database in the literature of the thermal conductivities of porous material and the
 452 fitting presented by Asadi et al., (2018). The experimental database of the thermal conductivities and
 453 densities corresponds to 185 experimental measurements (Bouguerra et al., 1998; Ching and Kaw-Sai,
 454 2010; Demirboğa, 2007; Demirboğa, 2003; Demirboğa and Gül, 2003; Gomes et al., 2017; Johnson
 455 Alengaram et al., 2013; Liu et al., 2014; Nguyen et al., 2017; Real et al., 2016; Sayadi et al., 2016; Xu
 456 and Chung, 2000). Furthermore, it shows the fitting of the thermal conductivity as a function of the
 457 density proposed by the ACI Committee (Demirboga and Kan, 2012). The corresponding empirical
 458 functions of the fittings are presented. The results of this study are in accordance with those of the
 459 literature performed on different concretes.

474

475

476

Fig. 16 shows the average sorption isotherms of the concretes used and the standard deviation for three measurements at the age of 91 days. It highlights the effect of the GP and SF on the water vapor diffusion and the sorption isotherms. Firstly, we observed an increase of the hysteresis area with the replacement of cement by GP and SF. The latter changes the concrete microstructure and the pore-size distribution. We note that the sorption capacity of all the studied concretes is almost the same in the super-hygroscopic zone. The sorption isotherms exhibit hysteresis between the sorption phase and the desorption phase over the entire moisture range. The effect of hysteresis is not fully understood, but it is generally assumed that the moisture content at the top equilibrium for desorption is due to the entrapment of water within large pores surrounded by small pores, known as the "ink bottle effect" (Ishida et al., 2007). In fact, the hysteresis is due to the changes in the contact angle between the adsorbed water and the internal surface of the material. During the drying cycle, the water coating that exists on the surface of the internal capillary micro-pores is in contact with an already fully moist surface, while during the humidification cycle the water film formed is in contact with a dry and not yet wet surface (C.M. Chen and Wangaard, 1968).

477

486

487

488

489

In order to study the effect of the incorporation of GP and SF in concretes on the moisture storage capacity, the latter was deduced from the sorption isotherms for each concrete. This represents the ability of the material to adsorb and release moisture. The moisture storage capacity (called C_m) is often used for hydric transfer modeling. The C_m curves are shown in Fig. 1. For high humidity (>80%), the incorporation of GP in concretes increases their moisture storage capacity compared to the control concrete (Ref). This is attributed to the effect of porosity on this intrinsic mass transfer parameter. On the one hand, because the GP is less permeable, it slows down the diffusivity and storage of moisture. On the other hand, given the angular shape of the glass powder, it introduces small ITZ, in which the pozzolanic reaction between the glass rich in SiO_2 and the portlandite Ca(OH)_2 takes a long time to form the C-S-H that clogs the porosity (Bouchikhi et al., 2019; Idir et al., 2011).

490 In general, the storage capacity of humidity varies according to the relative humidity (RH). For RH
 491 ranging from 10% to 80%, the C_m value is low and remains constant. Then, it significantly decreases
 492 for the hygroscopic zones (RH > 80%). This variation is due to the type of sorption–desorption
 493 isotherm (type II according to the IUPAC classification (Sing KS., 1985)).

494
 495

Fig. 17: Moisture storage capacity of the concretes studied.

496 3.10. Water vapor permeability

497 The water vapor permeability of the concretes used is shown in Fig. 18, using the wet cup method.
 498 The results highlight a significant increase in water vapor permeability with the replacement of cement
 499 by GP and SF. This is explained by the changes of the concrete microstructure as shown above
 500 (porosity, pore size distribution and possible tortuosity and constrictivity) due to the tion of the binder
 501 (cement + GP) and the pozzolanic reaction of the GP. However, the use of SF in concretes increased
 502 the water vapor permeability, although it is assumed to reduce the concrete porosity. In fact, SF
 503 reduces the total porosity and the pore diameter of the concrete and increases its tortuosity (Omran and
 504 Tagnit-Hamou, 2016). The latter could affect the water vapor permeability of concretes with GP and
 505 SF compared to Ref.

Fig. 18: Water vapor permeability of the used concretes in [kg/m.s.Pa].

4. Conclusion

An experimental study was carried out on the effect of the partial mass replacement of cement by glass powder and silica fume in concretes. The objective was to assess the hygrothermal properties of the concrete and the impact of its microstructure. The results obtained for the concrete tested are satisfactory, making it a good material for building and construction. The following conclusions can be drawn:

- Due to its fineness, the GP used increases the concrete's consistency up to 55% and the porosity up to 20%.
- Despite the use of 5% of SF, the incorporation of the used GP in concrete decreases its compressive strength at 28 and 91 days compared to the control concrete with CEMI, but remains sufficient for structural applications.
- The incorporation of 20% and 30% of GP in concrete reduces its heat capacity by 1.4% and 2.3%, respectively compared to control concrete. However, the addition of 5% SF shows slightly effects on heat capacity.
- Cement replacement by 20 or 30% GP and 5% SF significantly decreases the thermal conductivity of the concrete due to the microstructure changes.
- Finally, the replacement of cement by GP (20% and 30%) and SF (5%) in concrete increases its moisture storage capacity (C_m) for the super-hygrothermal zones as well as its water vapor permeability (up to 5 times for 30GSF-I compared to the control concrete).

The experimental characterization campaign reported in this work has not only enriched the database of concrete properties but has also supplied the numerical simulation model with reliable input data to predict their hygrothermal behavior. Therefore, further numerical investigation will be achieved to

530 highlight the advantages of using these materials in terms of energy performance, durability and the
531 environmental impacts.
