Abstract. Exchanges of biogenic volatile organic compounds (BVOC) between plants and the atmosphere are likely to vary, in amount and composition, between different plant species but also for a single plant during its development. However, the effect of plant development stages, including senescence, on BVOC exchanges remains poorly investigated, especially in the case of crop plants. We investigated the BVOC exchange patterns for wheat plants, the most grown crop species worldwide, during seed maturation, senescence and after harvest. Fluxes were measured online, *in situ*, at the plant scale by combining automated chambers and a Proton Transfer - Reaction - Quadrupole ion guide - Time of Flight - Mass Spectrometer (PTR-Qi-Tof-MS). The high resolution and sensitivity of this method enabled the measurement of a large mass spectrum of compounds emitted at very small amounts, allowing a precise characterization of BVOC exchanges. We found that the overall BVOC emissions increased twofold during the senescence stage compared to the maturation stage. Methanol was found to be the most emitted compound (49 – 60% of the overall flux on a molar basis) followed by acetone (7.5 – 8.2% of the overall flux on a molar basis) during each developmental stage investigated. Acetaldehyde was another

26 major emitted compound contributing mainly during late senescence to the overall flux (9.7%).
27 When normalized for temperature and light conditions, most BVOC emissions increased during
28 senescence, showing a clear effect of senescence on BVOC exchanges. Chamber emissions were
29 comparable to whole ecosystem fluxes measured at the same site by eddy covariance the previous
30 year. The OH reactivity of the emitted compounds was evaluated based on known reaction rate
31 constants and was the largest during the first senescence stage, peaking at 12 s^{-1} in the chambers.
32 The results of this study show the need for considering plant phenology when computing BVOC
33 emissions from crops.

34 Keywords: BVOC, dynamic chamber, crop, development stage, PTR-Qi-Tof-MS.

35 **1. Introduction**

36 Plants synthesize and release an incredible diversity of volatile organic compounds (VOCs) into
37 the atmosphere; more than 1700 biogenic VOCs (BVOCs) have already been identified (Knudsen
38 et al. 2006). BVOC emissions from terrestrial vegetation are estimated to be $760 \text{ Tg (C) yr}^{-1}$
39 representing 90% of total emissions at global scale (Sindelarova et al., 2014). Besides the
40 importance of these compounds in the interaction between plants and their environment, BVOCs
41 are known to impact air quality, climate, human health and vegetation. Indeed BVOCs contribute
42 to the formation of tropospheric ozone (Fehsenfeld et al., 1992), of secondary organic aerosols
43 (SOA) (Ziemann and Atkinson, 2012) and increase the lifetime of methane in the atmosphere by
44 reducing the oxidative capacity of the atmosphere (Isaksen et al., 2009). These issues explain the
45 growing interest, over the last decades, in BVOC emissions into the atmosphere.

46 BVOC species are diverse and include several organic classes such as terpenes, fatty acid
47 derivatives, alcohols, alkanes, alkenes, esters and acids, among others (Pichersky and Gershenzon

48 2002; Peñuelas and Llusà 2001). Several factors influence - quantitatively and qualitatively -
49 BVOC exchanges between plants and the atmosphere. First, the biosynthesis of VOCs by plants
50 is strongly linked to the genetic information of the plant (Degen et al. 2004; Delphia et al. 2009;
51 Splivallo et al. 2012). Thus, emissions of these compounds vary greatly from one species to
52 another and even within the same plant species (Gonzaga Gomez et al., 2019; Splivallo et al.,
53 2012). Secondly, BVOC exchanges depend also on environmental factors, such as temperature,
54 light, relative humidity, atmospheric CO₂ and O₃ concentrations, nutrient availability and soil
55 moisture (Gouinguéné and Turlings, 2002; Laothawornkitkul et al., 2009; Staudt and Bertin,
56 1998). Finally, it has been shown that BVOC exchanges depend also on specific characteristics of
57 the plant, varying for example during plant development (Bachy, 2018; Bracho-Nunez et al.,
58 2011; Mozaffar et al., 2018; Rottenberger et al., 2005).

59 BVOC exchanges during different developmental plant stages have so far been poorly
60 investigated. In addition, most of the existing studies have focused mainly on the developmental
61 effect on isoprenoids and methanol emissions. For example, it has been reported that methanol
62 emissions are strongly associated with plant growth (Bracho-Nunez et al., 2011). Indeed, this
63 compound is formed in plants from the demethylation of pectin, a mechanism occurring during
64 cell wall alteration (Fall and Benson, 1996). An increase in emissions of this compound has also
65 been observed during leaf senescence of maize plants (Mozaffar et al., 2018). It has also been
66 shown that isoprene emission is lower in young leaves than in mature leaves. This may be due to
67 a higher respiration rate competing for pyruvate, a common substrate to isoprene biosynthesis
68 and respiratory processes (Loreto et al., 2007). Other examples are monoterpenes, sesquiterpenes
69 and acetone showing higher emission rates in young leaves and reduced or non-existent
70 emissions rates at leaf maturity (Bracho-Nunez et al., 2011).

71 It has been estimated that agricultural crops in Europe account for 27% of the overall BVOC
72 emissions (Karl et al., 2009), which represents a non-negligible contribution. Despite the species-
73 specific dependence of BVOC emissions, as mentioned before, most studies have focused on
74 BVOC fluxes from trees and thus on isoprenoids. For this reason fluxes from agricultural plant
75 species, which appear to be dominated by oxygenated VOCs (Karl, 2009), remain poorly
76 understood. These estimates are in fact mostly based on measurements made on a few plant
77 species, over a short time period and with analytical constraints. Therefore, since these
78 measurements may not be representative of the variety of crops, and regions, the contribution of
79 these ecosystems to the overall BVOC emissions remains inaccurate.

80 The widely used MEGAN 2.1 model (Guenther et al., 2012) provides estimates of BVOC
81 emissions from terrestrial ecosystems. Despite the recent improvement of this model, the
82 estimated emission rates from crops remain inaccurate (Guenther et al., 2012). This is mainly due
83 to the assignment of emission factors by default to all crop species given the lack of emission rate
84 measurements on these species. Indeed in MEGAN 2.1 crop plant species are all grouped into
85 one “functional plant type” for which one emission factor value is attributed. Current knowledge,
86 however shows that BVOC emissions vary strongly (composition and amounts) between species
87 and even between varieties of the same species (Gonzaga Gomez et al., 2019). Thus, emission
88 factors should be better investigated on most grown crop species such as wheat, rice, maize or
89 oilseed rape. In addition, despite the dependence of VOC emissions on the plant's age, in the
90 MEGAN 2.1 model, the plant developmental stage is not taken into account when estimating
91 emissions for all oxygenated compounds, apart from methanol. In order to achieve a more
92 reliable estimate of these emissions, more accurate emission factors for individual crop plants are

93 needed, as well as a better understanding of how the different drivers (e.g. light, temperature,
94 age) influence BVOC exchanges.

95 Wheat is the most widely grown crop in the world and in Europe, representing more than 15 %
96 and 33 % (FAOSTATS 2017) of the total croplands cultivated surface, respectively. However,
97 the studies on BVOC emissions from wheat plants are quite limited and show a large divergence
98 between results (Bachy, 2018; Butter et al., 1985; Gallagher et al., 2000; König et al., 1995;
99 Morrison et al., 2016; Piesik et al., 2011; Winer et al., 1992). Recently, Bachy (2018) conducted
100 a study over a wheat field where BVOC exchanges were investigated during the whole growing
101 season at the ecosystem level. The authors found that, like for most crop species, methanol was
102 the most emitted compound and the emissions of this compound and acetaldehyde increased with
103 plant senescence. However, their study could not distinguish between emissions originating from
104 plants and from soil. In addition, flux measurements were limited to a small number of
105 compounds in order to maintain a high measurement frequency, which raises questions of other
106 VOCs that could have been overlooked.

107 In order to improve the understanding and the quantification of BVOC fluxes in wheat crops, this
108 study aims to – (a) characterize, quantitatively and qualitatively, BVOC exchanges of wheat at
109 the plant level during ripening, senescence and harvest, over a wide spectrum of compounds; (b)
110 propose physiological mechanisms explaining the variations of emissions during the investigated
111 developmental stages and discuss how climatic factors (humidity, temperature, and light) can
112 influence these emissions. To achieve these objectives a Proton Transfer - Reaction - Quadrupole
113 ion guide - Time of Flight - Mass Spectrometer (PTR-Qi-Tof-MS) was used in combination with
114 multiple dynamic automated chambers for online measurements of BVOC fluxes from wheat

115 plants. The chamber fluxes were challenged against eddy covariance fluxes measured in a nearby
116 field the year before to verify the general relevance of our results.

117 **2. Materials and methods**

118 **2.1. Site**

119 Flux measurements took place on a field belonging to the experimental farm of Grignon owned
120 by AgroParisTech and located about 30 km west of Paris in France (48°51'N, 1°58'E). The site is
121 a 2 ha field, with a crop rotation of wheat and maize since 2011, located next to the ICOS FR-Gri
122 site on the south-east. The details about the ICOS site can be found in Loubet et al. (2011), Laufs
123 et al. (2017) or Vuolo et al. (2017).

124 Wheat (*Triticum aestivum* L.; Fructidor variety) was sown on October 21st, 2016 and harvested
125 on June 30th, 2017. Certain agricultural practices such as fertilizer, fungicide and herbicide
126 application are detailed in Appendix A. Indeed these practices are likely to impact the emissions
127 of VOC by plants as well as the measurements of these compounds.

128 **2.2. Experimental campaign**

129 The measurement campaign covered the period from June 10th to July 04th, 2017. Measurements
130 were performed simultaneously on two wheat plant replicates using two automated dynamic
131 chambers, based on the original design of Pape et al. (2009), modified and detailed in Gonzaga
132 Gomez et al. (2019). The complete plant above ground was enclosed in the \approx 35 L chamber
133 placed outdoors in the field. In short, the chambers consisted of an acrylic glass (PMMA)
134 cylinder covered by a fully light-permeable FEP film (50 μ m thick PTFE, MICEL). A motorized
135 lid also covered by FEP film was used to open the chambers between measurements intervals. A
136 quantum sensor (SOLEMS, PAR/CBE 80, Palaiseau, France) and a copper-constantan

137 thermocouple device ensured the continuous monitoring of air temperature and
 138 Photosynthetically Active Radiation (PAR) inside the chambers. An axial fan (D341T-012GK-2,
 139 MICRONEL) was used to purge ambient air into the cuvette at $\approx 14 \text{ L min}^{-1}$. Each chamber was
 140 equipped with two twenty-meter-long PFA sampling tubes (1/8 inch internal diameter): one for
 141 the inlet air (ambient air) and one for the outlet air (inside chamber air) sampling. Each of these
 142 sample tubes was heated to 50°C to avoid condensation of the air until it reached the PTR-Qi-
 143 ToF-MS (Ionicon, Analytik GmbH, AU), which was used to measure BVOC concentration at 10
 144 Hz. In the present work, the instrument was operated at drift tube pressure and temperature of
 145 $4 \pm 0.0001 \text{ mbar}$ and $80 \pm 0.06^\circ\text{C}$, respectively. The inlet flow rate was set to $150 \pm 5.42 \text{ ml min}^{-1}$
 146 and the E/N value (where E is the electric field strength and N the gas density) to about
 147 $132 \pm 0.03 \text{ Td}$ (1 townsend = 10^{-17} V cm^2). An infrared gas analyzer (Li-Cor 840 model, Li-Cor,
 148 Lincoln, Nebraska, USA) was used to follow CO_2 and H_2O concentrations from the inlet and
 149 outlet air sampling of each chamber. In order to determine the effect of chambers on VOC
 150 measurements we previously measured on an empty chamber. We thus detected some heavy
 151 compounds emitted by the chambers (m/z 118.063, 190.962 and 192.960) which were removed
 152 from the analysis. Further details about the experimental device, including chambers and PTR-
 153 Qi-TOF-MS operation, can be found in Gonzaga Gomez et al. (2019).

154 2.3. PTR-MS concentration

155 The pre-processing steps provided averages and standard deviations of count rates (cps in counts
 156 per seconds) for the compounds (ion peaks) selected R_i . The mixing ratio of the compound χ_i (in
 157 ppbv) was calculated as in Abis et al., (2018) and Gonzaga Gomez et al. (2019):

$$158 \chi_i = 1.657 \cdot 10^{-11} \times \frac{U_{\text{drift}} T_{\text{drift}}^2}{k p_{\text{drift}}^2} \times \left(\frac{cps_{R_i H^+}^{\text{norm}}}{cps_{H_3O^+}^{\text{norm}} + cps_{H_2O, H_3O^+}^{\text{norm}}} - \frac{cps_{R_i H^+}^{\text{norm}}(\text{zeroair})}{cps_{H_3O^+}^{\text{norm}} + cps_{H_2O, H_3O^+}^{\text{norm}}(\text{zeroair})} \right) \times S_i \quad (1)$$

$$159 \quad cps_{R_iH^+}^{norm} = \frac{TR_{H_3O^+}}{TR_{R_iH^+}} \times cps_{R_iH^+}$$

160 where U_{drift} is the voltage of the drift tube (V), T_{drift} is the drift tube temperature in Kelvin (K),
 161 $cps_{R_iH^+}$ is the count rate (cps) of the product ion, $cps_{H_3O^+}$ and $cps_{H_2O.H_3O^+}$ are the count rates of
 162 the source ion and the first water cluster, k is the protonation rate constant assumed identical for
 163 all compounds ($2.5 \cdot 10^{-9} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$), *norm* stands for normalized, $TR_{H_3O^+}$ is the
 164 transmission factor for H_3O^+ , $TR_{R_iH^+}$ is the mass-dependent transmission factor for the
 165 protonated compound R_i , p_{drift} is the pressure in the drift tube, and S_i is the normalised sensitivity
 166 of the analyzer. Here *zeroair* stands for the count rates measured for zero air under the same
 167 conditions of pressure, temperature and voltage. The standard transmission curve from the
 168 supplier was used to compute the normalised counts per seconds $cps_{R_iH^+}^{norm}$ (Table B1, Appendix
 169 B). The $cps_{H_3O^+}^{norm}$ was computed from ion m/z 21.022 ($H_3^{18}O^+$) by multiplying by the isotopic
 170 factor 487.56, the first water cluster was taken as the ion peak m/z 37.028. The number
 171 $1.657 \cdot 10^{-11}$ is a constant specific to the instrument, accounting for the reaction time in the drift
 172 tube and detailed in Appendix B.

173 2.4. Mixing ratio calibration and uncertainties

174 S_i was determined as explained in Gonzaga et al. (2019), section 2.9: a standard cylinder
 175 containing 102 ppbv of benzene, 104 ppbv of toluene, 130 ppbv of ethylbenzene and 336 ppbv of
 176 xylene (122 ppbv Ortho, 121 ppbv Meta, 123 ppbv Para; BTEX, Messer) was diluted with
 177 synthetic air. S_i was then computed as the slope between measured mixing ratios as computed by
 178 equation 1 when $S_i=1$, and the mixing ratio prescribed by the dilution system. Assuming that the
 179 protonation rate constant was similar for all compounds a single S_i was computed ($S_i = 2 \pm 0.15$)

180 for all compounds except methanol for which a comparison with another PTRMS itself calibrated
181 for methanol was used to determine $S_{\text{methanol}} = 15$. However, acknowledging that assuming an
182 identical protonation rate constant k , and hence a single S_i for all compounds may lead to
183 systematic errors, we evaluated this potential bias in the computed concentrations. To do so, we
184 computed the ratio S_i / S_{toluene} , using data from another experiment performed with the same
185 instrument the year before (data from Loubet et al. 2021), as well as the using data from the
186 literature (Koss et al. 2018), with an instrument similar to ours, though not exactly the same. This
187 exercise (Table B2) shows that for most compounds the systematic error made by assuming a
188 single k is limited to less than 40% error, which is the range expected from theoretical estimations
189 of k . However, for ethanol, formaldehyde, methanol and propene, the bias may be high (from ~3
190 to ~40), with a tendency to underestimate the actual mixing ratio. For methanol, a specific
191 calibration was performed in this study against another PTRMS which was itself precisely
192 calibrated. For the ethanol, formaldehyde and propene the bias may have been be large, and
193 especially for ethanol. For monoterpenes there might also be large differences in S_{methanol} , but this
194 may be specific to the species composition at each site, since each monoterpene may fragment in
195 different patterns (Tani et al., 2003).

196 Since no specific calibration was performed, except for toluene and methanol during this study,
197 we did not correct our data using the S_i / S_{toluene} shown in table B2, but rather proposed alternative
198 estimates in standard emission factors in the discussion section. Nevertheless, the calibration data
199 from Koss et al. (2018 and Loubet et al. (2021) also provided some estimates of the overall
200 uncertainty on the mixing ratio determination, which is also provided in Table B2 as a relative
201 standard deviation. Assuming these relative uncertainties would be similar in different

202 experiments, we estimated the uncertainties in mixing ratios would have been on average 15%
203 and ranged from 1% to 100%.

204 **2.5. Uncertainties in calculated concentrations due to humidity**

205 It is well documented that PTR-MS sensitivity is strongly influenced by relative humidity (RH),
206 resulting in uncertainty in the calculated BVOC concentration (Baasandorj et al., 2015; Christian
207 et al., 2004; Feilberg et al., 2010; Kari et al., 2018; Thomas Karl et al., 2003; Pang, 2015;
208 Steinbacher, 2004). Such humidity influence can lead to either an overestimation or an
209 underestimation of the BVOC concentrations depending on the compounds considered and the
210 setting of other parameters of the PTR-MS, notably the E/N (ratio of electric field to gas density).
211 For example, several studies show a significant underestimation of formaldehyde concentrations,
212 ranging from a factor of 3 to 5, by PTR-MS with increasing humidity (Christian et al., 2004;
213 Thomas Karl et al., 2003; Steinbacher, 2004; Vlasenko et al., 2010). Baasandorj et al. (2015)
214 showed that the sensitivity of PTR-MS to acetic acid decreases with humidity when the collision
215 energy in the PTR-MS drift tube is high ($E/N > 125$ Td). In contrast, when E/N is low, a clear
216 increase in the sensitivity of PTR-MS to acetic acid with humidity was observed by the authors.
217 Changing the water vapor pressure from 0.61 to 3 kPa at E/N 142 Td, resulted in a significant
218 decrease of 30% in the sensitivity of the PTR-MS to acetic acid (Baasandorj et al., 2015) due to
219 an increase of the fragmentation of this compound at high RH (Feilberg et al., 2010). Assuming
220 Baasandorj et al. (2015) results could be transposed to our setup, we evaluated that this effect
221 would lead to an underestimation of the deposition flux of acetic acid of 35% on average.
222 Regarding GLVs compounds, Pang et al. (2015) showed a linear increase in sensitivity with
223 increasing humidity. Sensitivities increased between 20% and 35% when the humidity increased
224 from 0 to 70%. In contrast, mono- and sesquiterpenes do not appear to show significant humidity

225 dependence. In general, a slight increase in sensitivity was reported for some terpenes ranging
226 from 1% to 4% over a wide range of relative humidity from 0% to 100% (Tani et al. 2004).

227 In order to minimize the effect of humidity on PTR-MS sensitivity, the chambers remained open
228 during non-sampling periods to avoid overheating and plant over-transpiration. However, even
229 with these precautions, changes in humidity in the sampled air may have introduced uncertainties
230 in the calculated concentrations as discussed in this section.

231 **2.6. Leaf area and dry-weight estimations**

232 Wheat plants were no longer growing during the measurement period. Thus, the leaf area was
233 considered constant throughout the experiment, since senescence did not induce large changes
234 according to visual inspection. Leaf area was determined by plant harvesting at the end of the
235 experiment and subsequent scanning and image analysis using IMAGEJ[®]. Dry weight (g) was
236 obtained after placing the plant organs (leaves and fruits) for 48 hours in a stove at 80°C.

237 **Table 1 Wheat dry weight (DW) and leaf area in each chamber at the end of the experimental period.**

	Ear DW (g)	Leaf DW(g)	Biomass DW(g)	Leaf Area (m²)
<i>Wheat 1</i>	21.2	3.3	24.5	0.06
<i>Wheat 2</i>	16.4	2.0	18.4	0.05

238

239 **2.7. BVOC fluxes**

240 As detailed in Niinemets et al. (2011), after chamber closure, the time necessary to reach the
241 chamber steady-state can be estimated as 4 times the half-time of complete air replacement of the
242 chamber. According to Niinemets et al. (2011) this time allows for 94% of full system response
243 and it is a satisfactory approximation of the time required to reach a steady-state:

(2)

244
$$t_{ss} = 4 \frac{\ln(2) V}{Q_V}$$

245 where Q_V is the volumetric air flow rate ($m^3 \cdot h^{-1}$) into the chamber and V is the chamber volume
246 (m^3). Our system parameters gave a stabilization time t_{ss} of about 7 minutes. We hence chose to
247 start measurements 10 minutes after chamber closure to ensure sufficient time for mixing and to
248 facilitate overall automation. PTR-Qi-TOF-MS measurements in each sampling line (inlet and
249 outlet air) took 1 minute, of which only the last 30 seconds were kept to allow signal
250 stabilization. Each chamber was opened again immediately after the end of measurements.
251 Measurements were taken every hour and so during a complete cycle each chamber remained
252 closed for 12 minutes of 1 hour.

253 The flux of each BVOC was calculated based on the concentration difference of the compound
254 measured in the outlet and inlet air of the chambers:

255
$$F = \frac{(C_{out}(VOC) - C_{in}(VOC)) Q_V}{DW} \quad (3)$$

256 where F is the BVOC flux expressed in $\mu g \cdot g^{-1}(\text{biomass dry weight}) \cdot h^{-1}$, $C_{out}(VOC)$ and
257 $C_{in}(VOC)$ are the outlet and inlet BVOC concentrations in $\mu g m^{-3}$, DW is the dry biomass of
258 plants in g (leaves and/or ear organs) inside the chamber, and Q_V is expressed in $m^3 \cdot h^{-1}$.

259 **2.8. Net photosynthesis**

260 Equation 3 (Von Caemmerer and Farquhar, 1981) was used to calculate the net photosynthesis:

261
$$P_n = \frac{(\chi_{in}(CO_2) - \chi_{out}(CO_2)) Q_m}{S} \quad (4)$$

262 where Pn is the net photosynthesis ($\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$), $\chi_{\text{in}}(\text{CO}_2)$ and $\chi_{\text{out}}(\text{CO}_2)$ are the CO_2 dry
 263 molar ratios from chamber inlet and outlet air, respectively ($\mu\text{mol CO}_2 \text{ mol}^{-1}$), S is the leaf area
 264 (m^2), and $Q_m = V_{\text{mol}}(\text{air}) \times Q_V$ is the molar air flow rate (mol. s^{-1}).

265 2.9. Standard emission factors

266 As discussed in section 1, BVOC emissions are strongly affected by environmental factors and in
 267 particular temperature and light, which are hence always used in models as drivers to simulate
 268 BVOC emissions. However, individual BVOC species can respond differently to temperature and
 269 light. Some compounds depend only on temperature, notably those originating from storage
 270 pools, while others depend on light and temperature, in particular when linked with the
 271 photosynthesis pathway, such as isoprene. In order to normalise measured emissions for
 272 temperature and light, the standard emission factor was calculated by fitting the following
 273 equation from Guenther et al. (1995):

$$274 \quad F = E_S C_L C_T \quad (5)$$

275 Where E_S is the standard emission factor and F is the measured BVOC flux, both expressed in μg
 276 $\text{g}_{\text{DW}}^{-1} \text{ h}^{-1}$. C_T and C_L are coefficients describing respectively the temperature and light dependency
 277 of the flux. For BVOC compounds depending on light and temperature (model TP), such as
 278 isoprene, C_T and C_L were computed as:

$$279 \quad C_T = \frac{\exp\left[\frac{C_{T1}(T - T_S)}{R T_S T}\right]}{1 + \exp\left[\frac{C_{T2}(T - T_M)}{R T_S T}\right]}, \quad C_L = \frac{\alpha C_{L1} \text{PAR}}{\sqrt{1 + \alpha^2 \text{PAR}^2}} \quad (6)$$

280 with the empirical constants $C_{T1} = 95000 \text{ J mol}^{-1}$, $C_{T2} = 230000 \text{ J mol}^{-1}$, $T_M = 314 \text{ K}$, $\alpha =$
 281 0.0027 , $C_{L1} = 1.066$, and where T is the leaf experimental temperature (K), T_S is the leaf

282 temperature at standard conditions (303 K), R the gas law constant ($8.314 \text{ J mol}^{-1} \text{ K}^{-1}$), and
283 PAR the photosynthetically active radiation (PAR) flux ($\mu\text{mol}_{\text{photon}} \text{ m}^{-2} \text{ s}^{-1}$). For BVOC species
284 depending only on temperature (like monoterpenes, model Tonly), $C_L = 1$ and C_T was computed
285 as:

$$286 \quad C_T = \exp(\beta(T - T_S)) \quad (7)$$

287 with the empirical constant $\beta = 0.09 \text{ K}^{-1}$.

288 We fitted the measured flux for each individual BVOC with the two proposed dependency
289 models (eq. 5 and 6) and selected the model with the highest R^2 coefficient to estimate the
290 standard emission factors (SEF) at each developmental stage. We noticed that for the most
291 exchanged BVOC species the temperature dependency model C_T showed most of the time the
292 best R^2 (see Appendix C).

293 **2.10. BVOC tentative identification**

294 Identification was attempted with the software PTR-MS VIEWER 3 (Ionicon) coupled with the
295 NIST database. Exact identification of all ions presented in this study was not possible. Indeed
296 because of the principle of mass spectrometry, distinction of compounds having the same
297 molecular weight (isobaric) or the same chemical formula (isomeric) was not possible. Thus,
298 some compounds have been suggested for these masses based on the literature, and in
299 comparison with GC-MS measurements in a campaign conducted in 2018 at the same farm
300 (Kammer et al., 2019). The concentration of the m/z 43.018 compound strongly correlated (0.98
301 correction factor during ripening and senescence) with the m/z 61.029 (acetic acid), which
302 strongly suggest that the m/z 43.018 is a fragment of acetic acid. Based on the linear regression
303 slope between m/z 43.018 and m/z 61.029, a correction factor of 2.7 was worked out for acetic

304 acid concentrations. However, due to uncertainties in the evaluation of this correction factor, we
 305 did not systematically apply this correction factor to the data, but rather proposed an alternative
 306 evaluation of the acetic acid standard emission factor.

307 **Table 2. List of ions detected in this study for which a tentative identification is proposed. The measured**
 308 **mass-to-charge ratio (m/z) of the ions, their potential compounds and/or chemical formula as well as the**
 309 **measured m/z peak deviation from the theoretical m/z are presented. In bold compounds that are discussed in**
 310 **this study due to their relevant contribution to the overall fluxes or commonly cited in literature.**

311 a. The m/z 43.018 fragment of acetic acid led to a correction factor of 2.7 of acetic acid concentrations and fluxes.
312 This correction was not systematically applied but rather used to evaluate an alternative standard emission factor for
313 acetic acid in the discussion section.

314 b. Triazoles are documented degradation products of “azole” fungicides which were used on the wheat during the
315 spring and are known to be persistent in the ecosystem for several months.

316 c. Isotopic pattern consistent at m/z +1 and m/z +2
317

318 2.11. Wheat plant developmental periods

319 The experiment started at the maturation of the seeds. The beginning of plant senescence was
320 identified by a gradual decrease in the rate of photosynthesis as discussed in Taiz et al. (2015) or
321 Mozaffar et al. (2018). Three developmental periods have been distinguished: (1) Ripening,
322 during which the plants have constant photosynthetic activity, (2) Senescence 1, when the
323 photosynthesis decreases gradually but plants remain green and (3) Senescence 2, characterized
324 by no photosynthetic activity and plants turning progressively yellow (chlorosis) (Figure 1).
325 Chlorosis occurred from Jun 21st to 29th. Afterwards, the plants were cut at the base (about 20 cm
326 above the ground) simulating a harvest and measurements continued for 4 days.

327
328 **Figure 1. Temporal evolution of daily photosynthesis rate (mol CO₂ m⁻² day⁻¹) for the two wheat plants over**
329 **developmental stages. The striped zone corresponds to missing data.**

330 **2.12. Statistical analyses**

331 Data analyses were performed with R (RStudio 1.1.463, R version 3.5.2). A Student's t-test was
332 performed in order to evaluate whether the mean BVOC fluxes were significantly different from
333 zero. The fluxes were first averaged per day for each ion before performing the t-test to limit
334 temporal correlation. Similarly the mean fluxes and 95% confidence intervals for each ion were
335 computed as follows. For each day, ion and plant, the daily mean emission was first computed.
336 Then the averaged daily emission and the corresponding confidence interval were computed over
337 all days and both plants.

338 **2.13. Comparison with eddy covariance fluxes obtained in a nearby field the year before**

339 Given the limited number of replicates of our experimental design with only two wheat plants, no
340 statistically significant differences could be assessed to determine if there is a real effect of plant
341 development stages on BVOC emissions. To overcome this difficulty, we used Eddy covariance
342 (EC) fluxes measured with the same instrument at the same site one year prior to the present
343 study. These measurements by EC were taken during the same developmental stages and on the
344 same soil. These data were compared with the emission factors reported here and their variations
345 with plant developmental stages. These data were reported by Loubet et al. (2021), and are
346 referred to as the COV3ER-2016 dataset in the following sections. The data were taken from the
347 repository associated with this publication (<https://doi.org/10.15454/IRZ9XX>), and are not
348 detailed here.

349 Similarly to what was done in this study with net plant photosynthesis (Figure 1), ripening,
350 senescence 1, and senescence 2 periods were determined based on measured net ecosystem
351 exchange (Appendix D). For each of these periods, the standard emission factors estimated in this

352 study were used to compute the SEF-based whole plant VOC emissions using air temperature and
353 incoming photosynthetically active radiation as measured in COV3ER-2016 and equations 5-7.
354 These SEF-based whole plant VOC emissions were compared to hourly measured fluxes in
355 COV3ER-2016 which were scaled to $\mu\text{g g}^{-1}(\text{DM}) \text{h}^{-1}$ by multiplying the fluxes in $\text{nmol m}^{-2} \text{s}^{-1}$ by
356 $ion_mass \times 3600/1000 \times AGB$, where AGB is the total above ground biomass that was 1224 g
357 m^{-2} during that period.

358 **2.14. OH reactivity**

359 In order to evaluate the impact of the measured BVOC emissions, and their change with plant
360 stages, on the atmospheric chemistry, we evaluated their potential OH reactivity. Once emitted,
361 BVOCs can reduce the atmospheric reactivity mainly through their reaction with the OH radical,
362 which leads to an accumulation of other compounds such as methane. As the reactivity with the
363 OH radical strongly depends on the compound, the impact on atmospheric reactivity depends not
364 only on the emissions in terms of quantity but also on its composition. Thus, in order to evaluate
365 this impact, measured BVOC concentrations of the compounds identified in Table 2 were used to
366 calculate a theoretical OH reactivity ($cROH$ for calculated OH reactivity), which consists of the
367 sum of the reaction frequencies of all chemical compounds with OH. In practice $cROH$ was
368 calculated as the sum of the products of each compound concentration $[X_i]$ (in molecule cm^{-3}) by
369 the reaction rate coefficient of this compound with OH, k_{OH+X_i} (in $\text{cm}^3 \text{molecule}^{-1} \text{s}^{-1}$):

$$370 \quad cROH = \sum k_{OH+X_i}[X_i] \quad (8)$$

371 This calculated OH reactivity represents the expected total loss rate of OH, which is the inverse
372 of OH lifetime (s^{-1}). The relative uncertainty in $cROH$ was computed as the sum of relative

373 uncertainties in concentration (assumed equal to that on mixing ratio) and in k_{OH+X_i} which was
374 retrieved from the literature (see Table G1, Appendix G for details on k_{OH+X_i}).

375 **3. Results**

376 **3.1. Meteorological variation during the campaign**

377 Air temperature, photosynthetically active radiation (PAR) and air relative humidity (RH),
378 presented similar temporal variability for both wheat chambers, with a clear diurnal dynamics
379 pattern (Figure 2). On average, the air temperature during measurements was 2.3 °C larger inside
380 the chambers than above the canopy during daytime, but maximum differences reached 10°C,
381 denoting a noticeable impact of chambers on the plant microclimate. Maximum diurnal
382 temperatures remained in general between 30 and 40°C during the entire measurement period,
383 exceptions are: June 19th and 20th, during which the temperature increased above 40°C; and July
384 01st, during which the temperature remained below 30°C, concomitantly with a low PAR. It can
385 also be noted that the period from June 27th to July 2nd was marked by poor weather conditions
386 with some rainfall events. During that period, temperature presented a less pronounced diurnal
387 pattern with smaller temperature ranges. The PAR transmissivity of the chamber was evaluated to
388 be 89% (Pape et al., 2009). During daytime, PAR was on average 264 $\mu\text{mol m}^{-2} \text{s}^{-1}$ higher above
389 the canopy than inside the chambers. This was expected due to the presence of plants surrounding
390 the sensor in the chamber and the chamber itself. The relative humidity inside the chambers was
391 close to the one measured above the canopy (0.1 to 1.8% higher inside the chambers during
392 daytime) and hence was representative of the ambient air. Although the chambers were affected
393 by temperature, it is important to keep in mind that they remained open most of the time and

394 therefore the conditions inside the chambers were affected only during the short periods of
395 closure (12 minutes every hour).

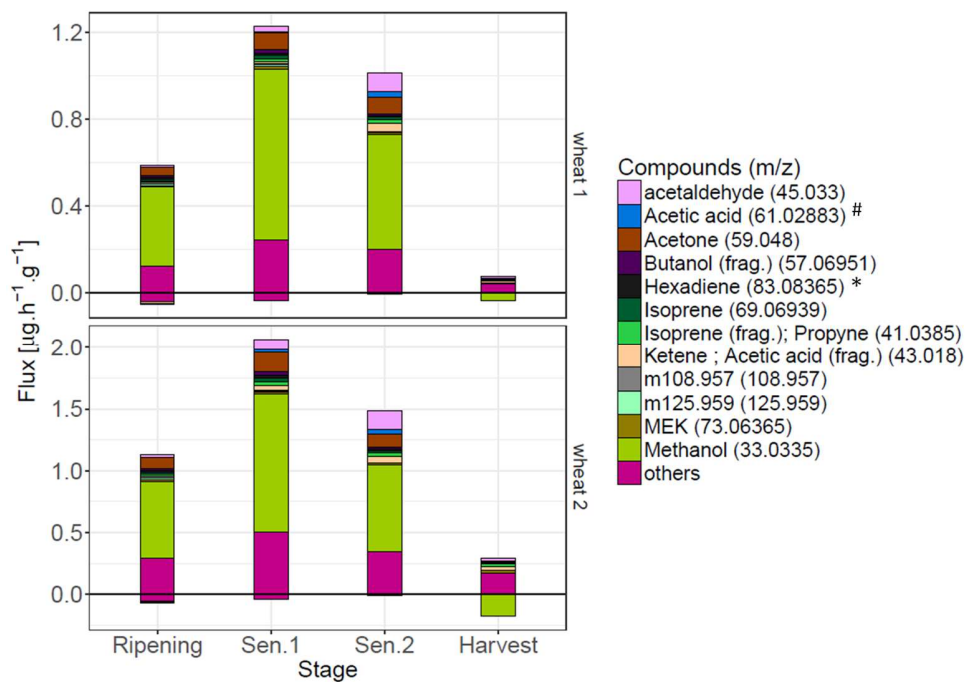

396

397 **Figure 2** Environmental conditions measured inside each chamber (*Wheat_1*, and *Wheat_2*) and at 1 meter
398 above canopy (ICOS site). PAR is given in $\mu\text{mol m}^{-2} \text{s}^{-1}$, relative humidity (RH) in %, rain in mm and
399 temperature in $^{\circ}\text{C}$.

400

401 **3.2. BVOC fluxes variation between developmental wheat periods**

402 The overall fluxes for the different developmental periods were generally well reproduced
 403 (qualitatively and quantitatively) between the two wheat plants (Figure 3). Although the overall
 404 BVOC emission rate was generally higher for *Wheat_2* plant, compared to *Wheat_1*, especially
 405 during *Ripening* (emission rate about twice as large), it remained of the same order of magnitude.
 406 For both plants the overall emission rate increased considerably during the first period of
 407 senescence (*Sen1*), decreased slightly during the seconde period of senecence (*Sen2*) and then
 408 declined abruptly after harvest. Net deposition was also observed, occurring mainly during
 409 *Ripening* and *Sen1*, and after harvest in the case of methanol.

410
 411 **Figure 3: Overall BVOC fluxes and composition for each developmental period of wheat plants. We show for**
 412 **comparison all 12 compounds that were among the 5 most exchanged during at least one developmental stage.**
 413 **7The category “others” includes the fluxes of all the other detected ions. # Acetic acid not corrected for m/z 43**
 414 **fragment. * Hexadiene could also correspond to a fragment of hexenol, a green leaf volatile (GLV).**

415 3.2.1. Qualitative BVOC fluxes variation

416 The most exchanged compounds for each developmental period and their contribution to overall
417 fluxes is depicted in Figure 3. All compounds that were among the top 5 compounds for each
418 developmental stage were selected, which represented 12 compounds in total. Together, these
419 major compounds represented about 80% of the net overall fluxes for each period, except harvest.
420 It can be noted that the composition of these most emitted compounds varies according to the
421 stage of development. In general, the most emitted compounds were: methanol, acetaldehyde,
422 acetic acid and acetone. Methanol was the most emitted compound for all periods, excepted
423 harvest, contributing to 60%, 59% and 49% of the overall BVOC flux during *Ripening*, *Sen1* and
424 *Sen2* (average of both chambers), respectively (see Appendix E). During *Ripening*, acetone was
425 the second most emitted compound, contributing 9% to the overall fluxes. During senescence,
426 acetone, acetaldehyde and acetic acid were the most emitted compounds after methanol,
427 contributing, respectively 8%, 3% and 1% to the overall net fluxes during *Sen1* and 8%, 10%,
428 3% during *Sen2* (see Appendix E). The remaining most emitted compounds each presented a
429 minor contribution to the overall fluxes. These ions were: m/z 69.069 (Isoprene; Methyl butenol
430 fragment), m/z 73.064 (Methyl ethyl ketone), m/z 83.084 (Hexadiene), m/z 108.957 (NO₄P) and
431 m/z 125.959 (NO₅P). The likely fragments of acetic acid, isoprene and butanol fragments, at m/z
432 43.018, 41.039, 57.069, respectively, also appeared among the most exchanged compounds. If
433 m/z 43.018 is accounted as acetic acid, this increases its contribution to the overall flux,
434 especially during *Sen2* where it reaches 7.3% of the overall fluxes (Appendix E). After harvest,
435 no compounds made a significant individual contribution to overall emissions, apart from
436 methanol which was mainly taken up and represented around 36% of the overall flux.

437 3.3. Fluxes temporal variation for individual BVOC

438 In general, the temporal fluxes variation of the most emitted BVOCs showed similar trends for
439 both wheat plants, despite a few differences being observed mostly after harvest (Figure 4).
440 However, *Wheat_2* showed emission rates higher than *Wheat_1* for all compounds, except during
441 *Sen2* for a few compounds. This difference was small for methanol but sometimes reached a
442 factor of 2 for hexadiene, acetone, acetaldehyde and isoprene. Clear diurnal dynamics were
443 observed for most compounds throughout the whole measurement period, except for acetic acid
444 during *Ripening* and *m/z* 108.957 and 125.959 ions during *Sen2*.

445 Several temporal trends can be observed among the different compounds. For example, some
446 compounds, such as methanol, acetaldehyde, acetone, isoprene, hexadiene and hexanal, presented
447 a gradual increase in emission rates during *Sen1*, while for *m/z* 108.957 and 125.959 ions,
448 emission rates gradually decreased at the beginning of senescence and reached a minimum during
449 *Sen2* and after harvest. Some small amounts of deposition were also noticed for some compounds
450 including acetaldehyde and acetic acid, occurring mainly during *Ripening* and *Sen1*. An
451 important deposition of methanol was observed mainly after harvest (Figure 4).

452

453 **Figure 4: Fluxes variation during the measurements period for some of the most exchanged compounds.**
 454 **Acetic acid was not corrected for m/z 43 fragment in this figure. Hexadiene could also correspond to a**
 455 **fragment of hexenol, a green leaf volatile (GLV).**

456 In order to better analyze the BVOC flux variation during the investigated periods, flux statistics
 457 over each stage and for each major compound are depicted in Figure 5. Overall, most compounds
 458 presented a larger averaged emission during *Sen1*. However we observed 5 types of behaviors: (i)
 459 a significant increase in average emission rates from *Ripening* to *Sen1*, followed by a significant

460 decrease during *Sen2*, and an abrupt decrease during harvest. This behavior was observed for
461 methanol, isoprene, hexenal, hexenone, hexadiene and *m/z* 101.092. In the case of methanol, the
462 flux turned from a net emission to a net deposition during harvest; (ii) a significant increase from
463 *Ripening* to *Sen1*, but a further increase during *Sen2*, and a drastic decrease during harvest. Such
464 was the case for acetaldehyde and acetic acid; (iii) a significant increase from *Ripening* to *Sen1*,
465 no significant variation during *Sen2*, and a decrease during harvest. This behavior concerns
466 acetone and MEK, the latter of which showed a peak in emissions two days after harvest; (iv) *m/z*
467 108.957 and 125.959 showed a significant decrease from *Ripening* to *Sen1*, from *Sen1* to *Sen2*,
468 and from *Sen2* to harvest; (v) no significant variation from *Ripening* to *Sen1* and to *Sen2*, and a
469 significant decrease from *Sen2* to harvest, being the case for monoterpenes.

470 BVOC emissions from plants are known to depend strongly on temperature and light conditions.
471 Given the large variation of these climatic factors between the different periods investigated, the
472 flux differences observed between the different periods could be either due to plant development
473 or to variation in temperature and light conditions. The standard emission factors (SEF),
474 calculated for each compound during each developmental stage (Figure 5) can be seen as fluxes
475 at standard conditions of temperature and light. Thus, the SEF allow comparing the fluxes
476 between the different developmental stages while eliminating the effects of temperature and light.
477 Figure 5 shows that SEF varied with plant development, but SEF variations were often different
478 when compared to the measured fluxes. Overall, SEF were higher during *Sen2*, contrary to the
479 measured fluxes which were either smaller or of similar magnitude to that during *Sen1*. Based on
480 SEF, different behaviors are identified: compounds for which SEF increased between periods
481 (acetaldehyde, acetic acid, acetone, isoprene, hexanal), those for which SEF decreased (*m/z*
482 108.957, 125.959 and monoterpenes), those for which SEF decreased during *Sen1* and then

483 increased during *Sen2* (methanol), and those for which only during *Sen2* SEF decreased (*m/z*
 484 101.092) or increased (MEK), while for hexadiene SEF remained stable among all periods.

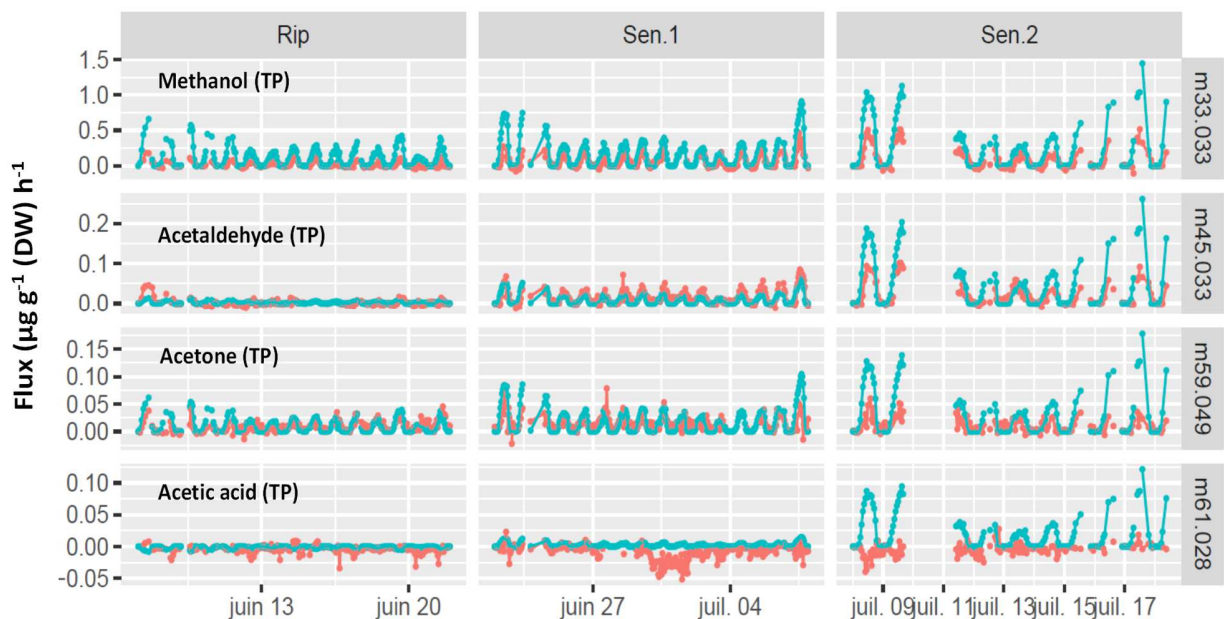

485
 486 **Figure 5. Top: Mean fluxes ($\mu\text{g g}^{-1} \text{h}^{-1}$) estimated for each developmental period (dots), corresponding 95%**
 487 **confidence interval (error bars), and mean fluxes over the entire measurement period (grey bar). Bottom:**
 488 **standard emission factor SEF at standard temperature (30°C) and light ($1000 \mu\text{mol m}^{-2} \text{s}^{-1}$) estimated for each**
 489 **developmental period (dots), corresponding 95% confidence interval (error bars), and SEF estimated for the**
 490 **whole measurement period (grey bar). SEF were obtained by fitting the measured flux with the temperature**
 491 **and light dependency (TP) or the temperature dependency only (Tonly) model given by (Guenther et al.,**
 492 **1995) as explained in the text. The R^2 coefficients are provided in Appendix C. SEF are not shown for harvest**
 493 **since there was no plant left in the chamber, apart from a small portion of the plant stems. Compounds were**
 494 **grouped by similar scale of mean emission to facilitate visualization, only the y-scale changes between groups.**
 495 **Hexadiene could also correspond to a fragment of hexenol, a green leaf volatile (GLV). For acetic acid, an**
 496 **alternative evaluation of the SEF is given in the dashed rectangle, for which m/z 43 was considered a fragment of**
 497 **acetic acid.**

498

499 **3.4. Comparison of modelled VOC fluxes with eddy covariance fluxes in COV3ER-2016**

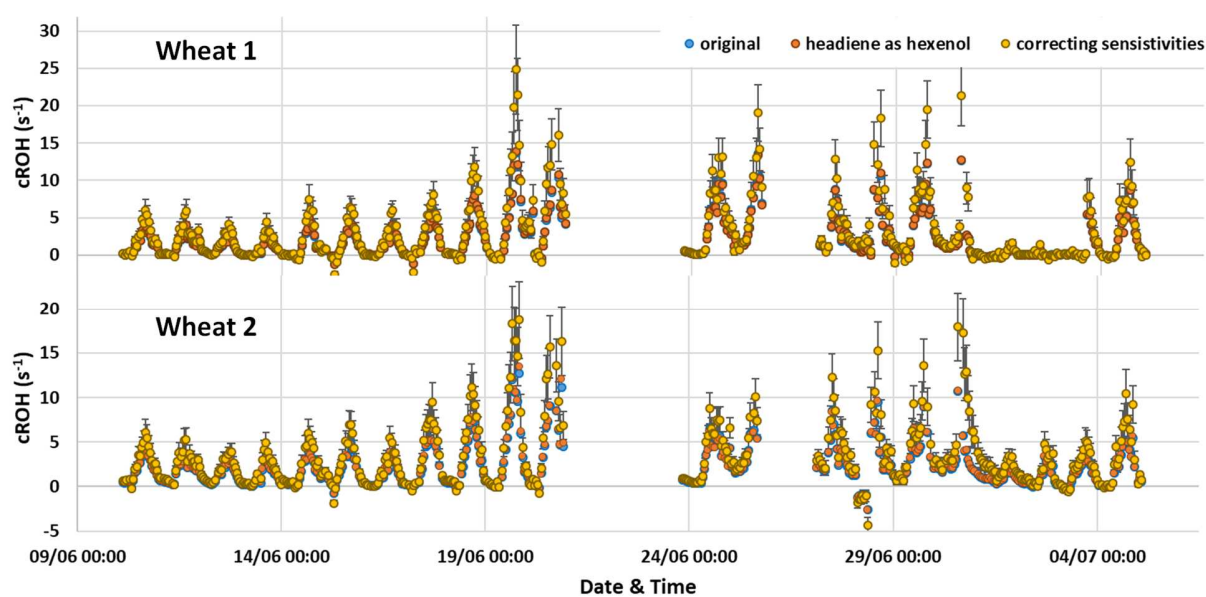

500 The SEF-based whole plant VOC emissions compared overall quite well with the COV3ER-2016
501 whole ecosystem fluxes (Figure 6). This is especially true for acetone, during ripening and early
502 senescence (*Sen1*), where with a slope of 0.8 and 1.1 in x-y regressions. Acetaldehyde SEF-based
503 whole plant VOC emissions were lower than whole ecosystem fluxes during *Rip* and *Sen1* (by a
504 factor of 5 to 2), while methanol plant fluxes were larger than whole ecosystem fluxes during the
505 same period (by a factor of ~2). During maturation and chlorosis (*Sen2*) the SEF-based whole
506 plant VOC emissions were systematically larger than COV3ER2016 whole ecosystem fluxes, by
507 a factor of ~2. For acetic acid, the SEF-based whole plant VOC emissions were systematically
508 larger than the whole ecosystem fluxes measured in 2016, although the orders of magnitude were
509 similar during *Rip* and *Sen1*. See Appendix F for details on linear regressions.

510
511 **Figure 6. Comparison between measured whole ecosystem VOC fluxes in COV3ER-2016 (red) and SEF-based**
512 **whole plant VOC emissions as derived in this study (blue) over the ripening (*Rip*), and senescence periods**
513 **(*Sen.1* and *Sen.2*). Here acetic acid fluxes are not corrected for m/z 43 fragments in both datasets.**

515 **3.5. OH reactivity**

516 ROH showed a diurnal variability (Fig. 6), with maxima during day-time and minima during
517 night-time, following temperature and PAR profiles, and thus the variability of total BVOCs
518 fluxes. Similarly to what was described in section 3.2.1 on BVOCs fluxes variation, ROH
519 remained of the same order of magnitude for both wheat chambers, with higher values during
520 *Sen1* (19th- 20th of June 2017). Average day-time ROH was similar for both plants with 2.4 ± 3.0 -
521 $2.5 \pm 2.4 \text{ s}^{-1}$ for wheat 1 and wheat 2, respectively. Maxima of 13.6 and 12.7 s^{-1} were recorded for
522 wheat 1 and wheat 2, respectively, at *Sen1*. Interestingly, higher values of ROH were recorded for
523 wheat 1 compared to wheat 2 during *Sen2*. These values remain in the lower ranges of OH
524 reactivity compared to other ecosystems, especially for measurements from dynamic chambers
525 (Bsaibes et al., 2020; Kim et al., 2011; Nölscher et al., 2013; Sinha et al., 2008), bearing in mind
526 that flow rates and chamber setups may modify the absolute values of the reactivity. We
527 evaluated that the uncertainty in calibration factors may lead to potentially underestimating the
528 OH reactivity by 50% with an overall uncertainty of 25% (Fig. 7).

529

530 **Figure 7. Calculated OH reactivity of the outlet air of the two wheat chambers. The effect of sensitivity**
531 **corrections and considering hexadiene as an hexenol fragment were evaluated here.**

532 Regarding the contribution of the main emitted compounds, methanol which was the most
533 emitted compound in general, accounted for 12 - 17% of the cROH, acetaldehyde represented
534 16%, while other mainly emitted OVOCs accounted for much less (acetone 0.3- 0.4%, acetic acid
535 0.3- 0.4%, etc.). However, even though isoprene had a minor contribution to the overall flux, its
536 contribution to cROH exceeded that of the mentioned OVOCs and reached 34- 36%, on average.
537 Overall, senescence induced a marked increase in OH reactivity of up to 4-fold during senescence
538 1 and 2-fold during senescence 2 compared to the ripening period.

539 **4. Discussion**

540 **4.1. Flux dynamics in relation with vegetation development**

541 Grass species, which include wheat as the most widespread cultivated grass species, are known to
542 emit relatively large amounts of oxygenated VOCs and some monoterpenes (Fukui and Doskey,
543 2000; Karl, 2009; Kirstine et al., 1998). Indeed, in this study oxygenated compounds dominated
544 the BVOC exchanges for wheat plants, with methanol being the most emitted compound during
545 all developmental periods followed by acetone, acetaldehyde and acetic acid (Figure 3). These
546 findings are also in good agreement with recent literature studies on grass species including
547 wheat (Bachy, 2018; Bachy et al., 2016; Gonzaga Gomez et al., 2019; Graus et al., 2013;
548 Mozaffar et al., 2018).

549 Our study showed that many BVOC species were released in larger amounts as the plants entered
550 senescence (*Sen1*), with emission rates decreasing thereafter as plant leaves turned yellow (*Sen2*).
551 It has been suggested that, for some BVOC, higher emissions occurring during senescence may
552 originate from the breakdown of cellular structures, cell organelles and macromolecules to

553 nutrients remobilization (Mozaffar et al., 2018; Rottenberger et al., 2005). In addition, chlorosis
554 is likely to increase BVOC diffusion through a degraded epidermal layer and cuticle (Mozaffar et
555 al., 2018). Thus, BVOC emissions are expected to rise as the leaves turn yellow and degradation
556 increases. However, our results showed a decrease in BVOC emissions during wheat chlorosis
557 (*Sen2*), which was probably due to unusual weather conditions during this period (i.e. heavy
558 rainfall and low temperatures). Indeed, emissions are likely to decrease when the temperature
559 decreases given the chemical properties of certain compounds, such as high solubility, or their
560 origin within plants, such as storage organs and enzymatic reactions (Cojocariu et al., 2004;
561 Hayward et al., 2004). Standard emission factors are in this case useful to distinguish the share of
562 flux variation due to temperature or endogenous plant variation. Most compounds showed an
563 increase in SEF during chlorosis (*Sen2*), except for *m/z* 101.092, 108.957, 125.959 and
564 monoterpenes. Thus, senescence induced higher emissions in wheat plants despite the presence of
565 rain, which may have increased deposition of soluble compounds (Bachy, 2018; Holzinger et al.,
566 2001).

567 In the following sections the most exchanged compounds are discussed more in details and
568 compared with literature findings.

569 **4.2. Compounds with increasing emissions during senescence**

570 **4.2.1. Methanol**

571 Methanol emission rates have already been found to increase with senescence for maize
572 (Mozaffar et al., 2018) and wheat plants (Bachy, 2018) in previous studies. In those studies,
573 emission rates of methanol increased slowly at the beginning of senescence reaching a maximum
574 emission rate during chlorosis. This is well in line with our results where methanol emissions

575 increased during the first phase of senescence (*Sen1*). However, emissions decreased during
576 chlorosis (*Sen2*), contrary to previous studies. Methanol emitted by plants is known to originate
577 from enzymatic reactions of pectin demethylation in the cell wall by Pectin Methyl Esterase
578 (PME) activity (Fall, 2003), a process occurring during growth but also during other events
579 impacting the cell wall structure such as senescence (Bachy et al., 2016; Karl et al., 2005;
580 Mozaffar et al., 2018). Thus, an increase in methanol emissions is expected with the progress of
581 senescence. Poor weather conditions during chlorosis, with a decrease in temperature and some
582 rain (Figure 2), hence explains the decrease in the measured methanol fluxes during chlorosis.
583 Indeed, due to the low temperatures, enzymatic activity was very probably inhibited, while
584 methanol solubility was improved during that period. Moreover, methanol being highly soluble
585 (≥ 100 mg/mL at 70° F; NTP, 1992) it is readily deposited on wet surfaces (Bachy, 2018;
586 Holzinger et al., 2001; Laffineur et al., 2012; Wohlfahrt et al., 2015). When normalized for
587 temperature, methanol emissions actually increased during chlorosis (*Sen2*), despite a probable
588 higher deposition due to the presence of wet surfaces.

589 **4.2.2. Acetone**

590 Increase in acetone emissions during plant senescence and biomass decay have previously been
591 reported in literature (Bachy, 2018; T. Karl et al., 2003; Mozaffar et al., 2018; Warneke et al.,
592 1999). Although acetone fluxes were bidirectional in the present study, average net flux always
593 resulted in net emissions for all the investigated periods. Contrary to our observations, in the
594 study of Bachy et al. (2018), acetone was on average deposited before the senescence of wheat
595 but was emitted during senescence. This difference may result from an acetone uptake by soil in
596 Bachy et al. (2016) since their measurements were at the ecosystem scale.

597 Schade and Goldstein (2001) found temperature to be the main environmental driver regulating
598 acetone emissions. This is consistent with the decrease in acetone emissions during the chlorosis
599 period, when temperatures were lower. Therefore, once normalized for temperature, emissions
600 increased during chlorosis and exceeded those of the first senescence period.

601 Acetone is known to be produced in plants via the cyanogenic pathway (Fall, 2003). In this
602 pathway, amino acids are converted into cyanogenic glycoside which is stored in the cell
603 vacuoles. Impacts against cell wall structure, resulting from the senescence process, may enhance
604 the contact of cyanogenic glycoside with β -glucosidase, a cell wall enzyme. This reaction leads to
605 acetone cyanohydrin that subsequently reacts with another cell wall enzyme, hydroxynitrile lyase,
606 to form acetone and hydrogen cyanide. This mechanism together with abiotic processes, through
607 the Maillard reaction that was also reported for acetone (Warneke et al., 1999), may explain the
608 observed increase in acetone emissions as senescence progresses. Indeed, Warneke et al. (1999)
609 showed that the thermochemical Maillard reaction can produce oxygenated VOCs (OVOCs) even
610 at typical ambient temperature (20-40°C). The wetting of leaves acts then as a desorption process
611 that replaces OVOCs molecules attached to the surface of plants by highly polar water molecules
612 in the aqueous phase. OVOCs can then be released to the air by Henry equilibrium. The wetting-
613 drying cycle was shown to be an efficient emission process that can last several tens of cycles
614 (Warneke et al., 1999). Since plants were not exposed to this wetting-drying cycle in our study,
615 relative humidity may have contributed to desorption of OVOC attached to the plants surface as
616 well demonstrated by Mozaffar et al. (2018), either through a water microlayer on the plant
617 surface or through interactions with polar water vapour molecules.

618 **4.2.3. Acetaldehyde**

619 The sharp increase in acetaldehyde emissions during leaf senescence in this study is in good
620 agreement with previous studies on maize (Mozaffar et al., 2018), wheat (Bachy, 2018) and tree
621 species (Rottenberger et al., 2005). Although acetaldehyde emissions from plants are highly
622 dependent on temperature, (Bachy, 2018; Cojocariu et al., 2004; Das et al., 2003; Hayward et al.,
623 2004; Karl et al., 2005), acetaldehyde emissions increased during senescence, and mainly
624 chlorosis, resulting from a senescence effect (Figure 5). Similarly to our observations, in the
625 study of Bachy (2018) over a wheat field, acetaldehyde emissions increased from the early stages
626 of senescence to reach higher levels during leaf chlorosis. In their study, acetaldehyde
627 contribution to the overall BVOC emissions during beginning of senescence (2%) and chlorosis
628 (6%) was similar to our findings, being 3% and 10% during *Sen1* and *Sen2*, respectively (see
629 Appendix E). Mozaffar et al. (2018), investigating BVOC emissions from senescent maize leaves
630 under controlled environmental conditions, found a delayed increase in acetaldehyde emissions,
631 with a pronounced emission increase only 2 days after leaf chlorosis started. Although missing
632 data do not allow a strict comparison of our study with Mozaffar et al. (2018), acetaldehyde
633 emissions increased on 24th and 25th June (Figure 4), which is about 2 days after photosynthesis
634 went down to zero and chlorosis started (Figure 1).

635 In terms of processes, the peroxidation of fatty acid by reactive oxygen species (ROS) might be
636 the main mechanism for the production of acetaldehyde (Jardine et al., 2009) during the
637 senescence period, as discussed by Mozaffar et al. (2018). It has also been suggested that
638 acetaldehyde emissions could originate from internal pools (Hayward et al., 2004), and increased
639 emissions during leaf senescence could result from the breakdown of cellular structures and

640 degradation of cell organelles (Rottenberger et al., 2005), although both studies were based on
641 tree species.

642 **4.2.4. Acetic acid**

643 The increase of acetic acid emissions during wheat senescence (Figure 5) observed here is
644 consistent with the study of Mozaffar et al. (2018) for maize leaf emissions. On the contrary, in
645 the study of Bachy et al. (2018), acetic acid fluxes resulted in an average net uptake during wheat
646 senescence. Given the ecosystem scale of their flux measurements, the authors invoked the
647 possible role of soil as an important acetic acid sink to explain the net uptake during senescence.
648 Indeed, it has been demonstrated that soil may act as an important sink for acetic acid (Bachy et
649 al., 2016). This hypothesis could explain the divergence between the ecosystem scale (Bachy,
650 2018) and plant scale studies (this study and Mozaffar et al., 2018). A further explanation would
651 be the ambient level of acetic acid. Indeed the deposition flux of a deposited compound will
652 increase with increasing its ambient level as is well known for instance with ammonia (Sutton et
653 al., 1995).

654 In terms of processes, the abiotic Maillard reaction was shown to be very effective for producing
655 acetic acid (Warneke et al., 1999). Mozaffar et al. (2018) showed good consistency of the
656 increase in acetic acid emissions with that mechanism during leaf senescence. Another process
657 that may favor acetic acid emissions is the decrease of leaf pH. Indeed, it has been demonstrated
658 that decrease in apoplastic pH leads to acetic acid emissions by displacing the acid-base
659 equilibrium towards the acid form (its conjugate base being acetate) and subsequently promoting
660 the aqueous-to-gaseous transfer by Henry equilibrium (Gabriel et al., 1999). Hill et al. (2002)
661 found a decrease in apoplastic pH with increasing leaf age (old leaves have a lower apoplastic pH
662 than young leaves). Thus, the increase in acetic acid emissions during senescence may have

663 resulted from a combination of a decrease of apoplast pH in senescent wheat leaves and the
664 Maillard reaction.

665 **4.3. Acetic acid and methanol uptake during wheat development**

666 Acetic acid uptake from other cereal species (Bachy et al., 2016; Kesselmeier et al., 1998) and
667 wheat (Bachy, 2018; Gonzaga Gomez et al., 2019) has been reported before and is well in line
668 with our results during *Ripening*. As already discussed, acetic acid exchanges result from both,
669 gas-to-liquid Henry equilibrium and acid-base equilibrium in the apoplast, as well as on any wet
670 surface. As a result, acetic acid can either be emitted or taken up by plants depending on the
671 concentration gradient between the plant and the atmosphere. If acetic acid concentration in the
672 atmosphere is larger than in the plant it is deposited. During plant development, acetate and acetic
673 acid may be converted to acetyl-CoA in the symplast and enter the plant metabolism, such as
674 Krebs cycle (TCA, TriCarboxylic Acids cycle) (Seco et al., 2007). Thus this process allows
675 maintaining a concentration gradient and, consequently, the continuous uptake of acetic acid by
676 the living plant. This process ends with senescence, which may explain the switch from
677 bidirectional acetic acid exchange to emission during that stage. Acetic acid deposition to wet
678 surfaces in the chamber does not seem to be a dominant process. Otherwise, we would have
679 expected some deposition after the rainfall events of 27 and 30 June, which was the case for
680 acetone and methanol. On the contrary, acetic acid deposition was clear in Sen2 when no rainfall
681 was observed (Figure 4).

682 Methanol uptake observed after harvest in this study may have resulted from its deposition and
683 dissolution on wet surfaces following rainfall events. Indeed, methanol which is soluble in water
684 can be taken up on water films that appear on the plant parts under wet conditions such as
685 reported before (Bachy, 2018; Holzinger et al., 2001; Laffineur et al., 2012; Wohlfahrt et al.,

686 2015). In addition, after harvest the amount of biomass in the cuvette was small, presenting no
687 significant methanol emission to compensate deposition.

688 **4.4. *m/z* 73.064 emission during harvest**

689 The *m/z* 73.064 ion may correspond to methyl ethyl ketone (MEK). It has been suggested that
690 MEK emissions from plants may come from reduction reactions of isoprene oxidation products
691 produced during oxidative stress (Cappellin et al., 2019). In this study the ion *m/z* 73.064 showed
692 a gradual increase in emission rates during the senescence stages and a noticeable peak in
693 emissions two days after cutting wheat plants (Figure 4). A possible explanation is the reduction
694 reaction of isoprene-hydroxy-hydroperoxides (ISOPOOH, an isoprene oxidation product) to
695 MVK and then to MEK by an enzyme, alkenal-one oxidoreductase (AOR), that is ubiquitous in
696 terrestrial plants (Canaval et al., 2020). These authors have shown that this MEK formation
697 process responds to stomatal opening in leaving plants. During senescence and after harvest the
698 AOR enzyme may be more accessible to the ambient air, because of cells breakdown during
699 senescence, therefore leading to the observed increase in MEK emissions at the senescence stage.
700 Moreover, the same study reports that AOR is present in stem flows (xylem and phloem), which
701 would explain the burst observed after harvest. This would be consistent with the observation of
702 much larger MEK than MVK fluxes at all stages. Unfortunately, ISOPOOH could not be
703 measured with our PTR-TOF-MS, as it requires a specific setup of the drift tube to minimize
704 metal-catalysed decomposition of ISOPOOH Canaval et al. (2020).

705 In addition, a significant difference in MEK emissions is observed between the two plants after
706 harvest. This is also observed for other compounds including isoprene. Since these plants belong
707 to the same variety, a possible explanation for these differences in emissions between the two
708 wheat plants may be an important soil spatial heterogeneity of the field and therefore a different

709 availability of nutrients, water and also light for each plant. These different conditions may result,
710 for each plant, in a more or less important production of isoprene as well as of the AOR enzyme
711 responsible for the reduction of ISOPOOH to MEK.

712 **4.5. Terpenes exchanges**

713 Isoprene emissions increased gradually as senescence started (*Sen1*) and decreased when wheat
714 plants entered chlorosis (*Sen2*) (Figure 4). However, when considering emissions in standard
715 conditions (SEF) an additional increase is found during chlorosis (*Sen2*) (Figure 5). Isoprene
716 increase with plant senescence has been reported before for wheat (Bachy, 2018) and maize
717 (Mozaffar et al., 2018).

718 Much smaller, but still significant, emissions were measured for the m/z 137.133 compounds
719 (potentially monoterpenes), generally an order of magnitude lower than isoprene emissions. A
720 clear significant decrease in standard emission factors is noticed when plants entered senescence
721 (Figure 5). This is consistent with literature where these compounds were found to present higher
722 emissions during the early developmental stages of leaves and reduced emissions upon maturity
723 and senescence for several plant species (Bracho-Nunez et al., 2011; Holopainen et al., 2010;
724 Mozaffar et al., 2018). This relation between monoterpene emissions and plant development has
725 been related to the antimicrobial or antifungal properties of these compounds and their great
726 importance in young leaves which are more susceptible to herbivores and pathogen attacks than
727 mature leaves (McCall and Fordyce, 2010). However, in the study of Bachy (2018) at the
728 ecosystem level, monoterpenes emissions increased when wheat plants entered senescence.
729 Monoterpenes emissions from soils have been reported before (Abis et al., 2018; Hayward et al.,
730 2001). Thus, the increase in monoterpenes emissions found in Bachy (2018) may have resulted
731 from soil emissions, which might explain the contradiction with our results.

732 **4.6. *m/z* 108.957 and 125.959: compounds decreasing emissions with wheat senescence**

733 Both *m/z* 108.957 and 125.959 compounds presented the same flux temporal trend with emission
734 rates decreasing gradually as plants entered senescence and reaching minimum values from the
735 second senescence period onwards (Figure 4). These ions may correspond respectively to
736 nitrogen compounds with the chemical formula NO_4P^+ and $\text{NO}_5\text{P.H}^+$. However, since this is not a
737 sure identification but rather some candidates that correspond very precisely to the mass, they
738 may actually correspond to a single compound since they are quite well correlated to each other.
739 To our knowledge, this is the first time these compounds are being reported in the literature
740 regarding studies on BVOC emissions from crops. It is unlikely that they are chamber
741 contaminants since they were not emitted by the empty chamber itself. In addition, if they were
742 coming only from the chamber, they would remain stable throughout the experiment, while a
743 clear daytime cycle is observed as well as a decrease during senescence.

744 **4.7. GLV exchanges during wheat development**

745 In earlier studies “green leaf volatiles” (GLV) compounds appeared to dominate BVOC
746 emissions from wheat plants (Butter et al., 1985; König et al., 1995; Piesik et al., 2011). The ions
747 *m/z* 99.079 and 101.092 were also detected in this study, and might represent hexenal and
748 hexenol compounds, respectively, which are part of the GLV. In contrast with earlier studies,
749 these compounds do not appear among the most emitted compounds in this study (Figure 3).
750 Hexadiene (*m/z* 83.084) may also be a fragment of hexenol which shows larger concentrations
751 than hexenol itself (Pang, 2015). Assuming *m/z* 83.084 is a fragment of hexenol, GLV fluxes
752 become much larger and in better agreement with the literature. GLV compounds have antibiotic
753 properties and inhibit the invasion of bacteria and other microorganisms into damaged tissues
754 (Croft et al., 1993). This is why they are known to be released from plants following mechanical

755 tissue damage (Fall et al., 1999). Thus, in previous studies plants may have suffered further tissue
756 damage, which could explain the larger emissions of these compounds.

757 According to our results, the average emissions of these compounds seem to increase with onset
758 of senescence, which is well in line with literature findings. GLV production is known to
759 originate from the oxidation of fatty acids, catalyzed by 13-lipoxygenase (13-LOX) (Dudareva et
760 al., 2013). Fall et al. (1999) found an increase in emissions of (Z)-3-hexenal as detached aspen
761 leaves dried out. The authors proposed that during leaf drying, cellular water levels declined until
762 cellular structures began to collapse. This collapse was likely to induce the formation of hexenal
763 and hexanal compounds by increasing the oxidation of fatty acids, such as α -linolenic acid, which
764 may be released from membrane lipids. Holopainen et al. (2010) reported GLV dominating
765 BVOC emissions during the later stages of senescence and leaf abscission of *Betula pendula*
766 Roth, and suggested that the disintegration of cellular organelles and dying cells were related to
767 these emissions. Mozaffar et al. (2018) also showed increased hexenal emissions during maize
768 leaf senescence, and suggested that it could result from an increase in fatty acid oxidation in order
769 to provide energy for the senescence process.

770 **4.8. Robustness of the inferred standard emission factors**

771 The comparison between SEF-based whole plant VOC emissions and COV3ER-2016 whole
772 ecosystem fluxes allows us to challenge the robustness of the SEF estimated in this study and
773 especially their evolution over the plant developmental stages. This comparison allows evaluating
774 the representativeness of the measurements made with the two chambers and the intra-specific
775 variability of the VOCs emissions, and also evaluating the variation of the VOCs emissions
776 during the investigated development stages of wheat. However, the eddy covariance method,
777 unlike the plant chamber measurements, takes into account not only plant VOCs exchange but

778 also soil exchange. In addition, we should bear in mind that different wheat varieties between the
779 two studies might explain some observed differences in VOCs emissions.

780 For methanol, the larger SEF-based whole plant VOC emissions (representative of the whole
781 plant emissions) compared to the whole ecosystem fluxes may be explained by a significant sink
782 at the ground surface, due for instance to methanol dissolution in soil water. Indeed, the
783 contribution of soil to methanol uptake, under wet or dew conditions often present at night, is
784 well documented in the literature (Bachy et al., 2016; Holzinger et al., 2001; Karl et al., 2004). In
785 COV3ER-2016, the soil water content at 10 cm was around 30% humidity in volume, which is
786 quite wet. The canopy wetness as measured by the wetness sensor indicated that around 20% of
787 the day the canopy was wet. Overall, ripening was the wettest period.

788 Regarding acetic acid emissions, the SEF-based whole plant emissions did not match the EC
789 fluxes. Similarly to methanol, this is most likely due to the strong contribution of the soil to acetic
790 acid uptake, which was probably high enough to dominate the exchange of this compound and
791 overlook plant emissions during senescence. Indeed, Bachy et al. (2016) showed that the soil was
792 an important sink for acetic acid.

793 For all compounds, the observed differences between SEF-based whole plant emissions and EC
794 fluxes, especially large during *Sen2*, may also be explained by the temperature gradient in the
795 canopy and source location. Indeed, if the air temperature is replaced by the soil temperature in
796 the SEF model to mimic emissions by the bottom of the canopy, the modelled fluxes of methanol,
797 acetaldehyde and acetone fit much better to the measured ones during the senescence 2 phase
798 (Appendix F, Figure F.3 and Table F.1). This may be an indication of *Sen2* emissions rather
799 coming from the bottom leaves that are decomposing the most. In the chamber measurements,
800 these leaves were exposed to the same temperature as the entire plant due to efficient mixing in

801 the plant cuvette, which is not the case for the whole canopy that exhibits a large temperature
802 gradient between the cooler ground and the hotter top of the canopy. Moreover, this temperature
803 gradient is likely to increase with senescence due to vanishing transpiration leading to a lower
804 capacity to dissipate solar radiation into evaporation.

805 Comparison of the SEF and γ_{age} estimated in this study, in COV3ER2016, in Bachy et al. (2020)
806 and in Guenther et al. (2012), shows high similarities in SEF between this study and Guenther et
807 al. for methanol and acetone, but lower SEF and higher γ_{age} for acetaldehyde in this study
808 compared to Guenther (Table 3). On the contrary, COV3ER2016 compares very well with
809 Bachy et al. (2012), both in terms of SEF and γ_{age} for methanol and acetaldehyde. For
810 acetaldehyde this study COV3ER-2016 and Bachy et al. all agree well in terms of SEF and γ_{age} ,
811 while acetone emissions are larger in COV3ER2016 than in the three other datasets, and γ_{age} is
812 lower than 1 in COV3ER-2016.

813 This comparison suggests that methanol emissions by chamber measurements give larger
814 emissions (by a factor of ~3 to ~4) compared to whole ecosystem fluxes, probably due to soil and
815 plant recapture which would correspond to a large fraction of the emissions. Moreover, the effect
816 of senescence on methanol emissions is negligible in chamber measurements but large and
817 consistent at the canopy scale (factor of 3). The reason is still unclear but may be linked to
818 increased soil emissions (or decreased soil and plant recapture) during senescence.

819 **Table 3. Standard emission factors (SEF) and γ_{age} compared to existing dataset for wheat. G2012 stands for**
 820 **Guenther et al. (2012), B2020 for Bachy et al. (2020) and COV3ER-2016 for Loubet et al. (2021).**

Compound	Standard emission factor $\mu\text{g m}^{-2} \text{h}^{-1}$				γ_{age} -					
	This study	COV3ER-2016		G2012	B2020	This study	COV3ER-2016		G2012	B2020
		Ta	Tsoil				Ta	Tsoil		
methanol	914	235	306	900	252	1.01	2.4	3.0	1.02	2.7
acetaldehyde	18	18	23	80	19	6.90	6.4	8.1	1.00	5.6
acetone	85	106	152	80	15	1.30	0.6	0.7	1.00	-

821

822 For acetaldehyde, whole plant emissions and whole ecosystem emissions are very similar and a
 823 quarter of what is used in Megan 2.1 for crops. Senescence consistently induced an increase in
 824 acetaldehyde emissions by a factor of 6 to 8 depending on the study, while Megan 2.1 did not
 825 attribute any aging effect on acetaldehyde emissions. This consistently suggests a revision of the
 826 emission factors and aging effects for acetaldehyde. For acetone, this study suggests Megan 2.1
 827 SEF are valid, while the aging factor is unclear and diverges between studies.

828 Overall, this comparison suggests a real effect of senescence on the exchange of VOCs from
 829 wheat plants leading to a clear increase in the emissions of acetaldehyde during this
 830 developmental stage, and for methanol but at the ecosystem scale only. It also indicates that the
 831 VOC fluxes measured on the two wheat plants in this study are well representative.

832 5. Conclusions

833 In this study, BVOC exchanges from wheat plants were investigated from ripening to senescence
 834 and after harvest, using 2 dynamic chambers, which constitutes a low number of replicates. With
 835 regard to the emissions composition during the different investigated periods, methanol was the
 836 most emitted compound (49 – 59% of the overall flux) followed by acetone, during ripening and
 837 beginning of senescence (7.5 – 8.2% of the overall flux), and acetaldehyde, during the chlorosis

838 phase of senescence (9.7 of the overall flux). We showed that the composition of BVOC
839 emissions varied with wheat plant development. We noticed an increase in the contribution of
840 acetaldehyde and acetic acid to the overall emissions as senescence progressed (from 1.6 to 9.7%
841 and from 1.9 to 7.3% of the overall flux, respectively). We also demonstrated that the amounts of
842 BVOC exchanges varied significantly from one development period to another. The overall
843 BVOC emissions appeared to be twice as large during senescence compared to ripening. In
844 general, once normalized for temperature and light conditions, emissions of the major compounds
845 increased as senescence progressed. After harvest, BVOCs were emitted in small (3 times less
846 than during the ripening on average) but significant amounts, most likely from wheat stems. This
847 suggests that after harvest, the wheat stems left in the field may be a non-negligible source of
848 BVOC. OH reactivity of the emitted BVOC was calculated and showed a small reactivity on
849 average compared to measurements in isoprene or monoterpenes emitter canopies. The OH
850 reactivity however showed a peak of 12 s^{-1} during the first stage of senescence and a significant
851 contribution after harvest. Overall, senescence induced a marked increase in OH reactivity of up
852 to 4-fold during senescence 1 and 2-fold during senescence 2 compared to the ripening period.

853 Our measurements lasted only 4 days after the harvest. In order to consolidate our results, it may
854 be important to reproduce these measurements under similar conditions (soil, climate, agricultural
855 practices) on the same species but using more measuring chambers to enable statistical analyses.
856 Moreover, since the impact on atmospheric chemistry is highly dependent on the species of
857 compounds emitted, a good characterization of the emissions, including low emitting compounds,
858 is necessary. It would therefore be very useful to use GC-MS or a fast-GC in conjunction with
859 PTR-MS BVOC flux measurements in order to carry out an accurate identification of the

860 compounds. This would allow to better attribute fragments in particular of acetic acid at m/z 43
861 and green leaves volatiles at m/z 83.

862 BVOC emissions, and in particular oxygenated compounds, varied in composition and amounts
863 with the development of wheat. This suggests that the current practice of assigning standard
864 emission factors (SEF) by default to the entire plant season without considering larger emissions
865 during plant senescence, may lead to an underestimation of BVOC emissions by wheat plants and
866 possibly other crop species.

867 Comparison between whole plant emissions and ecosystem scale emissions suggests that
868 methanol recapture in the canopy may represent a large fraction of the plant emitted methanol,
869 while acetaldehyde emitted at the plant and ecosystem scales are comparable between the two
870 approaches. It also clearly demonstrates a 5-to-8-fold increase of acetaldehyde emissions during
871 senescence.
