ABSTRACT

Creating invariant representations from an ever-changing speech signal is a major challenge for the human brain. Such an ability is particularly crucial for preverbal infants who must discover the phonological, lexical and syntactic regularities of an extremely inconsistent signal in order to acquire language. Within visual perception, an efficient neural solution to overcome signal variability consists in factorizing the input into orthogonal and relevant low-dimensional components. In this study we asked whether a similar neural strategy grounded on phonetic features is recruited in speech perception.

Using a 256-channel electroencephalographic system, we recorded the neural responses of 3-month-old infants to 120 natural consonant-vowel syllables with varying acoustic and phonetic profiles. To characterize the specificity and granularity of the elicited representations, we employed a hierarchical generalization approach based on multivariate pattern analyses. We identified two stages of processing. At first, the features of manner and place of articulation were decodable as stable and independent dimensions of neural responsivity. Subsequently, phonetic features were integrated into phoneme-identity (i.e. consonant) neural codes. The latter remained distinct from the representation of the vowel, accounting for the different weights attributed to consonants and vowels in lexical and syntactic computations.

This study reveals that, despite the paucity of articulatory motor plans and productive skills, the preverbal brain is already equipped with a structured phonetic space which provides a combinatorial code for speech analysis. The early availability of a stable and orthogonal neural code for phonetic features might account for the rapid pace of language acquisition during the first year.

SIGNIFICANCE STATEMENT

For adults to comprehend spoken language, and for infants to acquire their native tongue, it is fundamental to perceive speech as a sequence of stable and invariant segments despite its extreme acoustic variability. We show that the brain can achieve such a critical task thanks to a factorized representational system which breaks down the speech input into minimal and orthogonal components: the phonetic features. These elementary representations are robust to signal variability and are flexibly recombined into phoneme-identity percepts in a secondary processing phase. In contradiction with previous accounts questioning the availability of authentic phonetic representations in early infancy, we show that this neural strategy is implemented from the very first stages of language development.

AUTHOR CONTRIBUTIONS: G.D.L. conceived and supervised the project. G.G. implemented the experimental design. M.P. and G.G. collected the data. G.G. performed the analysis. G.G. and G.D.L. wrote the manuscript. A.F. provided the pre-processing tools and manuscript revision.

1 INTRODUCTION

2 A major, fundamental challenge for any brain is to build stable representations of a changing world. In particular
3 regarding speech, the subtle phonetic distinctions between "bog", "dog" or "big" must be perceived steadily despite
4 the large acoustic differences separating the raspy voice of a whispering elderly man and the fluty screams of a little
5 girl. Since the richness of the human lexicon is based on fine phonetic differences of this sort, how infants come to
6 discover them in a highly variable signal has long been the subject of debate.

7 Recent proposals, based on neuronal recordings during object (Behrens et al., 2018) and face recognition (L. Chang
8 & Tsao, 2017), suggest that in order to deal with signal inconsistency, the brain factorizes the input into independent
9 and orthogonal low-dimensional components, each coding for a different dimension of variation. The components
10 are thought to be subsequently recombined to yield unified percepts. Can such an account be applied to speech?
11 Apart from any neural consideration, linguists have proposed an abstract definition of phonemes as bundles of
12 orthogonal elementary features, each corresponding to a binary code that summarizes an articulatory dimension
13 and its acoustic correlates (Halle, 2013). For instance, the phonemes "b" and "d" from the example above share all
14 parameters (+consonantal and -vocalic, +obstruent and -sonorant, +voiced, etc.) except for the place of articulation
15 (+labial/-alveolar vs. +alveolar/-labial). Given their linguistic characteristics (distinctive, minimal and combinable),
16 these features might correspond to the basic decomposition axes harnessed by the brain to overcome speech
17 variability. In the last years, high-resolution intracranial recordings on adults (Mesgarani et al., 2014) and fMRI adult
18 data (Arsenault & Buchsbaum, 2015) have provided evidence in line with this hypothesis: a partial neural
19 specialization for phonetic features was observed during passive listening of speech.

20 For what concerns infants however, vocal production develops slowly during the first year through vocal plays in an
21 effort to imitate ambient language (Kuhl & Meltzoff, 1996). Babbling, which signals the beginning of a relatively
22 controlled articulation, enriches vocalizations only from the second semester. Given their initial inability to produce
23 most phonemes, can preverbal infants use a code originally defined by articulatory gestures? The prevailing view
24 rejects such an eventuality. During the first semester infants are thought to analyze speech merely along domain-
25 general spectrotemporal dimensions (Kuhl, 2004). They would gradually converge to an adult-like phonetic space
26 only later, through native language exposure and the motor feedback provided by the progressive acquisition of
27 articulatory/motor skills (Kuhl et al., 2008; Westermann & Reck Miranda, 2004; Vilain et al., 2019). Yet, from birth
28 on, infants are capable of perceiving stable speech segments despite acoustical variations. For instance, they identify
29 phonemes independently of the speaker (Dehaene-Lambertz & Pena, 2001) or the co-articulation context (Mersad
30 & Dehaene-Lambertz, 2016) and can track phonologic information across changes in prosody (Fló et al., 2019).
31 Moreover, words start to be stored at 6 months, thus earlier than predicted by mainstream accounts (Tincoff &
32 Jusczyk, 1999; Bergelson & Swingley, 2012). By revealing the capacity to overcome signal variability, these

33 observations prompt to reconsider the format of early speech encoding. We hypothesized that pre-babbling infants
34 factorize the speech signal along independent low-dimensional components, creating a structured phonetic space.
35 The latter would (a) account for the refined linguistic abilities documented in very young infants (Dehaene-Lambertz
36 & Gliga, 2004); and (b) facilitate the discovery of phonetic regularities beyond surface differences thereby providing
37 the ideal basis for lexicon acquisition.

38 To test our proposal, we exposed twenty-five 3-month-old infants to 120 natural consonant-vowel syllables and
39 examined their event-related brain potentials (ERPs) using time-resolved multivariate pattern analyses. We first
40 assessed whether linear classifiers could separate neural responses according to phonetic distinctions. We then
41 examined how decoders trained on particular data subsets performed once a given variation was controlled. This
42 analytical procedure was crucial to the aim of the study, in that the level of generalization beyond the training set
43 enabled to determine the precise format of the neural codes underlying decodability (Kriegeskorte & Douglas, 2019)
44 At a minimum, we expected linguistic and speaker information to be encoded in parallel, as suggested by previous
45 behavioral and EEG studies (Kuhl, 1979; Dehaene-Lambertz & Pena, 2001). In other words, we expected estimators
46 trained on ERPs to syllables produced by a female voice to obtain similar results when tested on ERPs to syllables
47 pronounced by a male speaker. We then examined generalization performances across co-articulatory contexts (e.g.
48 are syllables containing “i” and “o” processed through a common consonantal code?) and across featural dimensions
49 (e.g. are both the obstruent “b” and the sonorant “m” encoded as “labial”?). Only a complete generalization along
50 all these steps can assure that infant speech encoding is ultimately based on phonetic features. Furthermore, tracing
51 the time course of the generalization patterns and analyzing class confusability gave us the opportunity to elucidate
52 whether consonants and syllables were deconstructed into, or reconstructed from, elementary parts.

53 RESULTS

54 Experimental sessions lasted about 1 hour with a total of ~3100 stimuli presented to each baby. Syllables were
55 chosen to independently vary the consonantal dimensions of manner (obstruent vs. sonorant) and place of
56 articulation (labial vs. alveolar vs. velar). Each consonant was coupled with two vowels (/i/ and /o/) and produced
57 by a male and a female speaker in five distinct utterances to ensure acoustic and co-articulatory variability across
58 tokens with the same phonetic profile (Figure 1A).

59 The dimensions of manner and place of articulation were chosen due to the different levels of consistency
60 characterizing their acoustic correlates: whereas manners are reflected in prominent spectrotemporal prototypes
61 (Stevens, 2000), the acoustic cues for place are more subtle (Shannon et al., 1995) and complex (Smits et al., 1996),
62 hence fundamentally dependent on the context of production (Fowler, 1994). Following these observations, our
63 ability to detect stable place contrasts across different production circumstances is commonly seen as the ultimate
64 challenge to address in order to understand human speech perception. Intriguingly, although able to form place-

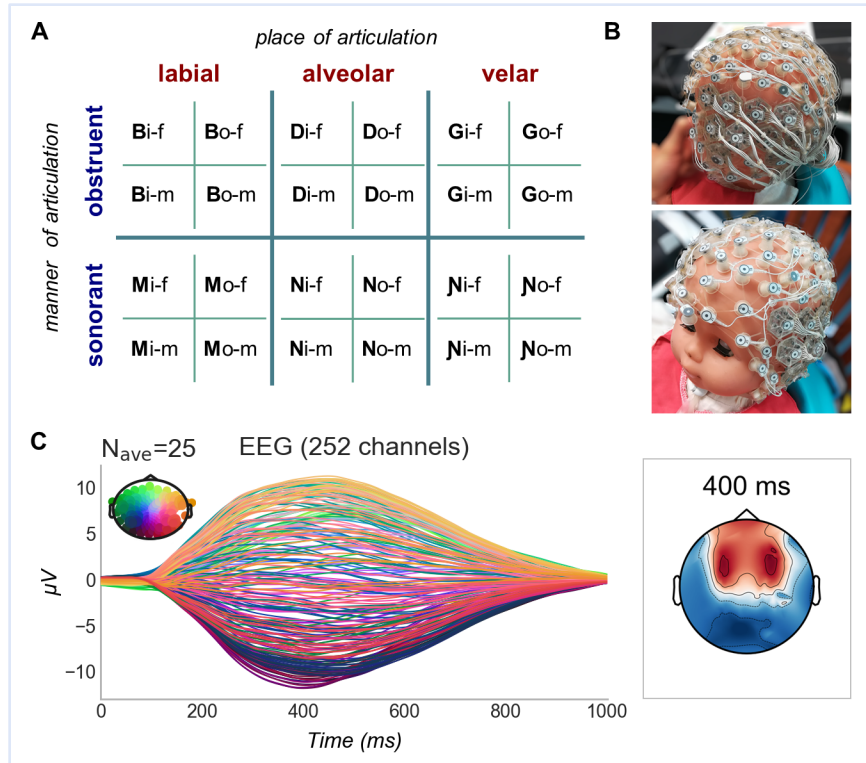

Figure 1: Experimental set-up and average syllable-related potential.

(A) Stimuli sub-conditions and their phonetic characteristics (f=female, m=male voice).

(B) 256 channels super-high-density net on the head of an infant manikin: tight grids of custom electrodes are arranged over the auditory linguistic areas of the superior temporal lobe (see also Figure S2).

(C) Grand average ERP: all conditions are pulled together.

65 based categories, animals have been shown to process place contrasts in a context-dependent way (Sinnott &
 66 Gilmore, 2004). An initial investigation of the similarity structure embedded in our stimuli set (Figure S1) confirmed
 67 the diverging nature of manner and place acoustic cues. Along an average sound duration of 400ms, the auditory
 68 pairwise dissimilarity of the stimuli was best described by manner of articulation distinctions up to 140ms (i.e. during
 69 the consonantal portion) and later by the vowel (Figure S1D). Acoustic similarities were additionally shaped by voice
 70 gender throughout the entire syllable, while they did not have any straightforward relationship with the place of
 71 articulation (Figure S1D).

72 Infant ERPs were recorded with a high-density custom net featuring 256 channels (Figures 1B and S2; see also Figure
 73 1C for the grand average across all syllables). While the intensive electrode coverage combined with the thinness of
 74 infant skulls maximized the spatial resolution of our recordings, univariate analyses are poorly suited for separating
 75 the activity of neuronal clusters that are spatially close. We thus opted for a more powerful multivariate analysis
 76 approach (Stokes et al., 2015): we trained and tested series of linear estimators on brief (20ms) consecutive windows
 77 all along the high-density ERPs. Our goal was to define the granularity of the infant coding scheme for speech: is it
 78 syllabic, phonetic or featural?

79

80 **Successful classification is achieved on the basis of dynamic and discrete neural patterns**

81 We first assessed whether infant neural responses were separable according to phonetic classes. Figure 2A-B show
82 that obstruents were distinguished from sonorants starting from 80ms after syllable onset ($p_{\text{clust}} = 0.0001$; peak
83 performance observed at 200ms: $\text{AUC} = 0.735 \pm 0.08$, chance = 0.5), while places of articulation were reliably classified
84 over two time windows: 220-480ms ($p_{\text{clust}} = 0.0001$; peak at 260ms: $M = 0.545 \pm 0.039$); and 540-720ms ($p_{\text{clust}} = 0.0028$;
85 peak at 640ms: $M = 0.534 \pm 0.042$). As for what concerns vowels, the two alternatives in our design (/i/ and /o/) differ
86 in both height and backness, precluding the isolation of phonetic sub-classes. Nonetheless, Figure 2C shows that
87 vowel identity was reliably discerned in between 260 and 600ms ($p_{\text{clust}} = 0.0001$; peak at 480ms: $M = 0.596 \pm 0.08$,
88 chance = 0.5) and from 760ms onwards ($p_{\text{clust}} = 0.0001$; peak at 860ms: $M = 0.56 \pm 0.067$, chance = 0.5).

89 To fully characterize the neural dynamics underlying such performances, the same classifiers were systematically
90 tested on their ability to decode across time. In case a neural activation is maintained or recursive, a successful
91 estimator (which is specific to a certain pattern of brain activity) will achieve above-chance scores at multiple time
92 points (King & Dehaene, 2014). Figure 2D illustrates how classifiers generalized only over a limited amount of time
93 lags, indication that the neural activity was progressing along a functional pathway. Concretely, the “cone” shape
94 arising from the generalization matrices discloses the retrieval of evolving neural codes: the activity supporting
95 classification was either transferring across cortical regions, transformed within the same region over time or both.
96 Presumably, the mild widening of the generalization performance observable in the second portion of the trial might
97 denote a change in the representational format reached relatively late after syllable onset.

98 We started to objectivize these interpretations by using classifier weights to reconstruct informative activity patterns
99 (see Methods). Discriminative activity was diffuse over the scalp, resembling the auditory ERP topographies arising
100 from multiple perisylvian sources that are typical of this age (Figure S3). Crucially, substantiating the occurrence of
101 distinct encoding stages, informative clusters were qualitatively different during the first and second time-windows
102 that provided reliable classification. Change was particularly appreciable in the individual topographies (Figure S3A-
103 B) which are free of the blurring effect created by averaging across participants. We additionally observed that
104 sensors supporting manner and place classification were somewhat separable (Figure S3); and found significant
105 differences between brain activity patterns precisely distinctive for either labials, alveolars or velars (Figure S4,
106 where a detailed overview of place-informative activations is also reported). These findings uncover that infant
107 syllable perception is supported by discrete and local, although distributed and partially overlapping, neural
108 responses, as described for adults (E. F. Chang et al., 2010; Correia et al., 2015).

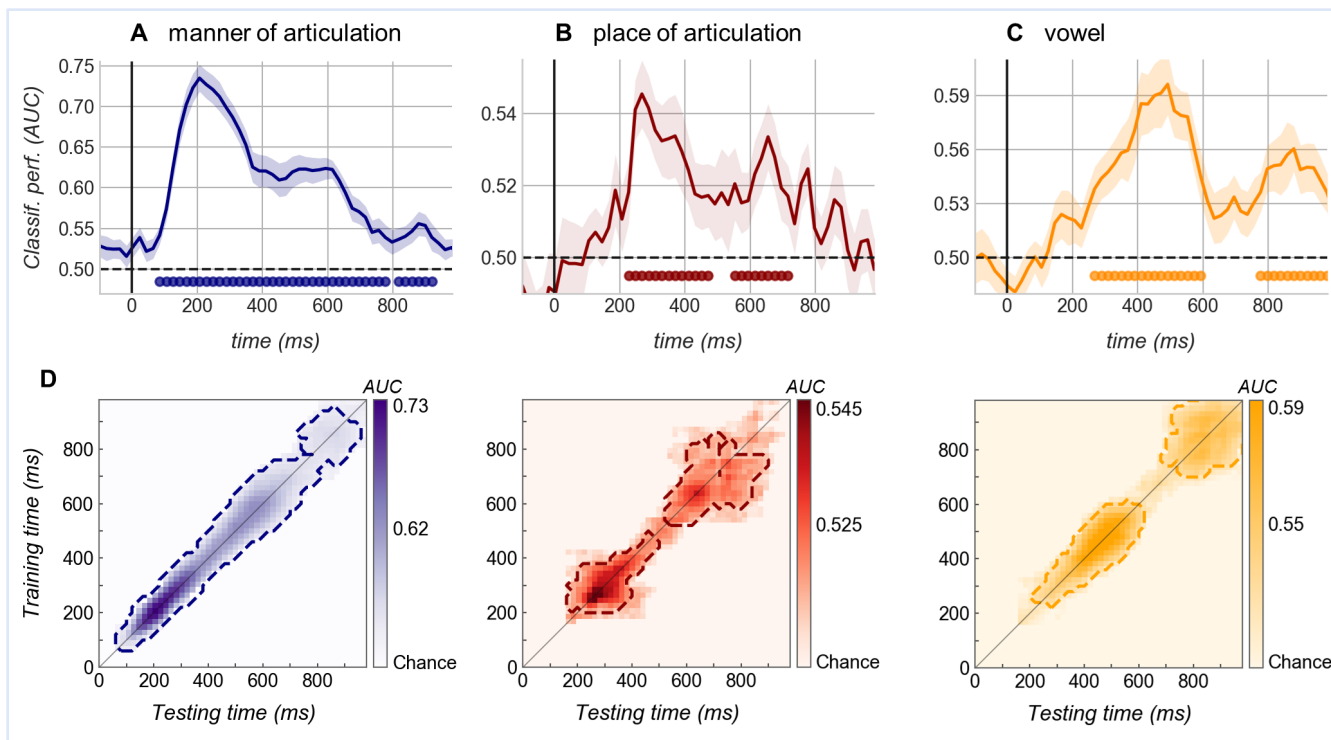

Figure 2: Classification performances of estimators trained on single time windows (20ms) along the ERP.

Top: Estimators are tested at the trained time sample. Shaded areas correspond to the standard error (SEM) across subjects, dotted black lines mark theoretical chance level and filled circles indicate significant scores (cluster-corrected t-test). (A) Performance of classifiers trained on manner distinctions: obstruents (/b/, /d/, /g/) vs. sonorants (/m/, /n/, /ŋ/). (B) Performance of classifiers trained on place distinctions: labials (/b/, /m/) vs. alveolars (/d/, /n/) vs. velars (/g/, /ŋ/). (C) Classification of vowel identities: /i/ vs /o/. (D) Temporal generalization matrices: each panel displays above-chance decoding scores of estimators trained on a single time window (y-axis) and tested at every possible time sample (x-axis) along the ERP. The diagonal thin lines demark classifiers trained and tested on the same time sample. Dashed contours indicate significant clusters (manner: $p_{\text{clust}}=0.0001$; place: $p_{\text{clust}}=0.0001$ and 0.0028 , vowel: $p_{\text{clust}}=0.0097$ and $p_{\text{clust}}=0.0108$).

109 **A stable code across speakers and co-articulated components**

110 Second, we examined the invariance of the neural code by training new sets of manner and place estimators on a
 111 single context (e.g. stimuli spoken by the female voice) and testing them on the alternative untrained condition (e.g.
 112 stimuli pronounced by the male voice). We considered the speaker context in a first analysis and the co-articulation
 113 in a second analysis. Since several adult and infant studies have shown that linguistic and non-linguistic information
 114 are encoded separately from an early processing stage (Formisano et al., 2008; Bristow et al., 2008), we expected
 115 full generalization across voice genders. Concerning the co-articulatory context, either infants computed only holistic
 116 syllable representations – in that case no generalization should be observed (e.g. an estimator that discriminates
 117 “bo” versus “do” on the basis of a whole-syllable code would perform at chance when tested on “bi” versus “di”) –

118 or consonants are encoded independently of the subsequent vowel, leading to successful cross-condition
119 classification.

120 For manner, the timing of cross-context decoding was virtually identical to that seen in the overall analysis, and the
121 accuracy only marginally reduced (Figure 3A; Tables S1 and S2). Such generalization proves that the infant brain
122 encodes manner features uniformly and irrespective of harmonic particularities, corroborating and extending
123 previous behavioral evidence from older infants (Hillenbrand, James, 1983). Remarkably, clear generalization across
124 voices and vowels was obtained also for place (Figure 3B). The time-course of classification, with two distinct
125 decodable periods, and its accuracy were comparable to those achieved in the initial analysis (Figure 3B, Tables S1
126 and S2). Since the acoustic cues for place vary considerably with the context (Liberman et al., 1967; Dorman et al.,
127 1977), these cross-condition performances clearly reveal that the infant brain is able to extract an invariant phonetic
128 code beyond acoustic differences, even in the challenging case of place contrasts.

129 Complementarily to these results, vowel estimators trained on single manner or place conditions fully generalized
130 to the alternative contexts (Figure 3C and Table S1). Thus, the cross-decoding patterns observed so far demonstrate
131 that syllables are not perceived holistically but are broken down into sub-components independently of the co-
132 articulated vowel for consonants, and consonantal features for vowels.

133 **Syllables are factorized into phonetic features, which are secondarily integrated into consonant codes**

134 Note that holistic and unrelated representations of each of the six consonants might suffice for classifiers to sort
135 trials in arbitrary subsets (e.g. /b/,/d/,/g/ vs /m/,/n/,/ŋ/), as done in the previous sections. Crucially, if the infant
136 code for speech is truly based on phonetic features, successful classification should be obtained for one featural
137 dimension regardless of the variation in the other phonetic domains. That is to say, estimators would retrieve the
138 same manner code across labials, velars and alveolars and the same place code in obstruents as in sonorants. To
139 evaluate this possibility, we trained sets of estimators at one featural context (e.g. manner classifiers were trained
140 only on labials) and tested them *within* the same (labials) and *across* untrained phonetic contexts (e.g. alveolars or
141 velars). If the code was based on invariant features, the two tests should yield similar performances.

142 This criterion revealed two distinct stages (Figure 4A): during an early time-window, both manner and place
143 estimators achieved successful generalization, with a classification accuracy approaching that obtained within the
144 trained condition. Initial phonetic representations are therefore based on an orthogonal code for phonetic features.
145 Beyond ~450ms however, classification performance was significantly lower across featural domains as compared
146 to within, suggesting a change in the representational format. Particularly, cross-condition decoding was impossible
147 for place, while manner information was more resilient but nevertheless altered by the variation in place context
148 (Figure 4A). We hypothesized that secondary processing stages encompass the combination of multiple elementary
149 dimensions, i.e. during this later time window features might be merged into a broader code.

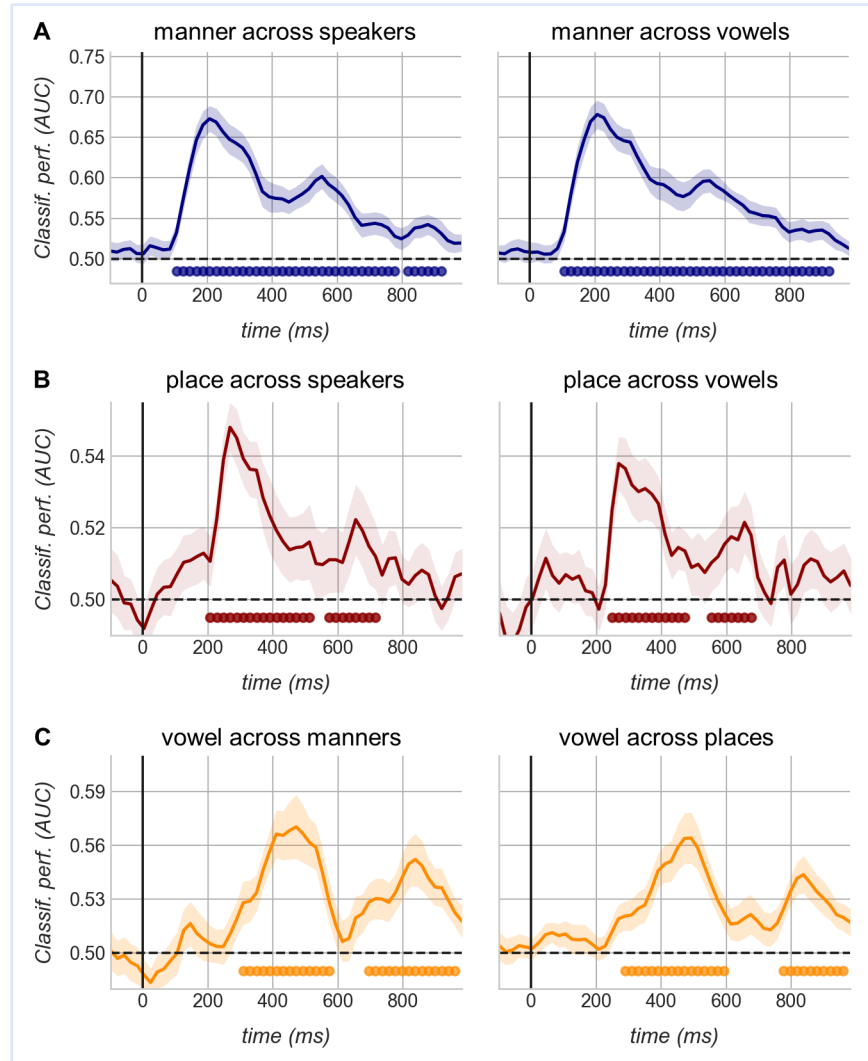

Figure 3: Cross-condition decoding.

(A) Left: generalization of manner estimators across voice conditions: classifiers trained on syllables produced by one speaker are tested on stimuli uttered by the other speaker. Right: generalization of manner estimators across vowel conditions: classifiers trained on consonants associated to one vowel are tested on syllables containing the alternative vowel. (B) Same as A, but for place estimators. (C) Left - vowel classification across manners: classifiers are trained on obstruents then tested on sonorants and vice versa. Right - vowel classification across places: vowel estimators are trained on one place condition (e.g. labials) and tested on the other two (e.g. alveolars and velars). Shaded areas correspond to the standard error (SEM) across subjects; dotted black lines mark theoretical chance level. Filled circles indicate scores significantly above-chance (exact p-values are reported in Table S1). Performances from all possible training/test directions are averaged.

150 To gain additional evidence on a secondary integration stage, we trained algorithms on whole syllable identities (i.e.
151 12 labels: “bi” vs “bo” vs “di” vs “do” vs “gi” vs “go” etc.) and explored their error patterns at test. In this analysis
152 above-chance accuracy scores (Figure S5A) are difficult to interpret per-se, as class separation might be driven by
153 either one or a mixture of stimuli sub-components. Between-class confusion, on the other end, provides exhaustive
154 information about all the facets of the stimuli encoded by the brain at a given moment. For instance, whereas neural
155 codes based on the whole syllable would produce a purely diagonal confusion matrix, representations based on the
156 identity of the phonemes (i.e. idiosyncratic combinations of manner and place features) would trigger conspicuous
157 mislabeling among pairs of stimuli sharing the same consonant. Using multiple linear regression, we tested whether
158 and when pairwise neural syllable confusion (Figure 4B-left and S5A-bottom) was explained by either consonant
159 and/or whole-syllable codes (Figure 4B-middle) once manner, place and vowel distinctions were entered as variables
160 of non-interest (Figure S5B-top). Complementarily with the decoding outcomes in Figure 4A, the consonant
161 regressor did significantly predict the patterns of neural separability, but *only* in between 500 and 700ms (Figure 4B-
162 right; $p_{\text{clust}} = 0.006$). Conversely, the syllable regressor never reached significance (Figure 4B). Thus, following the
163 encoding of orthogonal features, place and manner codes were integrated into comprehensive consonant
164 representations.

165 **Consonant and vowels remain separate**

166 Lastly, we queried a possible interconnection between consonant and vowel processing. The results obtained so far
167 contain a few interesting hints in this regard. As shown in Figures 2 and 3, vowel decodability follows a double-peak
168 pattern very similar to that observed for consonantal dimensions, but peak scores are achieved markedly later and
169 at times when consonantal place is hardly discriminable. Together with the invariance of vowel codes across
170 consonantal features (Figure 3C), these observations reveal that infants encoded the two phonemes composing the
171 stimulus orderly and individually.

172 As a final step, we tested whether the two phonemes were merged into a syllabic unit. Using a similar logic as above,
173 we compared the performance of consonant and vowel estimators *within* and *across* vowel and consonant
174 conditions. The presence of an integrated syllabic code would generate a drop in performance across context. As
175 displayed in Figure 4C, no interaction was found, suggesting that consonant and vowel representations were kept
176 separated, at least until 1 second after syllable onset.

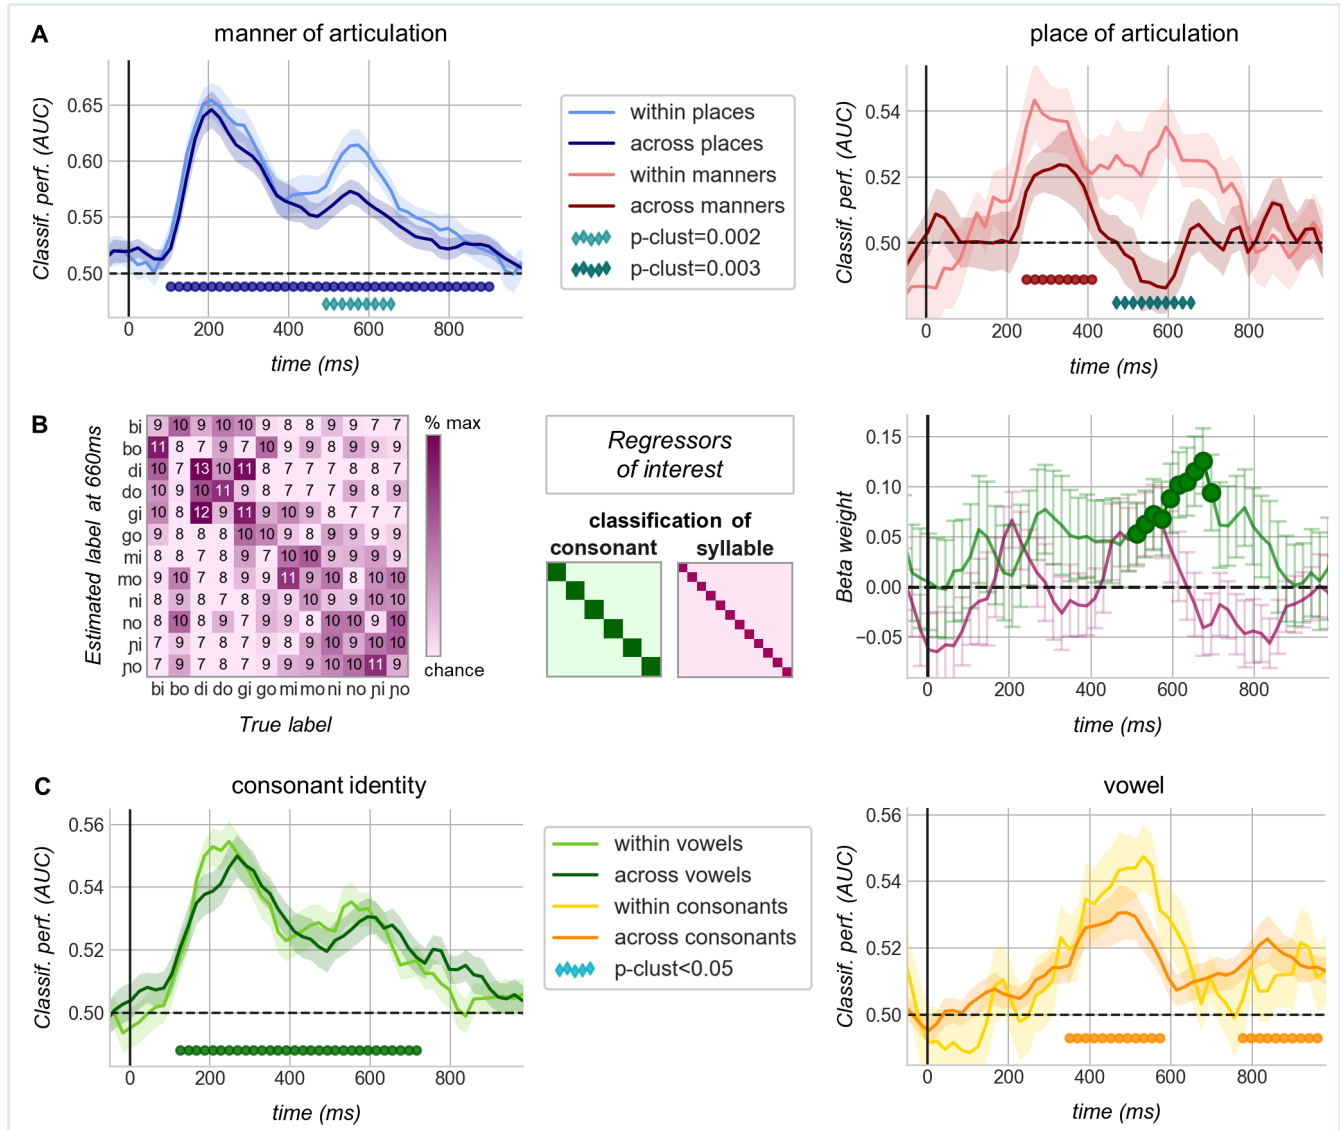

Figure 4: Orthogonal feature codes are merged into phoneme identities at a late stage of processing.

(A) Time-resolved performance of estimators trained on a single phonetic feature (e.g. manner estimators trained on labials: /b/ vs. /m/). In light colors: classification within the trained condition (e.g. test on labials); in darker colors: performance at novel phonetic contexts (e.g. test on alveolars: /d/ vs. /n/, and velars: /g/ vs. /ŋ/). Scores from all possible training conditions or train/test directions are averaged. Shaded areas correspond to the SEM across subjects. Filled circles indicate significant generalization across contexts (100-900ms: $p_{\text{clust}}=0.0001$ for manner; 240-420ms: $p_{\text{clust}}=0.001$ for place). Diamonds indicate higher performance *within* as compared to *across* conditions (exact time window of significance for manner: 480-640ms; for place: 460-660ms).

(B) Left: example of a neural confusion matrix at time t (660ms) obtained with a 12-class (syllables) decoding problem (average across subjects). Numbers within each cell indicate the percentage of times a given syllable from the x-axis was classified with the label reported on the y-axis. Off-diagonal values diverging from 0 signal misidentification (chance=8.3%). Middle: theoretical confusion matrices depicting a perfect separation between (i.e. the ideal classification of) consonants and broad syllable identities (classes are ordered as in the left matrix). Darker

colors correspond to the values 50% and 100% respectively, whereas light colors correspond to 0%. These matrices were entered as predictors of interest in a multiple regression analysis to explain neural syllable confusion at each time point. Right: the obtained beta-weights averaged across subjects and marked by filled circles when significantly above zero (cluster-based permutation t-test). Vertical lines correspond to SEM. Three additional predictors (place, manner and vowel discrimination) were entered in the multiple regression as variables of non-interest, their visualization and beta-weights are illustrated in Figure S5.

(C) Left: performance of estimators trained on discriminating all consonants (/b/ vs /d/ vs /g/ vs /m/ vs /n/ vs /ŋ/) coupled with one vowel (e.g. “-i”) and tested within the same (light green) and across the other vocalic context (e.g. “-o”; dark green). Right: performance of vowel classifiers trained on a single consonant (e.g. /b/) and tested within the same consonant (yellow) and across the remaining five (orange). Filled circles mark significant generalization across contexts (consonant classifiers: 80-900ms, $p_{\text{clust}}=0.0001$; vowel classifiers: 340-560ms, $p_{\text{clust}}=0.0001$ and 760ms onwards, $p_{\text{clust}}=0.0002$).

177 DISCUSSION

178 Altogether, the classification patterns observed in this study reveal two speech encoding formats in the infant brain.
179 During a first stage each articulatory-phonetic domain is encoded independently, thus each speech instance is
180 characterized by its coordinates along the manner and place dimensions described by linguists. In a second stage
181 multiple features are combined into a unified and idiosyncratic representation, still allowing phoneme classification
182 but hindering full generalization of featural decoding across phonemes. This functional progression is consistent with
183 the dynamic nature of the neural codes as revealed by the matrices in Figure 2D and the corresponding informative
184 activity patterns in Figures S3-4. Lastly, although our experiment was mainly focused on consonant encoding, similar
185 processing stages for vowels are likely.

186 The present study draws a striking parallelism between the neural underpinnings of preverbal and adult speech
187 perception (e.g. Mesgarani et al., 2014; E. F. Chang et al., 2010; Correia et al., 2015). In addition, it demonstrates
188 that human neural codes for speech are stable even for those phonetic features reflected by inconsistent acoustic
189 correlates (i.e. the place of articulation). While the recovery of articulatory motor patterns has been proposed as a
190 solution to overcome signal variability, we show that a phonetic code is already in place ~12 weeks after birth, when
191 production skills are still severely limited (Kuhl & Meltzoff, 1996). Our results are thus in disagreement with
192 mainstream views postulating that motor patterns acquisition, with the consequent mapping between articulatory
193 movements and acoustic outcomes, mediates a switch from domain-general to language-specific processing (Kuhl
194 et al., 2008; Westermann & Reck Miranda, 2004; Laurent et al., 2017; Vilain et al., 2019). Instead, our findings provide
195 a new representational solution able to account for the speech abilities observed in early infancy: a vectorized
196 encoding system which projects the signal onto a reduced number of relevant orthogonal axes.

197 The innate, or acquired, origin of this code needs further study to be understood. Broadly speaking, previous
198 neuroimaging research describing sonority-related phonological biases in newborns (Gomez et al., 2014) proves the

199 plausibility of innate linguistic constrains for humans. Strikingly, preterms born at 30 weeks of gestation have been
200 shown to detect place of articulation changes through a network of temporal and frontal brain areas similar to that
201 recruited at later ages in analogous settings (Mahmoudzadeh et al., 2013, 2016). Considering that the vocal
202 production of these neonates is nonexistent and their sucking behavior very weak and poorly organized, this
203 evidence corroborates our claim for a decorrelation between phonetic perception and articulatory-motor skills.
204 Moreover, the fact that the same discrimination abilities are carried by similar cortical regions across different ages
205 points to a continuity in the codes these regions use, and therefore to a genetically determined mechanism.
206 Nevertheless, it has been recently proposed that early orofacial stereotypies such as tongue protrusion/retraction
207 may provide fetuses and newborns with a primordial knowledge of the shape and configurability of the upper vocal
208 tract (Choi et al., 2017). Such information, combined with sound exposure, might foster an integrative/multi-modal
209 representational space for speech before the onset of canonical babbling.

210 Whichever its origin, the early availability of a code based on phonetic features could play a crucial role in word
211 learning. To discover words, infants must cope not only with acoustical but also with phonological variation due to
212 the segmental context: for example, in order to apprehend that “wet shoes” and “we[p] pants” share the same word
213 “wet”, English infants should apply a rule stating that an alveolar stop consonant borrows the place of articulation
214 from the subsequent stop (Darcy et al., 2009). Phonotactic rules of this sort pertains phonetic features rather than
215 holistic phonemes. Several behavioral studies reported that infants are sensitive to phonotactic cues already by the
216 age of 9 months: they prefer to listen to sequences that are phonotactically legal in their native language (Friederici
217 & Wessels, 1993; P. W. Jusczyk et al., 1993) and use their phonotactic knowledge to find word boundaries in
218 continuous speech (Mattys & Jusczyk, 2001). At this age, coherently with our argument, phonotactic rules are easily
219 learned when expressed at the level of phonetic features while they are not detected when they concern the identity
220 of the phonemes (Saffran & Thiessen, 2003). A featural encoding of speech is further consistent with the
221 documented ability of young infants to use phonetic details in word-referent mapping (Swingley & Aslin, 2002;
222 Ballem & Plunkett, 2005; Fennell & Waxman, 2010). Phonetic features might then correspond to an essential and
223 quickly available building block for human language acquisition.

224 The present study further demonstrates that manner and place encoding is followed by a combinatorial process,
225 which is still exquisitely phonetic in nature. In this regard, it is worth to highlight that, once taken phoneme identity
226 into account, we found no evidence for a broader, comprehensive syllabic representation (Figure 4B-C). Such (null)
227 result is inconsistent with studies depicting the syllable as the natural unit of speech perception/processing (Räsänen
228 et al., 2018). For example, 4 days after birth neonates can categorize utterances using the number of their syllabic
229 constituents but not the number of phonemes (Bijeljac-Babic et al., 1993). Around one month of age they
230 discriminate changes within well-formed syllables (CVC and VCCCV; C=consonant, V=vowel) but fail to discern the
231 same kind of alteration within chains of consonants (Bertoncini & Mehler, 1981). Besides, pre-school children and

232 illiterate adults access and manipulate syllables far more easily than phonemes (Morais et al., 1986). Whereas these
233 findings have led various authors to designate the syllable as the basis for speech representation, our results refute
234 the hypothesis of a syllabic unit perceived as a whole and thereafter decomposed into phonetic sub-parts. The
235 discrepancy might come from studying online processing, as we did in the current paper, vs. assessing the content
236 of a memory slot, as done in the behavioral studies. Indeed, behavioral paradigms imply the memorization of a given
237 element that is later compared to a new one or manipulated upon request. Only a full articulatory event (e.g. a
238 spoken syllable) or an external pointer to syllable subparts (e.g. a grapheme) might be storable in working memory.
239 Ultimately, our evidence for phoneme-identity neural codes complements adult data (Zhang et al., 2016) in
240 corroborating the reality of the phoneme as psycholinguistic object (Kazanina et al., 2018). Moreover, a neural
241 separation between consonants and vowels is particularly meaningful in light of the proposal suggesting diverging
242 functional roles for these components in language: while consonants are more informative for lexical distinctions,
243 vowels are particularly apt to mark structural organization (Nespor et al., 2003). Coherently with our findings, and
244 just as adults (Toro et al., 2008), infants have been shown to exploit such “division of labor” in order to extract lexical
245 and syntactic information already by the age of 12 months (Hochmann et al., 2011).

246 In summary, our results indicate that infants project the high-dimensional speech signal onto several axes of neural
247 responsivity corresponding to phonetic features. This process creates a structured and highly generalizable space
248 that is robust to surface variability across speakers or co-articulatory contexts. As outlined for faces (L. Chang & Tsao,
249 2017), a factorized representational system is more efficient and more flexible than exemplar coding (e.g. Port, 2007;
250 2010) and therefore ideally suited for the bootstrapping of language acquisition. In support of this claim it has been
251 shown that when non-pertinent acoustic variability is high within the experimental setting (as it is in real-life
252 scenarios) infants are particularly prone to use minimal phonetic contrasts to learn words (Rost & McMurray, 2009).
253 Efficiency and flexibility characterize the second-stage integrative code as well: elementary components, i.e. the
254 phonetic features, are recombined into intermediate representations, i.e. consonants and vowels, optimizing in this
255 way the accessibility of lexicon and syntax (Hochmann et al., 2011).

256 To conclude, pending more definitive experimental evidence, we point out the possibility that an abstract phonetic
257 code might be available from birth and endow infants with the ability to discriminate phonemes from most languages
258 (Peter W. Jusczyk, 2000). As an additional conjecture, we envision that the second-stage integrative process could
259 be subject to learning: areas downline of the first processing phase might become selective for the most frequently
260 encountered feature combinations. Further experiments, spanning a range of languages and ages, will be needed to
261 investigate how the observed codes adapt to the inventory of native phonemes.

262

263 MATERIAL AND METHODS

264 Participants

265 25 full-term, normal-hearing infants (12 females, 13 males) coming from a French-speaking environment were tested
266 between 12 and 14 weeks after birth (mean age= 12 weeks and 6 days). An additional 16 participants were excluded
267 from analysis because of: excessive agitation during the experimental session (n=6), insufficient number of trials
268 after artifact rejection (n=3, the artifact rejection procedure is described below), technical problems during data
269 collection (n=3), aberrant global field power (GFP) in the average of all syllable-related potentials (i.e. peak GFP<4μV,
270 n=4). The protocol was approved by the regional ethical committee for biomedical research (CPP Region Centre
271 Ouest 1). Parents gave their written informed consent before starting the experiment.

272 Stimuli

273 Stimuli consisted of 120 speech sounds constructed upon 6 consonants: /b/, /d/, /g/, /m/, /n/, /ŋ/. These consonants
274 were selected to cover two manner features, i.e. obstruent (/b/, /d/, /g/) and sonorant (/m/, /n/, /ŋ/), and three
275 places of articulation, i.e. labial (/b/, /m/), alveolar (/d/, /n/), and velar-palatal (/g/, /ŋ/). In case each consonant was
276 spoken always in the same way throughout the experiment, there would have been one-to-one correspondence
277 between the articulatory profiles (e.g. obstruent + labial) of the stimuli and their spectrograms; while our goal was
278 precisely to disentangle phonetic from merely acoustic stimuli representations. Each consonant was therefore
279 associated with two vowels, /i/ and /o/, and produced by a male and female speaker to obtain 2 manner x 3 place x
280 2 vowel x 2 voice factor design (i.e. 24 sub-conditions). To increase acoustic variability (and extend the external
281 validity of our measurements), speakers were asked to repeat the same tokens several times changing their
282 intonation. For every sub-condition we selected 5 utterances, distinct in low-level acoustic characteristics such as
283 pitch and duration. In the resulting set of syllables each manner of articulation condition contained 60
284 spectrotemporal profiles (3 consonants x 2 vowels x 2 voices x 5 utterances); similarly, each place of articulation was
285 presented in 40 (2 consonants x 2 vowels x 2 voices x 5 utterances) spectrotemporal versions.

286 Speech signals were recorded in a silent chamber using a dynamic microphone (Beyerdynamic DT 290 broadcast
287 headset) on a linear PCM recorder (DR-05, TASCAM) at a sampling rate of 44.1 kHz. Recordings were first cleared
288 from background noise in Audacity 2.1.3 (<https://www.audacityteam.org>) and further edited with PRAAT software
289 (Boersma & Weenink, 2017). Acoustic transients (clicks) were manually removed and stimuli length was adjusted to
290 fall within the range of 350-425ms. Tokens were normalized for peak amplitude and average (i.e. root-mean square)
291 intensity, obtaining maximal audibility and loudness equalization. All stimuli were placed on the left channel and a
292 click was positioned on the right channel at the exact time-point of syllable onset. The left channel was connected
293 to the audio amplifier (mono input to the loudspeakers) while the right channel was connected to the EEG amplifiers
294 through the DIN port to create a TTL signal. Brain voltage and clicks were recorded simultaneously with the same
295 temporal resolution providing a precise mapping between EEG recording and stimulation.

296 Articulation, and in particular the manner, is known to affect consonant duration, introducing the risk of possible
297 confounds between this low-level cue and the phonetic feature. To validate our set of syllabic stimuli, we therefore
298 assessed consonant lengths through a gating procedure (Grosjean, 1996). Over multiple trials, each stimulus was
299 listened in portions of progressively increasing duration (10ms steps), starting from the end of the syllable and
300 proceeding backwards, toward its beginning. The duration of the longest portion for which no consonantal sound
301 was perceived was subtracted from the total length of the stimulus. Consonant duration assessed in this way ranged
302 between 80 and 210 ms ($M \pm SD = 154 \pm 25$) and varied homogeneously across categories (i.e. /b/, /d/, /g/, /m/, /n/,
303 /ŋ/; $F(5,114) = 1.42$, $p = 0.222$). Most importantly, consonant duration did not change as a function of manner nor

304 place of articulation. In an ANOVA with these two factors, the effect of manner ($F(1,114)<1$), the effect of place
305 ($F(2,114)=1.28$, $p=0.280$) and their interaction ($F(2,114)=2.25$, $p=0.109$) were not significant.

306 **Procedure**

307 Subjects were tested in a soundproof Faraday cage equipped with a computer screen and loudspeakers on the top.
308 Infants were held by a caregiver, their position was chosen to guarantee personal comfort and at the same time
309 enable good-quality data acquisition. Syllables were broadcast through the loudspeakers at 70 decibels, in a latin-
310 square randomized order and with an inter-stimulus interval (ISI) randomly picked between 600 and 1000ms. To
311 minimize body movements we presented engaging visual animations that were unsynchronized with the auditory
312 stream. Sleep was highly encouraged at any time; on average our subjects slept for 65% of the experimental session.
313 Pauses were made whenever needed. The experiment finished with the presentations of 3136 tokens
314 (corresponding to approximately 63 minutes of listening time) or as soon as infants became restless.

315 **EEG recording and data preprocessing**

316 The electroencephalogram (EEG) was continuously digitized at 500 Hz (Net Amps 300 EGI amplifier combined with
317 NetStation 5.3 software) from 256 channels. We used a prototype HydroCel net (EGI; Eugene, OR, USA) referenced
318 to the vertex. The sensor layout of this prototype diverges from the classical geodesic 128-locations partitioning
319 (Tucker, 1993) in that 20 of the standard temporal positions are covered by 2 tight grids of sensors (70 electrodes
320 on each side, organized in hexagonal pods) with no sponge inserts (Figure S2). Electrodes are made of carbon fibers
321 embedded within a plastic (ABS) substrate and coated with silver-chloride.

322 *Artifact detection and correction*

323 Data preprocessing was conducted through custom-made MATLAB scripts based on the EEGLAB toolbox 14.0
324 (Delorme & Makeig, 2004). While following the main preprocessing steps normally used in developmental studies,
325 we introduced some modifications inspired by efforts carried to improve adult data quality (Jas et al., 2017; Mognon
326 et al., 2011). Namely, we identified artifacts on the continuous recordings with the employment of adaptive rather
327 than absolute/predefined thresholds. In this way, we could account for inter-individual variability and the
328 heterogeneous influence that reference distance and vigilance state exert on the voltage. Moreover, we did not
329 discard but corrected local and transient artifacts, exploiting the redundancy of information provided by our dense
330 sensor-layout (Figure S2) and high sampling rate.

331 As a first step, EEG recordings were band-pass filtered ([0.5 - 40Hz]) and the mean voltage of each electrode was set
332 to zero. Artifacts were detected before segmentation by a series of algorithms with adaptive thresholds. These
333 algorithms rejected samples on the basis of: the voltage amplitude and its first derivative; the variance across a
334 500ms-long moving time window; the fast running average and the deviation between the fast and the slow running
335 averages within a 500ms-long sliding time window. Thresholds were set independently for each subject and for each
336 electrode upon the distribution of these measures along the whole recording (threshold = median +/- n *IQ, where
337 IQ is the interquartile range of the distribution). Two additional algorithms identified whether the power within the
338 0-10Hz band was excessively low or within 20-40Hz excessively high relative to the total power; and whether the
339 voltage amplitude displayed by each sensor at a given time point was disproportionate relative to that recorded by
340 the other sensors at the same instant. For these last two algorithms, thresholds were computed upon the
341 distribution across channels.

342 The output of the artifact detection procedure was a rejection matrix with the same size of the EEG recording. We
343 used this matrix to mark time points with prominent artifacts (*bad times*) and channels that did not function properly
344 (*bad channels*). We identified as *bad times* periods longer than 50ms with a percentage of rejected channels superior

345 to 30% or beyond 2IQ from the 3rd quartile of the distribution of the percentage of rejected channels across time.
346 Similarly, *bad channels* were the ones not working properly for more than 30% of time or with a percentage of bad
347 samples that went beyond 2IQ from the 3rd quartile of the distribution of the percentage of rejected samples across
348 channels.

349 Periods defined as *bad times* were not corrected because there was not enough information available to reconstruct
350 the signal. For the rest, two kinds of correction were applied. When the rejected segments had a very short duration
351 (50ms max, e.g. heart beats or jumps) we relied on the assumption that, during these periods, most of the variance
352 came from noise. For each of them, principal components were estimated (PCA) and the first n components
353 determining 90% of the variance were removed. Otherwise, we corrected *bad channels* and long rejected segments
354 that did not contain *bad times* using spherical splines interpolation (Perrin et al., 1989). Spatial interpolation was
355 carried out only if at least 50% of the neighboring channels were intact. Corrected segments were realigned with the
356 rest of the data which were then high-pass filtered (0.5Hz) to eliminate possible drifts resulting from this operation.
357 The artifact detection-correction procedure was applied iteratively, keeping previously identified bad samples aside
358 for the subsequent artifact detection steps.

359 *Epoching*

360 EEG recordings (and the corresponding rejection matrix) were segmented into epochs starting 200ms before and
361 ending 1400ms after syllable onset. Trials were rejected if more than 15% of their samples contained artifacts.
362 Epochs were also discarded based on their Euclidean distance from the average, i.e. when their mean or maximum
363 distance from the average response was an outlier in the distribution ($> 3^{\text{rd}}\text{quartile} + 1.5 * \text{IQ}$). Following automated
364 rejection, the remaining epochs were visually inspected and a few trials still presenting obvious aberrancies were
365 manually eliminated.

366 Since multivariate pattern analysis requires a conspicuous amount of trials, we included subjects with a minimum of
367 40 trials/sub-condition. In our final group of infants (N=25), the mean trial rejection rate was 28.7% (12.4 to 53.5%).
368 On average, the number of artifact-free epochs available per subject in each sub-condition (e.g. “bi-female”) was 70,
369 providing 840 trials for each manner of articulation condition and 560 trials for every place of articulation condition.

370 Before submitting them to the main analyses, epochs were low-pass filtered at 20Hz, mathematically re-referenced
371 to the mean of all channels and down-sampled (with a moving average of 2 time points) to 250Hz. All the main
372 analyses (decoding) were carried at the single trial level. Nonetheless, epochs were also averaged per either sub-
373 condition or manner-/place-condition in order to examine evoked responses (ERPs, e.g. Figure S4C).

374 **Decoding**

375 Multivariate pattern analyses were conducted within subject, relying on the Scikit-Learn (Pedregosa et al., 2011) and
376 MNE (Gramfort et al., 2013, 2014) Python packages. To decode *in time* epochs were divided into 300 consecutive
377 windows of 20ms (from -200ms to 1000ms relative to stimulus onset), each corresponding to a matrix with the shape
378 n channels \times 5 samples (sampling rate = 250Hz, 5 samples=20ms). Each analysis was carried on a single window with
379 the general aim of predicting a vector of categorical data (y) from a matrix of single-trial neural data (X) which
380 included all EEG channels. To decode the manner of articulation trials were labelled as belonging to either the
381 category of “obstruent” or to the category of “sonorant” depending on whether /b/, /d/, /g/ or /m/, /n/, /ŋ/
382 exemplars were presented. To decode the place of articulation y comprised three classes: “labial” (/b/, /m/),
383 “alveolar” (/d/, /n/), and “velar” (/g/ and /ŋ/). For vowel decoding, trials were separated in two classes, “i” and “o”,
384 based on the vocalic portion of the stimulus.

385 All decoding analyses were performed within a stratified cross-validation procedure consisting of 100 iterations. At
386 each run, trials were shuffled and then split into a training and a test set containing 90% and 10% of trials
387 respectively. As compared to the most common folding approach, this cross-validation outline enabled to maximize
388 the number of iterations (and thus the reliability of the final performance) while maintaining a fixed and reasonable
389 amount of test trials. Importantly, stratification ensured (a) that the same proportion of each class was preserved
390 within each set (b) all sources of variability (e.g. voice gender) were evenly represented across sets (e.g. training and
391 test sets contained syllables produced by the female vs male speaker in the same proportion).

392 Given the high amplitude fluctuations typically seen in infant EEG background activity, we first aimed at improving
393 our signal-to-noise ratio. Once defined the training and the test set for a given run, we applied a “micro-averaging”
394 procedure, a strategy previously used on adults with the same purpose (Grootswagers et al., 2016). This consisted
395 in averaging together randomly picked groups of 16 epochs within each class. The number of trials to average being
396 arbitrary, we tried with 4, 8, and 12 and observed that by averaging 16 trials we could reach the best performance
397 without compromising its reliability. Note that such assessment was conducted on the first decoding analysis we had
398 planned (i.e. manner of articulation within a standard cross-validation schema) and the choice of 16 was then
399 adopted a priori for all the other decoding analyses. At the end of this operation, to ensure perfect balance among
400 classes, we equalized the number of (micro-averaged) epochs across categories. In practice, this consisted in
401 dropping 1 to 3 randomly picked trials from the most numerous class(es).

402 Next, following the z-scoring each feature (i.e. channel and time point across trials), a L1-norm regularized Logistic
403 Regression (Fan et al., 2008) was fitted to the training set in order to find the hyperplane that could maximally predict
404 y from X while minimizing a log loss function. L1 penalty was chosen to exclude less informative features from the
405 solution (their weights being set to zero). Such regularization can be conceived in terms of dimensionality reduction,
406 an optimization that enabled us to prevent overfitting (by reducing model complexity (Ng, 2004)) but still exploit the
407 high density of our EEG data. The other model parameters were kept to their default values as provided by the Scikit-
408 learn package. When decoding concerned more than two classes (e.g. place classification) we adopted a “one-vs-
409 rest” approach: for each class (i.e. each place of articulation) one model was fitted against all the other classes.

410 Once trained, the models were used to predict y from the test set and their performance was evaluated by
411 comparing estimates to the ground truth. All algorithms produced as an outcome vectors of probabilistic estimates.
412 These probabilities were scored by computing the area under the Receiver Operating Characteristic curve (AUC),
413 which summarizes the ratio between true positives (e.g. trials correctly classified as “obstruent”) and false positives
414 (e.g. trials classified as “obstruent” while a sonorant consonant was presented). The value of AUC ranges between 0
415 and 1, with 0.5 corresponding to chance level. Once again, in multiclass decoding a “one-vs-rest” scheme was used:
416 the AUC scores were computed for each class against all the others and then averaged. Lastly, for both binary and
417 multiclass problems, evaluations were averaged over all cross-validation runs.

418 As a proof of concept, the main decoding analyses were performed with two additional algorithms: L1-norm
419 regularized linear Support Vector Machine (SVM; (Fan et al., 2008)) and Linear Discriminant Analysis (LDA). For the
420 latter, a shrinkage estimator of the covariance matrix was used, taking into account the fact that the dimensionality
421 of our data vectors exceeded the number of samples in each class (Ledoit & Wolf, 2003). Importantly, we restricted
422 our alternatives to linear classifiers to make sure that the algorithms focused on explicit neural codes (Kriegeskorte,
423 2011). Beside slight variations in accuracy, alternative classifiers yielded very similar outcomes.

424 *Generalization across time (Figure 2D)*

425 Estimators trained at each time window t were systematically tested on (both the same and) every other possible
426 time window t' , i.e. every 20ms from 200ms prior to 1000ms after syllable onset. Such procedure was performed
427 within the cross-validation so that training set at t and test set at t' came from different groups of trials. In the
428 resulting “temporal generalization matrices” each row corresponds to the time lag at which the estimator was
429 trained and columns correspond to the time windows at which it was tested (King & Dehaene, 2014). The shape of
430 the performance within these matrices provides peculiar insights upon the dynamics of the underlying brain activity.
431 If the same neural code was found at t and t' , the classifier trained at t would generalize at t' . If, on the contrary,
432 information was passed to another stage of processing characterized by its own coding scheme, performance at t'
433 would be at chance (King & Dehaene, 2014).

434 *Generalization across conditions*

435 We examined the consistency of information used by classifiers in different harmonic and co-articulatory contexts
436 by performing cross-condition decoding. To ask whether the same neural codes supported the classification of
437 phonetic features and vowel identities across different harmonic contexts, we trained estimators on manner
438 contrasts (/b/, /d/, /g/ vs /m/, /n/, /ŋ/); place contrasts (/b/, /m/ vs /d/, /n/ vs /g/, /ŋ/) and vowel contrasts (/i/ vs
439 /o/) within one speaker condition (e.g. syllables pronounced by the female voice) and tested these same estimators
440 on the other speaker condition (e.g. syllables spoken by the male voice). The procedure regarding co-articulations
441 was analogous: we trained place and manner estimators on one vowel context and tested them on the other; we
442 trained vowel estimators on single manners or places and assessed their performance on the alternative ones.

443 To test the orthogonality of manner and place encoding we trained estimators on each featural condition separately.
444 More specifically, to reveal place-independent phonetic processing classifiers were trained on the manner
445 comparison (“obstruent” vs “sonorant”) at single place contexts (e.g. only labial sounds). These estimators were
446 then tested both at the trained place (e.g. labials) and at the two unseen places (e.g. alveolar and velar consonants).
447 In case manner neural codes were independent from the place of articulation, we expected classifier to perform
448 comparably *within* the trained place and *across* unseen place contexts. Following the same rationale, we asked
449 whether place codes are specific to manners of articulation by training classifiers to discriminate labials vs. alveolars
450 vs. velars on one manner (e.g. only with obstruent sounds) and testing them within the same (e.g. obstruents) and
451 at the alternative manner condition (e.g. sonorants).

452 Moreover, we investigated the orthogonality of consonant and vowel representations with two complementary
453 procedures. First, we trained algorithms to distinguish each consonant based on single vocalic contexts (e.g.
454 separation of /b/ vs /d/ vs /g/ vs /m/ vs /n/ vs /ŋ/ when they were co-articulated with /i/) and tested them within
455 the same and across the alternative co-articulatory context (e.g. classify consonant identity among “bo”, “do”, “go”,
456 “mo”, “no”, “no”; note that for this schema, as for place classification, we adopted a “one-vs-rest” approach and the
457 percentage of correct classifications as evaluative metric). Analogously, we trained vowel classifiers on each
458 consonantal option and assessed their performance within the trained consonant and across the five alternative
459 ones. In case consonant and vowel were represented separately, we expected to obtain comparable scores *within*
460 and *across* conditions; oppositely, a degradation in performance across conditions would be indicative of
461 interdependence between the two.

462 For cross-condition decoding we modified the cross-validation scheme described above so that models fitted on
463 each training set were directly applied at all trials belonging to the untrained condition (i.e. the test set “*across*”). In
464 this way, we capitalized on the independence of train and test sets. Concerning the splitting of single-condition
465 datasets (i.e. the dataset “*within*”), the number of test trials was calibrated to guarantee a minimum of 2 micro-
466 averaged trials/class at test and at the same time maximize the amount of trials available for training. Note also that

467 in order to ensure an adequate number of training/test samples, the micro-averaging for the last two cross-decoding
468 schemas was reduced to groups of 8 epochs. Apart from these modifications, the decoding procedures resembled
469 those described above.

470 *Weight projection (Figure S3)*

471 The weights assigned by classifiers to EEG sensors reflect the degree to which the information captured by a given
472 sensor is used to maximize class separation. However, weights per se are very difficult to interpret. For example,
473 higher weights do not necessarily correspond to high levels of class-specific information as they could be assigned
474 to sensors that are employed to delineate and suppress noise (for a full explanation see (Haufe et al., 2014)). To
475 overcome this issue it is possible to project weights back onto an interpretable activation space by multiplying them
476 with the covariance in the data ($\text{cov}(X)$, where X is the $N \times M$ matrix of EEG data with N trials and M channels). In the
477 resulting vector (that has length M channels) large amplitudes indicate high degrees of class-specific brain activity
478 (Grootswagers et al., 2016; Haufe et al., 2014). Since our goal was to reconstruct informative activity peculiar to
479 each phonetic feature domain, we retrieved the coefficients of classifiers trained within each place condition to
480 obtain “pure” manner-distinctive patterns and trained within each manner condition to obtain “pure” place-
481 distinctive patterns. By doing so, we ensured that no information about place was available to manner estimators
482 and no information about manner was available to place estimators. After multiplying coefficients and EEG
483 covariance, the resulting activity estimations were averaged across places (to obtain informative activity for manner)
484 or manners (to obtain informative activity for place).

485 To identify sensors that were crucial specifically for manner or crucial specifically for place classification, we
486 computed the 10th and 90th percentiles of the informative activity values observed throughout the trial. At each
487 time point, channels whose informative activity amplitude fell below the 10th or above the 90th percentiles in one
488 phonetic domain but not the other were interpreted as particularly important to manner but not place classifiers or
489 vice versa (Figure S3).

490 **Neural syllable confusion and multiple regression analysis**

491 For this section we first built a twelve-class decoding problem by pulling together the female and male conditions
492 and then training algorithms to separate each syllable from all the others (i.e. “bi” vs “bo” vs “di” vs “do” vs “gi”
493 etc.). We adopted a “one-vs-rest” approach and used the same pre-processing steps described for the main analyses.
494 Within each cross-validation loop, we stored the error matrices displayed by these classifiers at test. After averaging
495 across runs, we obtained a series of matrices where the entry at row i and column j corresponds to the percentage
496 of samples belonging to class j and labeled as i by the classifier (Figure 4B-left and S5A-bottom). The diagonal of
497 these confusion matrices depicts class-wise accuracy, with theoretical chance being at 8.3% (Figure S5A-top). Given
498 that there is a variety of stimuli characteristics other than syllable identity which could lead to above-chance scores
499 (up to 50%), diagonal entries alone are hardly interpretable. On the other hand, misclassification patterns (i.e. off-
500 diagonal entries in the matrices) have the potential to reveal which dimensions of the stimuli the neural code honors
501 or disregards. To uncover the neural representational geometry (Kriegeskorte & Kievit, 2013) captured by our
502 algorithms and its evolution over time, we employed multiple linear regression. Specifically, we modeled each
503 confusion matrix as a linear combination of five classification performances: those of the ideal manner, place, vowel,
504 consonant and whole-syllable decoders (Figures S5B-top and 4B-middle). Concerning the matrix modelling manner
505 discrimination, for example, the predicted entries for those pairs of syllables sharing the same manner correspond
506 to 16.6%, whereas the predicted value for pairs of syllables not sharing the same manner is 0%. The five predictors
507 were used to explain the (neural) syllable confusion observed at each time point, generating a vector of beta-weights
508 for each of the five regressors. All matrices were z-transformed before estimating the coefficients. With this multiple

509 regression approach we capitalized on the opportunity to separate the potential impact of new variables of interest
510 (i.e. consonant and holistic syllable, Figure 4B) from that of influential dimensions already isolated by the previous
511 analyses (i.e. manner, place and vowel, Figure S5B) on syllable confusion patterns. Significantly above-zero beta-
512 weights assigned to a particular regressor indicate that, at a given time point, the classifier relies on the dimension
513 reflected by that model over and beyond the remaining four variables.

514

515 **Statistical analysis**

516 To calculate statistics we performed second-level tests across subjects employing the MNE dedicated functions.
517 Following the example in (Jean-Rémi King et al., 2016), we tested whether (a) time-resolved classification scores
518 were higher than chance; (b) time-resolved classification scores within the trained context were superior to those
519 across context; (c) whether multiple regression beta-weights were higher than zero; using one-sample cluster-based
520 permutation t-tests (Maris & Oostenveld, 2007) which intrinsically account for multiple comparisons. The analyses
521 considered one-dimensional clusters in all cases apart from the generalization across time matrices (with shape
522 training times \times testing times) for which clusters were bi-dimensional. Univariate t-values were calculated for every
523 score/beta-weight with the exclusion of those corresponding to the baseline period. All samples exceeding the 95th
524 quantile were then grouped into clusters based on cardinal or diagonal adjacency. Cluster-level test statistics
525 corresponded to the sum of t-values within each cluster. Their significance was computed by means of the Monte-
526 Carlo method: they were compared to a null distribution of test statistics created by drawing 10000 random sign
527 flips of the observed outcomes. A cluster was considered as significant when its p-value was below 0.05.

528 We compared labial-, alveolar- and velar-specific patterns of informative activity with 1-way repeated measures
529 ANOVA. Similarly to above, we addressed the multiple comparisons problem with a permutation procedure based
530 on spatio-temporal clusters. Neighboring elements that passed a threshold corresponding to a p-value of 0.01 were
531 grouped together and their significance was computed by comparing cluster-level statistics to a null distribution of
532 f-value sums created by drawing 10000 random permutations of the observed data. Again, a cluster was considered
533 as significant when its p-value was below 0.05. Since informative activity patterns are meaningful only in case of
534 successful decoding (Haufe et al., 2014), differences were evaluated only during the two time windows when place
535 classification was reliably above chance.

ACKNOWLEDGMENTS

This research was supported by grants from the Fondation NrJ, Fondation Bettencourt and from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation program (grant agreement No. 695710). We are grateful to Don Tucker and Amy Rowland (EGI and University of Oregon) for designing the 256-electrodes net; and to Bahar Khalighinejad for providing help with auditory spectrogram estimation. We are also thankful to Stanislas Dehaene, Yair Lakretz and Christophe Pallier for constructive feedback and suggestions. This paper is dedicated to Sébastien Marti, whose mentorship was essential. His smile, kindness and friendship remain in our hearts.

2 **Auditory spectrogram estimation and Representation Similarity Analysis**

3 This preliminary investigation was aimed at delineating the auditory representational geometry elicited by our
4 stimuli set (Kriegeskorte, 2008; Kriegeskorte & Kievit, 2013).

5 The time-frequency auditory representation of the speech sounds was estimated according to a model of the
6 peripheral auditory system (Chi et al., 2005) as implemented in the NSL Matlab Toolbox
7 (<http://nsl.isr.umd.edu/downloads.html>). This model comprises: a first step in which sound frequencies are spatially
8 separated along the basilar membrane; a second stage that simulates the transduction of basilar membrane
9 displacements into auditory nerve spikes; and a third phase of processing within the cochlear nucleus. The output
10 of the model is an auditory spectrum of the signal as it enters the inferior colliculi. The three stages and their
11 mathematical implementations are described in (Yang et al., 1992) and (Wang & Shamma, 1994). Auditory spectra
12 were computed based on consecutive windows of 10ms for each stimulus, obtaining a total of 120 bidimensional
13 (time x frequency) auditory representations. We then estimated pair-wise auditory dissimilarity following two
14 different approaches.

15 First, we calculated time-resolved auditory (dis)similarity. For this purpose, spectrograms were aligned upon the
16 consonant offset times determined with the gating procedure described in the Materials and Methods (*Stimuli*
17 section). Consonant offset was preferred over syllable onset because acoustic cues for the place of articulation are
18 generally proposed to reside within the formant transitions (i.e. at the time of the switch between consonant and
19 vowel portions) (Liberman et al., 1954). Since consonant duration varied across speech tokens, alignment based on
20 syllable onset would have led to a jittering of such transition times across spectrograms and this jittering could have
21 misleadingly attenuated relevant cues. The 5 auditory spectrograms corresponding to each sub-condition (e.g. the
22 5 utterances of “go-female”) were then averaged together (Figure S1B). For each (10ms long) spectral frame, we z-
23 scored amplitude values across frequencies and calculated the Euclidean distance between each pair of sub-
24 conditions. Standardization was applied in order to maximize our power of detecting phonetic distinctions despite
25 variation in fundamental frequencies (i.e. despite male and female voices being characterized by very distinct
26 pitches). The choice of the Euclidean metric is justified by its potentiality to mimic infant discriminative behavior
27 with higher fidelity relative to other distance measures (Sundara et al., 2018). The outcome of this first approach is
28 a series of 35 auditory distance matrices (Figure S1B), describing all together how pairwise auditory (dis)similarity
29 unfolds over time.

30 It has been proposed that the acoustic correlates of the place of articulation, a feature of major interest in the
31 current study, have an integrative and dynamic nature (Nossair & Zahorian, 1991). The employment of brief time
32 slices could have then potentially precluded us from capturing meaningful cues derivable from the spectral shape as
33 a whole. To account for this eventuality, our second approach relied on the Dynamic Time Warping (DTW) algorithm
34 (Sakoe & Chiba, 1978; Park & Glass, 2008) as implemented in the Python module *dtwdistance* (Meert & Van
35 Craenendonck, 2018). This technique enabled us to find the best alignment between each pair of spectrograms by
36 stretching and compressing them locally, along the time axis. Following z-scoring, we estimated the DTW distance
37 between each pair of utterances and obtained a comprehensive auditory dissimilarity matrix by averaging the
38 distance values corresponding to each pair of sub-conditions.

39 To investigate the relationship between the auditory space and the phonetic/harmonic dimensions of our speech
40 stimuli we tested the correlation of the auditory distance matrices with four theoretical matrices (Figure S1C). The
41 latter consisted of categorical models in which two syllables are identical (dissimilarity = 0) if they share the same
42 manner/place/vowel/voice, and different (dissimilarity=1) in case they do not. Concerning place of articulation
43 distinctions, some investigations in phonetics seem to suggest that labials/velars and alveolars could be acoustically

44 closer to each other relative to labial and velars (Cho & Ladefoged, 1999; Lisker & Abramson, 1964). Furthermore it
45 has been proposed that the alveolar feature may be “underspecified” (i.e. coronal may correspond to the default
46 place and therefore be somehow inactive/less contrastive) as compared to the labial or velar features (Cummings et
47 al., 2017; Stemberger & Stoel-gammon, 1991; Tsuji et al., 2015). To account for these possibilities, we built an
48 additional model where the distance between labials and alveolars and that between alveolars and velars was
49 quantified as “0.5”. Results obtained with the two place models were completely overlapping.

50 The match between auditory and theoretical dissimilarity matrices was quantified with a Mantel test for two-
51 dimensional correlations (Mantel, 1967) employing Spearman’s rho as test statistic and performing 10000
52 permutations for each test. The Mantel procedure, unlike the classical correlation methods, enabled to account for
53 the fact that distances here were not independent, i.e. every dissimilarity depended on two spectral
54 patterns/qualitative values, each of which also codetermined the similarities of all its other pairings in the matrix.
55 For what concerns the time-resolved outcomes, false discovery rate (FDR) correction was used to control for multiple
56 comparisons across spectral frames and results are show in Figure S1D. The comprehensive auditory dissimilarity
57 matrix was significantly correlated with manner (Mantel $r_s = 0.228$, $p = 0.0002$); vowel (Mantel $r_s = 0.297$, $p = 0.0001$)
58 and speaker distinctions (Mantel $r_s = 0.24$, $p = 0.0001$) but not place of articulation (Mantel $r_s = -0.029$, $p = 0.75$).

59 As a note, the reader may wonder the reason why we could not apply the same decoding strategies used on neural
60 data in order to characterize the auditory space. Generally speaking, the lower the number of samples and the higher
61 the ratio of features to sample size, the more a machine learning model will fit the noise in the data instead of a
62 meaningful underlying pattern (Jain & Chandrasekaran, 1982; Kanal & Chandrasekaran, 1971). In the case of our
63 auditory spectrograms, algorithms would need to be trained/tested on a maximum of 120 samples with 4480
64 features each (as a benchmark: samples for each neural estimator in the main analyses were approximately 1600
65 and contained 1260 features each). Evidently, such disproportionate dataset is ill-suited for the same kind of
66 estimators used on the ERPs: instability and overfitting would completely undermine the reliability (and therefore
67 interpretability) of the outcome.

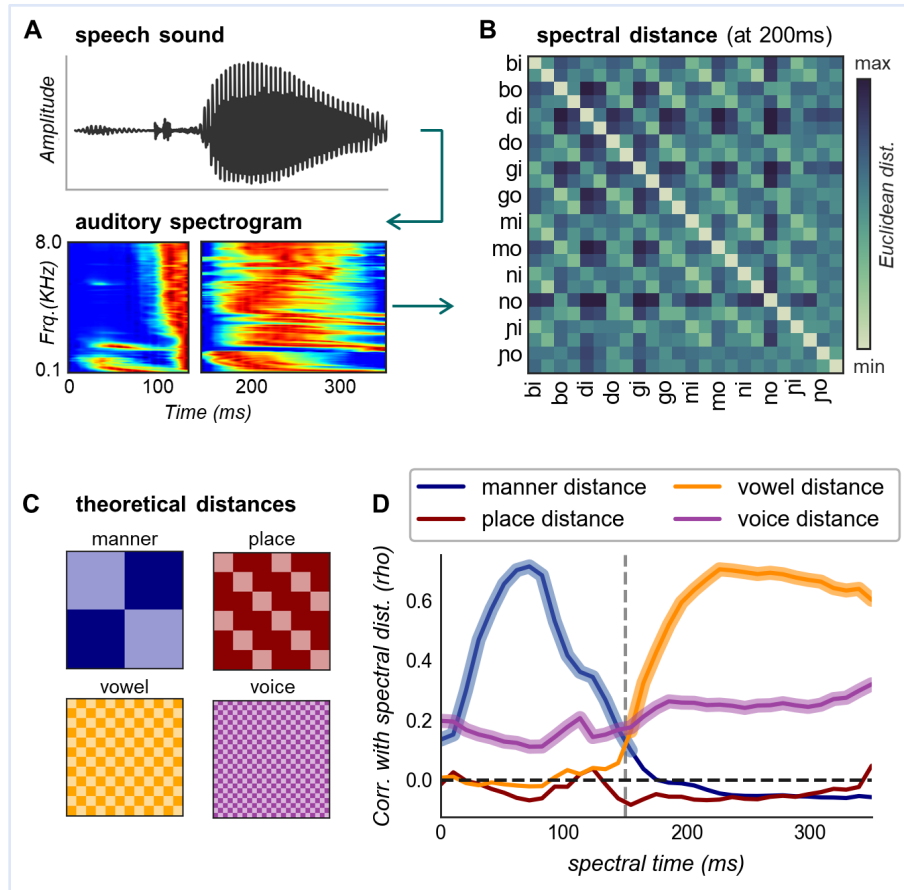

Figure S1. Representational content of the speech stimuli (Figure 1) as they reach the central auditory pathways.

(A) Auditory spectrograms were extracted from the speech sounds with a model of cochlear frequency analysis, then averaged by syllable type (top: one instance of “go” pronounced by the female voice; bottom: average spectrogram of all 5 utterances belonging to the sub-condition “go-female”). The blue-red scale reflects minimal-maximal energy, separately normalized in the consonant and vowel portions for mere illustrative purposes. (B) Example of dissimilarity matrix reporting the Euclidean distance between each pair of auditory spectrograms at spectral time=200ms. Each label (e.g. “bi”) indexes two sub-conditions: female and male. (C) Categorical dissimilarity models (conditions are ordered as in the matrix above): light colors indicate correspondence (distance=0) while darker colors signify lack of correspondence (distance=1). (D) Correlation between spectral and theoretical distance matrices as syllable unfolds (the dotted vertical line marks the switch between consonant and vowel). Thicker lines indicate significant time points ($p < 0.05$) after FDR correction. Full methodology description, rationale and complementary results are reported in the supplementary text above.

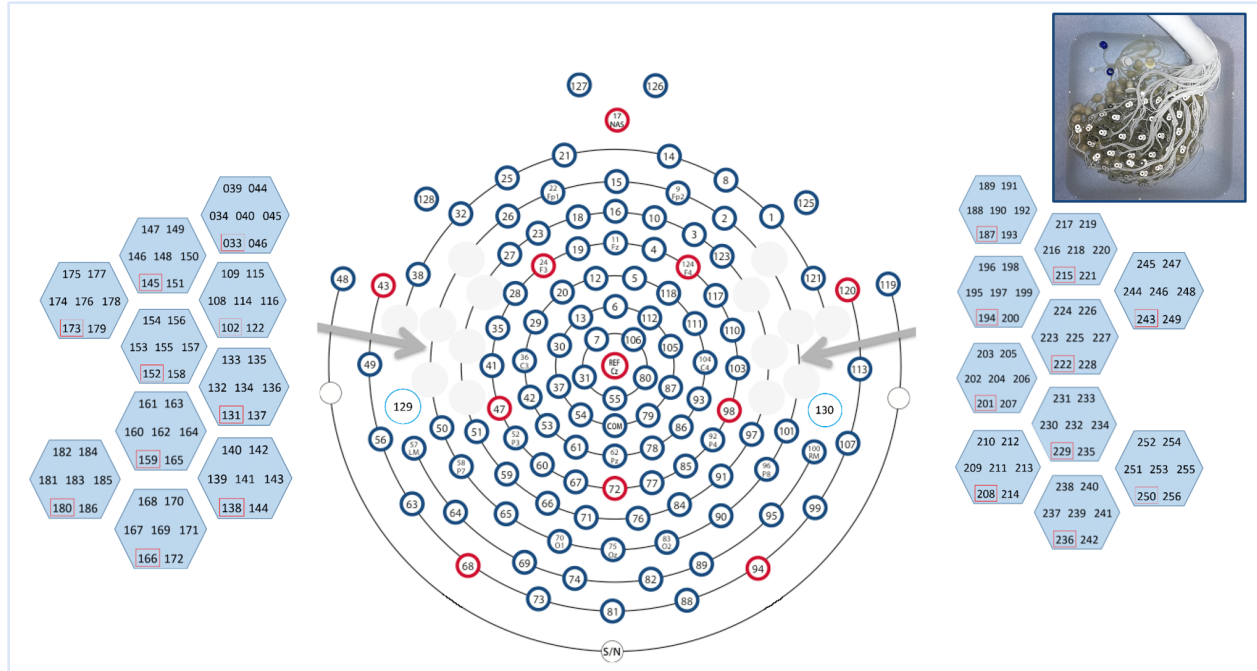

Figure S2 (complement of Figure 1). Prototype ultra-high density net

Tight grids of custom electrodes are arranged over the auditory linguistic areas of the superior temporal lobe: 20 temporal geodesic locations (128 partitioning) are filled with hexagonal pods, each containing 7 sensors displaced at a reciprocal distance of 5 mm.

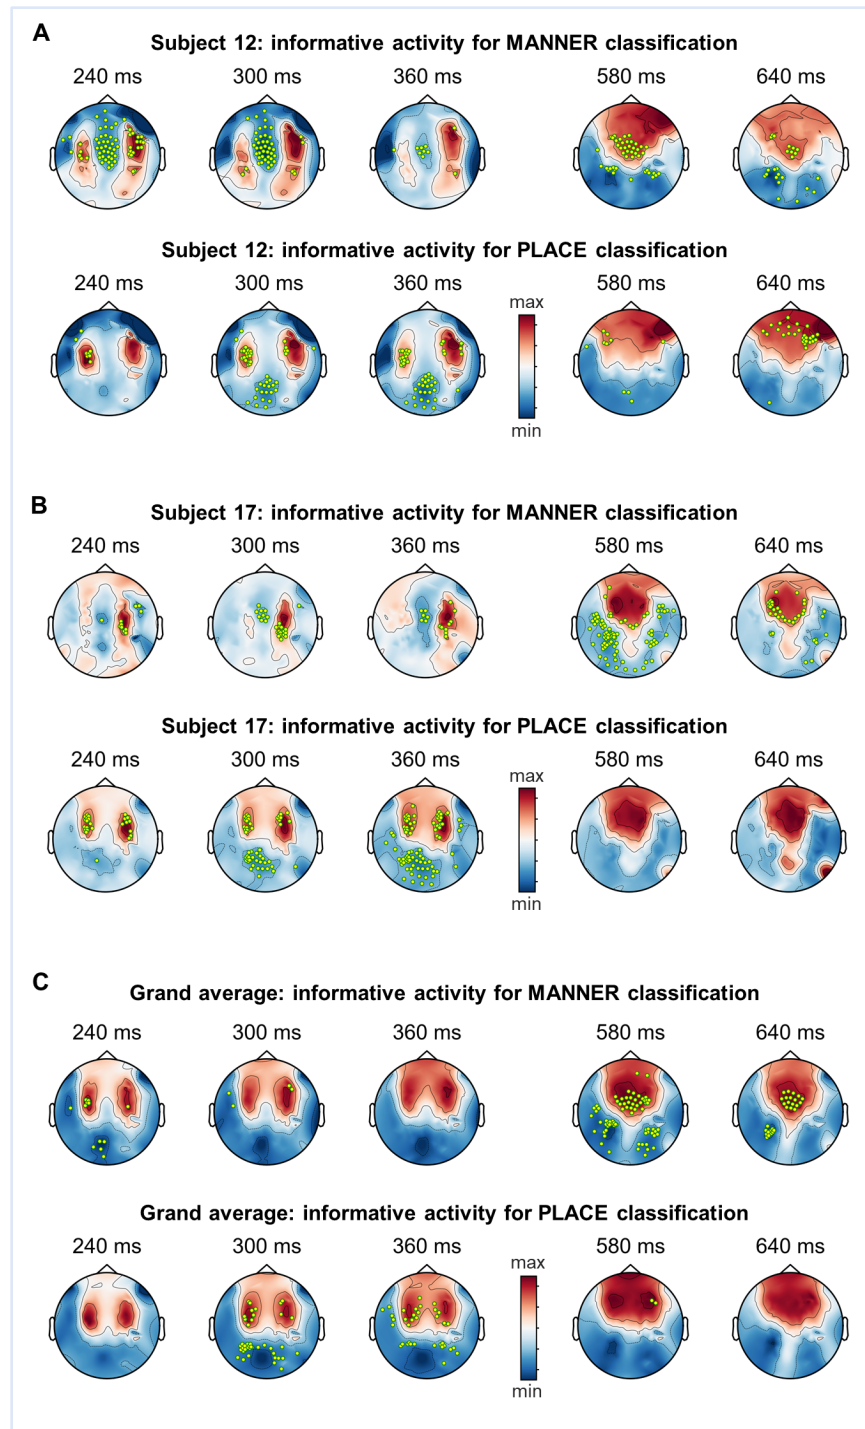

Figure S3 (complement of Figure 2). Discriminative loci change as a function of time and phonetic feature dimension

Classifiers weights are projected onto the EEG sensor activation space. Darker colors correspond to brain activity that was useful for classification. Marked in yellow are channels carrying crucial information to distinguish manner

but not place (top rows) or to discriminate place but not manner (bottom rows). Time points are chosen to provide an overview of the two time-windows with reliable classification. Panels (A) and (B) show the informative activity patterns reconstructed for two representative subjects. In (C) informative activity patterns are averaged across infants with the purpose of providing a visualization of the general trend. Note however that the interpretability of this grand average is limited since decoding analyses were carried within subject and discriminative loci are very much idiosyncratic. Overall, these topographies show that, as time passes, sensors conveying valuable information are located more medially over frontal areas. Moreover, informative locations for manner and place of articulation do not always overlap.

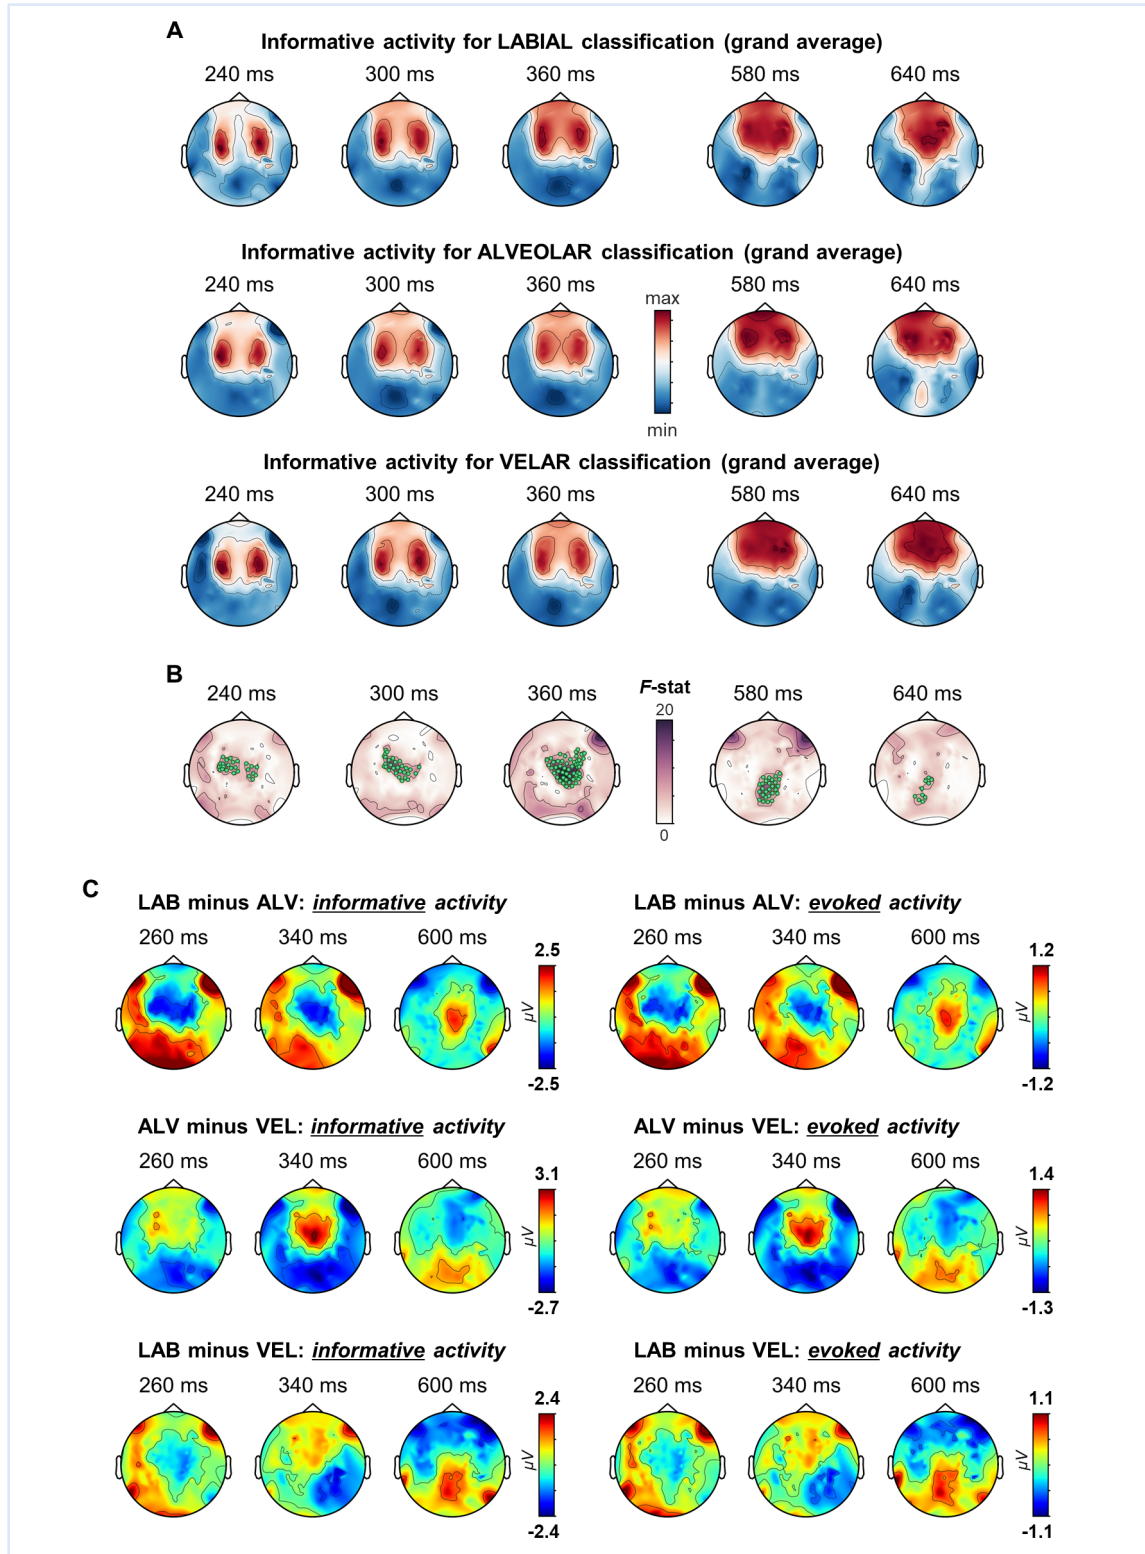

Figure S4 (related to Figure 2). Overview of place contrasts: informative and evoked activity patterns.

(A) In place decoding, three distinct models were fitted to separate each place of articulation from the other two (one-vs-rest approach). Their weights were projected back onto the activation space to reconstruct patterns of activity useful in characterizing either labials, alveolars or velars against the other places. Darker colors correspond to loci providing high degrees of class (i.e. place)-specific information. Patterns are averaged across subjects to provide an impression of the general trend; note however that weight idiosyncrasy undermines the interpretability of the grand average. (B) Results of one-way repeated measures ANOVA comparing discriminative activity for labials vs. alveolars vs. velars; channels containing significant differences are in green: early time-window: $p_{\text{clust}} = 0.0005$, late time-window: $p_{\text{clust}} = 0.0196$. (C) Reported on the left are differential informative activity patterns, on the right the same differences were computed on the evoked related potentials (ERPs). Given that amplitude ranges of informative and evoked brain activity were extremely similar (spanning from -8 to 7 μV in both cases), this figure displays two remarkable features: differential topographies are qualitatively overlapping while amplitude scales (colorbars) change substantially from the left to the right side of the panel.

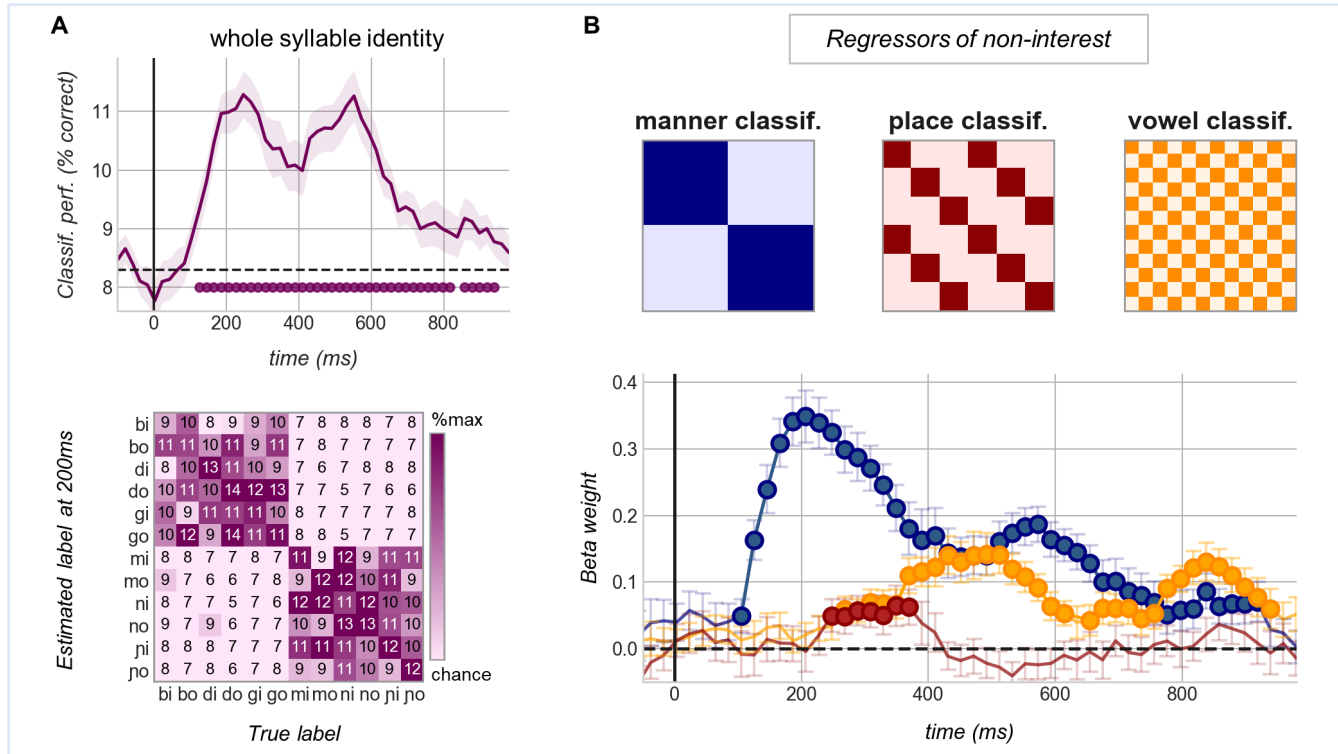

Figure S5 (complement of Figure 4).

(A) Top: time-resolved accuracy scores of classifiers trained on syllable identities: “bi” vs “bo” vs “di” vs “do” vs “gi” vs “go” vs “mi” vs “mo” vs “ni” vs “no” vs “ni” vs “no”. The shaded area corresponds to the SEM across subject, dotted black lines mark theoretical chance level, filled circles indicate when performance is significantly above chance (starting from 120ms: $p_{\text{clust}}=0.0001$) Bottom: confusion matrix yielded by the same classifiers at 200ms after stimulus onset. Numbers within each cell indicate the percentage of times a given syllable indicated along the x-axis was classified with the label reported on the y-axis. Off-diagonal values diverging from 0 signal misidentification (chance=8.3%). This example shows how, early on within the trial, classification is mainly driven by manner distinctions. (B) Top: theoretical confusion matrices depicting a perfect separation between (i.e. the ideal classification of) manners of articulation, places of articulation and co-articulated vowel (classes are ordered as in A). Darker colors correspond to the values: 16.6%, 33.3% and 16.6% respectively; light colors correspond to 0%. These matrices were entered as predictors of non-interest in the multiple regression analysis. Bottom: the obtained beta-weights, averaged across subjects and marked by filled circles when significantly above zero (100-920ms: $p_{\text{clust}}=0.0001$ for manner; 240-380ms: $p_{\text{clust}}=0.0195$ for place, 260-920ms: $p_{\text{clust}}=0.0001$ for the vowel). Vertical lines correspond to the SEM.

Classes based on:	generalization across:	time window (ms)	p-clust	peak performance		
				latency (ms)	score	SD
manner	speakers	100-920	0.0001	200	0.673	0.079
	vowels	100-920	0.0001	200	0.678	0.086
place	speakers	200-520	0.0001	260	0.548	0.035
		560-720	0.0014	640	0.522	0.047
	vowels	240-480	0.0001	260	0.538	0.034
		540-680	0.006	640	0.522	0.042
vowel	speakers	260-580	0.0001	460	0.561	0.078
		760-920	0.0002	800	0.554	0.052
	manners	300-580	0.0001	460	0.57	0.08
		680-960	0.0001	820	0.552	0.067
	places	280-600	0.0001	480	0.564	0.082
		760-960	0.0001	820	0.544	0.066

Table S1: Cross-condition decoding Summary of the decoding performances shown in Figure 3.

phonetic feature	time window (ms)	decoding analysis	comparison to overall classification		
			mean score	t(24)	p
manner	200 - 400	overall	0.685±0.065		
		across genders	0.643±0.057	2.278	0.032
		across vowels	0.649±0.0523	2.176	0.040
place	260-360	overall	0.538±0.039		
		across genders	0.548±0.031	-1.085	0.289
		across vowels	0.536±0.033	0.194	0.848
	580-680	overall	0.526±0.039		
		across genders	0.513±0.041	1.353	0.189
		across vowels	0.519±0.032	0.651	0.521

Table S2. Formal comparison between main and cross-condition decoding of phonetic features. Performance of estimators trained on exclusive conditions (“across”; Figure 3A-B) is compared to that of estimators trained on all conditions at once (“overall”; Figure 2A-B). AUC scores were averaged over 200ms (the first time point to be considered was set upon peak performance) and, once ascertained the normality of each distribution, contrasted with two-sided t-tests.
