Design of metastable oxychalcogenide phases by topochemical (de)intercalation of sulfur in $\text{La}_2\text{O}_2\text{S}_2$

Shunsuke Sasaki¹, Maria Teresa Caldes¹, Catherine Guillot-Deudon¹, Isabelle Braems¹, Gwladys Steciuk², Lukáš Palatinus², Eric Gautron¹, Gilles Frapper³, Etienne Janod¹, Benoît Corraze¹, Stéphane Jobic¹✉ & Laurent Cario¹✉

Designing and synthesising new metastable compounds is a major challenge of today's material science. While exploration of metastable oxides has seen decades-long advancement thanks to the topochemical deintercalation of oxygen as recently spotlighted with the discovery of nickelate superconductor, such unique synthetic pathway has not yet been found for chalcogenide compounds. Here we combine an original soft chemistry approach, structure prediction calculations and advanced electron microscopy techniques to demonstrate the topochemical deintercalation/reintercalation of sulfur in a layered oxychalcogenide leading to the design of novel metastable phases. We demonstrate that $\text{La}_2\text{O}_2\text{S}_2$ may react with monovalent metals to produce sulfur-deintercalated metastable phases $\text{La}_2\text{O}_2\text{S}_{1.5}$ and $\alpha\text{-La}_2\text{O}_2\text{S}$ whose lamellar structures were predicted thanks to an evolutionary structure-prediction algorithm. This study paves the way to unexplored topochemistry of mobile chalcogen anions.

Topochemistry enables a step-by-step control of chemical composition and atomic arrangements of materials by introducing, removing, or replacing specific atoms/molecules of host lattices without drastic modification of the overall crystal structure. It is one of the most versatile ways to design phases attainable only in mild synthesis conditions, i.e., at low temperature. Reactions aiming at the intercalation and the deintercalation of cationic species (mainly Li, Na, and other alkali metals) from an inorganic host have been extensively investigated since the sixties¹. These topochemical reactions recently highlighted by the 2019 Nobel Prize in Chemistry led to the stabilization of numerous metastable phases^{2–6} and also gave rise to major applications in Li-ion batteries⁷. In 1999, Hayward and co-workers opened up a seminal topochemistry route based on the deintercalation of oxygen anions. Namely, they succeeded in extracting oxygen atoms of the perovskite-type oxide LaNiO_3 at low temperature ($T = 200^\circ\text{C}$) using NaH as reducing reagent and oxygen getter to form the layered nickelate LaNiO_2 with Ni^{+} cations in square planar coordination⁸. This synthetic pathway received much interest, as extraordinary changes in physical properties (e.g., magnetism, electrical conductivity) could be expected thanks to the stabilization of unusual oxidation states and chemical environment of cations while maintaining the low dimensionality of the inorganic framework^{9–11}. In that respect the stunning discovery of the superconducting nickelate, $\text{Nd}_{0.8}\text{Sr}_{0.2}\text{NiO}_2$, has recently spotlighted the benefit of this topochemical approach¹². So far, such reactions were mainly limited to oxides and no topochemical deintercalation of sulfur at low temperature leading to metastable phases was reported.

To bring this situation to an end, we explore the intercalation/deintercalation of sulfur anions in lanthanum oxysulfides via an original soft chemistry route. We use the evolutionary structure prediction algorithm USPEX^{13,14}, and 3D electron diffraction¹⁵ to confirm and characterize the topochemical deintercalation of sulfur and the formation of new metastable compounds. Return very recently, we demonstrated the formation of layered transition metal chalcogenides by insertion of transition metals in layered precursors containing chalcogenide dimers or trimers^{16,17}. We took advantage of the ability of chalcogen oligomers to be easily reduced to form chalcogenide anions. In the case of sulfide dimers or trimers, the reductive cleavage $(\text{S}_2)^{2-} + 2\text{e}^- \rightarrow 2 \text{S}^{2-}$ or $(\text{S}_3)^{2-} + 4\text{e}^- \rightarrow 3 \text{S}^{2-}$ induced by contact with micrometric copper triggers the spontaneous intercalation of the metal into the precursor at low temperature. As a result, $\text{La}_2\text{O}_2\text{-Cu}_2\text{S}_2$ and BaCu_4S_3 were obtained from the reaction of $\text{La}_2\text{O}_2\text{S}_2$ or BaS_3 with elemental copper at 250°C . Our work also revealed that in the case of the reaction of BaS_3 with Ni at 340°C , sulfur could be extracted from the $(\text{S}_3)^{2-}$ containing precursor to form a $(\text{S}_2)^{2-}$ containing compound (e.g., BaS_2) and a binary transition metal chalcogenide (e.g., NiS_x)¹⁷. This observation suggests that the reduction of the oligomer by zero-valent metal can either lead to the intercalation of metal species or to the partial removal of chalcogen depending on the difference in free energies between the two antagonist reactions. It promoted us to explore more deeply the possible topochemical deintercalation of chalcogenides in layered precursors containing oligomers with various reducing reagents.

Results and discussion

Topochemical conversion from $\text{La}_2\text{O}_2\text{S}_2$ to $o\text{A-La}_2\text{O}_2\text{S}$. $\text{La}_2\text{O}_2\text{S}_2$ appears as the ideal precursor to test the possibility to extend such a concept of anionic topochemistry from oxides to chalcogenides (Fig. 1a). Its structure consists of fluorite-type $2/\infty[\text{La}_2\text{O}_2]^{2+}$ infinite layers separated from each other by discrete $(\text{S}_2)^{2-}$ sulfur

dimers aligned in parallel to these 2D blocks¹⁸. The deintercalation of one sulfur atom per dimer with metal should lead a priori to a $\text{La}_2\text{O}_2\text{S}$ compound (Fig. 1b) whose structure should be inherited from the layered structure of the precursor $\text{La}_2\text{O}_2\text{S}_2$ and that may come with potentially interesting optical properties as found in other oxysulfides^{19,20}. To confirm this hypothesis, we started our investigation by scanning the low-energy structures of $\text{La}_2\text{O}_2\text{S}$ compound using a designed crystal structure prediction (CSP) methodology detailed in Methods section. The combination of USPEX structure searching evolutionary algorithm with first-principles calculations makes it possible to locate two polymorphs, namely *hP* and *oA* crystal structures that are, respectively, stable and metastable (see Fig. 1c and S1–2 for details). Both phases are dynamically stable, justifying their respective location at global and local minima on the potential energy surface of $\text{La}_2\text{O}_2\text{S}$ (see their computed phonon dispersion curves in Figs. S3–4, as well as DFT details in SI). The most stable candidate exhibits a hexagonal layered structure with $2/\infty[\text{La}_2\text{O}_2]$ fluorite-type (111) slab alternating with sulfur atoms in octahedral environment of lanthanum ($P3m1$ space group). Note that, this is the exact structure of the $\text{La}_2\text{O}_2\text{S}$ compound already reported in the literature²¹, and commonly prepared at high temperature ($800\text{--}1200^\circ\text{C}$). This is interesting as it gives a direct validation of the modeling approach. In the following, this structure will be denoted *hP-La* $_2\text{O}_2\text{S}$ according to the Pearson notation (*h* for hexagonal and *P* for primitive cell). The second low-energy phase lies at 72 meV/atom above ground-state *hP-La* $_2\text{O}_2\text{S}$ (GGA PBE level of theory, see SI). Its structure is fully reminiscent to the one of the $\text{La}_2\text{O}_2\text{S}_2$ precursor: it is built upon the stacking of $2/\infty[\text{La}_2\text{O}_2]$ fluorite-type (001) slabs alternating with sulfur atoms in prismatic environments. In the same way with *hP-La* $_2\text{O}_2\text{S}$, this metastable polymorph with orthorhombic *Amm2* space group is named hereafter *oA-La* $_2\text{O}_2\text{S}$. The thermal and kinetic stability of these two structures were further confirmed by ab initio molecular dynamics (AIMD) simulation in which both *hP*- and *oA-La* $_2\text{O}_2\text{S}$ retained their main structural framework after 10 ps at temperatures up to 600 K (Fig. S5–S6). Consequently, the theoretical calculations clearly anticipate the possible existence of metastable *oA-La* $_2\text{O}_2\text{S}$ besides the already known phase *hP-La* $_2\text{O}_2\text{S}$.

The topochemical deintercalation of sulfur in the layered precursor $\text{La}_2\text{O}_2\text{S}_2$ was subsequently attempted by reaction with alkali metal Rb^0 at low-temperature in evacuated and sealed pyrex tubes. Once excess Rb (and its salts) was washed out by dry ethanol (see synthetic procedure in Methods section), the powder X-ray diffraction (XRD) patterns were collected on products synthesized at 200°C and 350°C . They are very similar and could not be indexed with any known phases (Fig. 2a). The energy dispersive X-ray (EDX) spectra of the bulk product powder clearly revealed the absence of rubidium and a molar ratio $\text{La} / \text{O} / \text{S}$ of $2.0(3) / 2.0(4) / 0.98(11)$ (see Fig. S7). These results indicate the formation of a $\text{La}_2\text{O}_2\text{S}$ phase without incorporation of Rb in the structure. The *hP-La* $_2\text{O}_2\text{S}$ XRD peaks were not detected at all in the X-ray pattern but the existence of the polymorph *oA-La* $_2\text{O}_2\text{S}$ predicted by USPEX could be readily established via Rietveld refinement (Fig. 2a) with goodness of fit $\chi^2 = 1.33$ and Bragg reliability factor $R(\text{obs}) = 1.68\%$ (see Table S3 for details). Scanning Transmission Electron Microscopy (STEM) also support the conclusion that the newly synthesized phase is *oA-La* $_2\text{O}_2\text{S}$. The stacking of $2/\infty[\text{La}_2\text{O}_2]$ infinite sheets with the fluorite-type (001) slab structure is clearly visible on the High Angle Annular Dark Field (HAADF) STEM image (Fig. 2b, c). In contrast, the fluorite-type (111) slabs characteristic of the stable polymorph *hP-La* $_2\text{O}_2\text{S}$ (Fig. S8) could not be found in the experiment STEM image. The EDX spectrum of a nanosized

Fig. 1 Topochemical reactivity of $\text{La}_2\text{O}_2\text{S}_2$. **a** Structure of $\text{La}_2\text{O}_2\text{S}_2$ reported by Ostorero et al. (SG: $Cmca$)¹⁸. Lanthanum, oxygen, and sulfur atoms are represented by white, red, and yellow balls, respectively. **b** Conceptual scheme of S–S bond cleavage under the donation of one electron per elemental metal M^0 that triggers subsequently the deintercalation of half sulfur atom of the S_2 dumbbell that possibly enables topochemical conversion of $\text{La}_2\text{O}_2\text{S}_2$ into the new polymorph of $\text{La}_2\text{O}_2\text{S}$. **c** The two low-energy dynamically stable phases of $\text{La}_2\text{O}_2\text{S}$ predicted by USPEX that are separated by 72 meV/atom.

single crystal indicated, similarly to the EDX analysis of the bulk powder, a La / S ratio of 2.0(3) / 1.0(2) consistent with the composition $\text{La}_2\text{O}_2\text{S}$ (see Fig. S9). The structural arrangement of the new $oA\text{-La}_2\text{O}_2\text{S}$ compound is directly inherited from $\text{La}_2\text{O}_2\text{S}_2$. This observation definitely supports the topochemical nature of the deintercalation process. Indeed, the sulfur deintercalation process does not modify at all the integrity of the $2/\infty[\text{La}_2\text{O}_2]$ slab but entails a shift of every second $2/\infty[\text{La}_2\text{O}_2]$ layer along the $1/2(b+c)$ direction of the $\text{La}_2\text{O}_2\text{S}_2$ structure (SG: $Cmca$). Raman spectroscopy confirmed the complete loss of the sulfur dimers along the topochemical reduction. Namely, the band associated to the S–S stretching modes located at 487 and 498 cm^{-1} in $\text{La}_2\text{O}_2\text{S}_2$ have totally disappeared after the deintercalation of one sulfur from $\text{La}_2\text{O}_2\text{S}_2$ (Fig. S10), confirming the conclusion made from the XRD pattern that the reaction of $\text{La}_2\text{O}_2\text{S}_2$ towards $oA\text{-La}_2\text{O}_2\text{S}$ was complete. Finally, the diffuse-reflectance spectra also support the cleavage of $(\text{S}_2)^{2-}$ dimers (Fig. S11). The absorption thresholds move from 2.56 eV in $\text{La}_2\text{O}_2\text{S}_2$, a value characteristic of a $\pi^*-\sigma^*$ electronic transition of sulfur pairs^{22,23}, to 3.88 eV in $oA\text{-La}_2\text{O}_2\text{S}$, a value significantly lower than the one observed in the $hP\text{-La}_2\text{O}_2\text{S}$ (4.13 eV). Our DFT calculations with the HSE06 functional fully confirmed the expected increase of the bandgap going from $oA\text{-La}_2\text{O}_2\text{S}$ to $hP\text{-La}_2\text{O}_2\text{S}$ (calculated gaps of 4.1 and 4.3 eV, respectively). Based on previous experimental and theoretical studies on $hP\text{-La}_2\text{O}_2\text{S}$ ^{24,25}, their optical bandgaps can be associated to a $\text{S-3p} \rightarrow \text{La-6s/La-5d}$ transition. Therefore, the difference of the bandgap values between the metastable and stable $\text{La}_2\text{O}_2\text{S}$ varieties is likely ascribed to changes in the local environment of sulfur and lanthanum atoms.

As a whole, we can conclude that during the reaction between $\text{La}_2\text{O}_2\text{S}_2$ and elemental rubidium, the alkali metal activates a redox reaction with $(\text{S}_2)^{2-}$ dimers that triggers the fracture of the S–S bonds. However, contrary to Cu^0 metals that intercalate into the $\text{La}_2\text{O}_2\text{S}_2$ host lattice¹⁶, Rb^0 led to the topochemical deintercalation of sulfur to afford the unprecedented $oA\text{-La}_2\text{O}_2\text{S}$ metastable phase. Preliminary calculations suggest that the

intercalation of metal versus the deintercalation of sulfur is dictated by thermodynamic considerations and that the choice of reducing agents is the decisive factor for the outcome of the reaction. Even though, complete theoretical investigations are needed to ascertain this assertion, some experimental work further highlight the decisive role of the reducing power. Indeed, no reaction occurred when $\text{La}_2\text{O}_2\text{S}_2$ was treated at 200–300 °C under reducing atmosphere, i.e., 5% H_2/Ar flow (Fig. S12). The reduction was activated at 350 °C, but it led to the thermodynamically stable $hP\text{-La}_2\text{O}_2\text{S}$, where the original fluorite (001) slab was deformed into the fluorite (111) slab. This result highlights the contrast between the common reducing agent such as H_2 atmosphere and the more powerful reducing agent Rb^0 , which favored, even at the same reaction temperature (i.e., 350 °C), topochemical reduction to $oA\text{-La}_2\text{O}_2\text{S}$.

Partial (de)intercalation of sulfur. At this stage, we might naturally wonder whether the topotactic deintercalation of $\text{La}_2\text{O}_2\text{S}_2$ is reversible or not at low temperature. To test this possibility, a portion of $oA\text{-La}_2\text{O}_2\text{S}$ was mixed with one molar equivalent of sulfur and heated at 200 °C (Fig. 3a) and the product was analyzed by XRD (Fig. 3b). The original $\text{La}_2\text{O}_2\text{S}_2$ material could be fully recovered with no other reaction product, confirming the full reversibility of the temperature-assisted intercalation/deintercalation processes based on the formation/rupture of sulfur dimers within the $\text{La}_2\text{O}_2\text{S}/\text{La}_2\text{O}_2\text{S}_2$ layered oxychalcogenides. To gain more insight into the reaction mechanism of the sulfur intercalation, we also tested the reactivity of $oA\text{-La}_2\text{O}_2\text{S}$ with only half molar equivalent of sulfur at low temperature to reach the target $\text{La}_2\text{O}_2\text{S}_{1.5}$ compound, i.e., a mid-composition between $\text{La}_2\text{O}_2\text{S}_2$ and $\text{La}_2\text{O}_2\text{S}$. The XRD pattern of the product obtained at 200 °C (Fig. 3b) revealed the conversion of $oA\text{-La}_2\text{O}_2\text{S}$ into an unknown intermediate phase along with a small amount of $\text{La}_2\text{O}_2\text{S}_2$. The XRD pattern of this intermediate phase was similar to the one of $oA\text{-La}_2\text{O}_2\text{S}$ but shifted to lower diffraction angles, suggesting the

Fig. 2 Structure characterization of *oA-La₂O₂S*. **a** Experimental XRD pattern of *oA-La₂O₂S* obtained by the reaction of *La₂O₂S₂* with *Rb⁰* metal at 350 °C. The Rietveld refinement was conducted using as input the structure predicted by USPEX. **b** Simulated HAADF-STEM images viewed along [010] and [100] directions obtained using the refined structure of *oA-La₂O₂S*. In the projected structure lanthanum, oxygen, and sulfur atoms are represented by white, red, and yellow balls, respectively. **c** The experimental HAADF-STEM image of *oA-La₂O₂S* superimposed by each of the simulated images. Only La atoms were observed as bright spheres (ADF signal is proportional to the *n*th power of the atomic number, with *n*=2).

existence of an intercalated *oA-La₂O₂S_x* phase ($1 < x < 2.0$). The same XRD pattern was observed in the attempt to deintercalate 0.5 S from *La₂O₂S₂* using 1.0 equiv. of *Rb⁰*, 1.0 equiv. of Ag, and 0.5 equiv. of *Ni⁰* (Fig. 3c). These diffraction patterns could be refined with the same space group as *oA-La₂O₂S* (*Amm*2) and cell parameters of ~ 8.5 Å, ~ 4.0 Å, and ~ 12.9 Å without any superstructure peak. This clearly proved the existence of an intermediate phase with a strong reminiscence of the *oA-La₂O₂S* structure. One of the reasonable assumptions is that this new phase replaced one half of monoatomic *S²⁻* with dimeric (*S₂²⁻*) anions retaining the main structural framework of *oA-La₂O₂S*. This partial dimerization should lead to the expected *La₂O₂S_{1.5}* composition. To confirm this hypothesis, we analyzed the elemental composition of the nanocrystal (≤ 100 nm) found in the sample after the thermal treatment of *oA-La₂O₂S* + 0.5 S. Its EDX spectrum acquired on STEM indicated the La / O / S ratio of 2.0(3) / 2.0(3) / 1.5(3), supporting the hypothetical composition *La₂O₂S_{1.5}* (see Fig. S13). Furthermore, both intercalation of 0.5 S and deintercalation of 0.5 S using metal species gave similar Raman spectra that featured a single intense peak at 413–417 cm^{-1} while Raman peaks from *oA-La₂O₂S* and *La₂O₂S₂* were absent (Fig. S14–S15). Since an intense peak around 400–500 cm^{-1} is characteristic of S–S stretching mode²⁶, these Raman spectra support the formation of *La₂O₂S_{1.5}* through the partial cleavage of S–S bonds.

To solve the crystal structure of this novel phase, we analyzed it by precession electron diffraction tomography (PEDT) (Fig. 4a, see Fig. S16 and Table. S4 for details)^{27,28}. This emerging technique allows the solution of complex structures using single nanocrystals. PEDT data were collected on several nanocrystals of

the novel phase. All data sets were analyzed using the computer programs PETS2.0²⁹, Superflip³⁰, and Jana2006³¹. Figure 4a shows the reconstruction of the reciprocal lattice planes *hk*0, *h*0*l*, and *0**kl* which are consistent with an orthorhombic unit cell $a = 8.348$ Å, $b = 3.961$ Å, and $c = 12.645$ Å ($V = 418.1$ Å³) and a non-centrosymmetric space group *Amm*2 (see SI). The structure was subsequently solved and refined using the program Jana2006 on the basis of electron diffraction data using the dynamical theory of diffraction^{32,33}. The structure analysis converged with electron Bragg reliability factor $R(\text{obs}) = 10.1\%$, revealing the layered structure displayed in Fig. 4b with the composition *La₂O₂S_{1.5}*. This structure consists of $2/\infty[\text{La}_2\text{O}_2]$ fluorite-type (001) infinite slab alternating with sulfur layers containing one third and two thirds of sulfur atoms in the *S²⁻* and (*S₂²⁻*) anionic forms, respectively. Using this *oA-La₂O₂S_{1.5}* structure model, both powder XRD patterns from sulfur intercalation and deintercalation, i.e., from *oA-La₂O₂S* + 0.5 S and *La₂O₂S₂* + 0.5 Ni reaction mixtures (Fig. 3), were successfully refined (Fig. S17 and Tables S5–S6). Large strain parameters had to be considered to reach satisfactory fitting. This can be interpreted as the signature of a stacking disorder occurring, as expected, during the intercalation or deintercalation processes in relation with the 2D structure of the host lattice and possible co-existence of different stages of (de)intercalation. The structure analysis was based on data collected on the most ordered crystals. However, in most of the electron diffraction data, diffuse scattering features along the [001] axis signified the presence of stacking faults in the crystal. Fig. 4c shows the high-resolution image obtained on a well-organized domain of *oA-La₂O₂S_{1.5}*. The experimental

The second visible lattice (blue) corresponds to a second adjacent crystal and was measured in the same data set. **b** The structure of $\text{oA-La}_2\text{O}_2\text{S}_{1.5}$ solved and refined from PEDT data set. The right side of the panel represents the simulated HAADF-STEM image along $[010]$ on the basis of the $\text{oA-La}_2\text{O}_2\text{S}_{1.5}$ structure model. **c** The experimental HAADF-STEM image acquired in a well-organized domain $\text{oA-La}_2\text{O}_2\text{S}_{1.5}$ superimposed with the simulated one.

contrast in the HAADF-STEM image (Fig. 4c) asserts the stacking of $2/_{\infty}[\text{La}_2\text{O}_2]$ fluorite-type (001) infinite slabs. A similar structure was predicted independently by the evolutionary algorithm USPEX for the composition $\text{La}_2\text{O}_2\text{S}_{1.5}$. Indeed, the structure

prophesied to be the most stable accorded well with the experimental structure obtained by the PEDT analysis (Fig. S18). The 2nd and 3rd most stable structures displayed intergrowth structures made of, respectively, corrugated or hexagonal

Fig. 5 Overview of the rich low-temperature sulfur topochemistry in the La-O-S system. The topochemical intercalation and deintercalation of sulfur in the oxysulfide compound $\text{La}_2\text{O}_2\text{S}_2$ lead to the formation of two new metastable compounds.

(fluorite-type (111)) 2D $[\text{La}_2\text{O}_2]$ slabs alternating with (quasi-)2D arrays of sulfur dimers/atoms. However, none of them could be found in our experiments.

To conclude, this work demonstrates the deintercalation and reintercalation of sulfur in a layered oxysulfide compound using an original topochemical approach. Alkali or transition metals may be used as reducing agent to trigger the reduction of the chalcogenide oligomers and breaking of the chalcogen–chalcogen bond. In the case of $\text{La}_2\text{O}_2\text{S}_2$, the low-temperature deintercalation of sulfur atoms proceeds in two steps to form two new metastable phases $\text{La}_2\text{O}_2\text{S}_{1.5}$ and $\text{oA-La}_2\text{O}_2\text{S}$ that both retain the layered feature of the precursor (Table 1). This is a fully reversible topotactic process as the sulfur atoms may be reintercalated at low temperature to form back the precursor $\text{La}_2\text{O}_2\text{S}_2$ (illustrated schematically in Fig. 5). This work gives therefore a glimpse of what could be the richness of the topochemistry of chalcogenide compounds and may open up an avenue to forthcoming batteries built upon mobile sulfur ions as well as to promising electronic or optical materials^{19,23–25}.

Methods

Topochemical conversion from $\text{La}_2\text{O}_2\text{S}_2$ into $\text{oA-La}_2\text{O}_2\text{S}$. The initial precursor $\text{La}_2\text{O}_2\text{S}_2$ was synthesized following the procedure described in our previous report¹⁶. $\text{La}_2\text{O}_2\text{S}_2$ and Rb (Aldrich, 98 + %) were weighed in a 1: 2 molar ratio and introduced into a silica tube whose bottom was protected by a carbon coating (cracking of acetone in the flame). All these preparations were done under argon atmosphere, then the silica tube was evacuated ($\sim 10^{-3}$ torr) and sealed. The mixture was heated to 200 °C at a rate of 20 °C h⁻¹ and held at that temperature for 2 h. Finally, the sealed tube was gradually cooled to room temperature. The obtained powder turns to be pale greyish-blue. The silica tube was opened under argon atmosphere and the content was washed with ethanol, which rendered the powder colorless. The colorless precipitate was contaminated by tiny flakes of carbon, which were removed by repetitive decantation with mechanical agitation. The precipitate was then washed with ethanol, water, and acetone, followed by dryness in vacuo to obtain the pure colorless powder of $\text{oA-La}_2\text{O}_2\text{S}$. The product was stable under ambient atmosphere. The same reaction performed at 350 °C gave identical results, i.e., pure $\text{oA-La}_2\text{O}_2\text{S}$ without any trace of *hP*- $\text{La}_2\text{O}_2\text{S}$.

Intercalation of sulfur anions into $\text{oA-La}_2\text{O}_2\text{S}$. The colorless powder of $\text{oA-La}_2\text{O}_2\text{S}$ (ca. 200 mg) was combined with S flakes (Aldrich, 99.99 + %) in $\text{oA-La}_2\text{O}_2\text{S}$: S = 1: 0.5 molar ratio and ground in an agate mortar under argon atmosphere. Then the mixture was pelletized and sealed in an evacuated ($\sim 10^{-3}$ torr) silica tube. The sealed mixture was heated to 150 or 200 °C at a rate of 100 °C h⁻¹ and held at the same temperature for 4 h ($T = 200$ °C) and 48 h ($T = 150$ °C, see results in Fig. 3b), respectively, followed by gradual cooling in a furnace to obtain a pale yellow pellet. To complete the intercalation, the obtained pellet was again subject to the thermal treatment at 200 °C in the evacuated silica tube. After 160 h of annealing, the mixture was fully converted into the pale yellow pellet of the pure $\text{La}_2\text{O}_2\text{S}_2$.

Partial deintercalation of sulfur from $\text{La}_2\text{O}_2\text{S}_2$ to get $\text{oA-La}_2\text{O}_2\text{S}_{1.5}$. To prepare $\text{oA-La}_2\text{O}_2\text{S}_{1.5}$, either 0.5 equiv. of Ni (Aldrich, <100 nm, 99%) or 1.0 equiv. of Ag (Aldrich, 2–3.5 μm, ≥99.9%) was added to 1.0 equiv. of $\text{La}_2\text{O}_2\text{S}_2$ (ca. 150–250 mg). The mixture was ground together under argon atmosphere until the powder became greyish and sticky. Then the powdered sample was pelletized, sealed in an evacuated ($\sim 10^{-3}$ torr) silica tube, and heated to 350 °C at a rate of 300 °C h⁻¹. The plateau temperature was maintained for 2 or 4 h before gradual cooling at RT for Ni and Ag, respectively (see Fig. 3c for XRD). Repeated thermal treatments did not lead to further consumption of $\text{La}_2\text{O}_2\text{S}_2$ even when excess Ag was added (i.e., using 1.1 equiv. of Ag). In the same way, when using Ni prolonged and repeated thermal treatments did not improve the yield of $\text{oA-La}_2\text{O}_2\text{S}_{1.5}$.

Characterizations. Powder X-ray diffraction (XRD) patterns were recorded at room temperature on a Bruker D8 Advance Diffractometer (Bragg-Brentano geometry, θ – 2θ), which employs Cu K α_1 radiation ($\lambda = 1.540598$ Å) produced through Ge (111) monochromator and a LynxEye detector. Rietveld refinements of these XRD patterns were performed with Jana2006 package³¹ using the fundamental parameter approach³⁴. XRD peaks from the known phases were fitted on the basis of the previously reported structure models (see Table S3 and S5–6 for the details). Anisotropic microstrain was considered by refining anisotropic peak broadening employing Stephen's tensor method³⁵. The chemical composition of $\text{oA-La}_2\text{O}_2\text{S}$ was inspected by energy-dispersive X-ray (EDX) spectroscopy on a JEOL 5800LV scanning electron microscope (SEM) operating at 20 keV. The flat-polished specimens were prepared by impregnation of powder samples with the epoxy resin and subsequent grinding with ethanol/diamond grit suspensions. The detailed procedures of Raman spectroscopy and diffuse-reflectance spectroscopy are described in the supporting information.

Scanning Transmission Electron Microscopy (STEM) imaging. Samples were prepared by dispersing the powder in ethanol and depositing the solution obtained on a holey-carbon-coated copper grid. Z-contrast imaging was performed on a Cs-probe corrected STEM Themis Z G3 (Thermo Fisher Scientific) equipped with a High Angle annular Dark Field (HAADF) detector (Fischione) operating at 80 or 300 kV accelerating voltage, with a 21.4 mrad convergence angle and 63–200 mrad collection angle. It is equipped with the 4-SDD detectors Super-X system allowing EDS analysis. Simulated images were obtained using the Dr Probe program³⁶.

Precession Electron Diffraction Tomography (PEDT) of $\text{oA-La}_2\text{O}_2\text{S}_{1.5}$. The black powder from the reaction of $\text{La}_2\text{O}_2\text{S}_2$ with Ni (*vide supra*) was crushed in ethanol. A drop of the suspension was deposited and dried on a gold grid with a thin film of holey amorphous carbon. 3D electron diffraction data (3D ED)¹⁵ were collected using the precession electron diffraction tomography (PEDT) technique on a Philips CM120 electron transmission microscope (TEM) ($V_{\text{acc}} = 120$ kV, LaB₆) with the precession device Nanomegas Digistar and a side-mounted CCD camera Olympus Veleta with 14 bit dynamic range. PEDT data sets were collected at the ambient temperature on several crystals using a 1-degree precession angle and a 1-degree tilt step (see Fig. S16 and Table. S4). 3D ED data were analyzed using the computer programs PETS2.0²⁹, Superflip³⁰, and Jana2006³¹. The structure analysis was performed from one data set that included the diffraction signal from two crystals (Fig. S16). For each data set, two *hkl*-type files are obtained: one for structure solution and kinematical refinement, and another file suitable for the dynamical refinement, where each ED frame is considered independent^{32,33}. The refinement procedure using the dynamical theory of diffraction (called “dynamical

refinement”) implemented in JANA2006 was used. For the analysis, the data coming from the two adjacent crystals were combined to increase the data coverage and the statistic of the refinement. The data indicate an orthorhombic unit cell $a = 8.348 \text{ \AA}$, $b = 3.961 \text{ \AA}$, and $c = 12.645 \text{ \AA}$ ($V = 418.1 \text{ \AA}^3$) and a non-centrosymmetric space group $Amm2$ ($k + l = 2n$ on hkl). The initial structure can be described with 8 atoms forming an alternation of infinite fluorite-type layers $[\text{La}_2\text{O}_2]$ and sulfuric layers stacked along c -axis (Fig. S16e). The model was validated by the dynamical refinement following the procedure suggested in Palatinus et al.^{32,33}. The refinement leads to satisfying values with $R(\text{obs})/wR(\text{obs}) = 10.12\%/11.42\%$ for 3523/4246 observed/all reflections. The refinement and crystallographic parameters are presented in Table S4.

Structure predictions by the evolutionary algorithm. USPEX (Universal Structure Predictor: Evolutionary Xtallography) works on the EA (evolutionary algorithm) to perform a global search of crystal structures. USPEX is developed by the A.R. Oganov laboratory since 2004 and its detail is described in the articles from his group^{13,14}. In this work, this EA code was interfaced with VASP (Vienna Ab initio Simulation Package) for DFT structure relaxation (shape, volume, atomic positions are optimized by VASP). The EA development allows the prediction of stable and metastable structures knowing only the chemical composition, i.e., 2 La and 2 O and 1 S here, to search 3D $\text{La}_2\text{O}_2\text{S}$ bulk phases. An initial population of 80 randomly created structures was considered as the first generation. Then the structures considered as worst were discarded. A structure was considered bad according to its fitness, that was the computed free enthalpy derived from ab initio total energy calculations (VASP). The remaining structures form the parent structures participated in producing the next generation. A new candidate structure was produced from parent structures using one of four operators: (i) heredity (50%), (ii) permutation (10%), (iii) lattice mutations (10%), and (iv) soft mutation (10%). 80% of the new candidates were generated from evolutionary operators, while 20% were produced randomly. We verified that our results were not sensitive to these parameters (initial population size, ratio between the four operators), by performing multiple runs with them varying from 10% around the nominal value indicated here. The USPEX search was terminated when the global structure minimum was found in the last 10 generations. Each USPEX job was run at least twice to ensure the convergence to a global minimum. As mentioned above, structure relaxations and energy calculations were done by the external code VASP (5 INCAR files, 5 steps per phase). The total number of atoms in the primitive cell is up to 40.

Acknowledgements

S.S. is financially supported by JSPS Overseas Research Fellowships. The electron diffraction experiments were performed within CzechNanoLab Research Infrastructure supported by MEYS CR (LM2018110) and supported by Operational Programme Research, Development and Education financed by European Structural and Investment Funds and the MEYS CR (Project No. SOLID21 CZ.02.1.01/0.0/0.0/16_019/0000760). TEM images were collected in the CIMEN Electron Microscopy Center in Nantes funded by the French Contrat Plan État-Région and the European Regional Development Fund of Pays de la Loire. We also acknowledge the Jean Zay/IDRIS GENCI (France) under project n° A0080911512 and Jean Zay Challenge for allocation of computing time. Louis-Béni Mvéle Eye'a is thanked for his help in the chemical synthesis work.

Author contributions

S.S. performed the synthetic work and characterization of the products; M.T.C., C.G.-D., and E.G. conducted TEM analyses; G.S. and L.P. studied the structure of *oA*-La₂O₂S_{1.5} by 3D electron diffraction; I.B. and G.F. performed the computational study; E.J., B.C., L.C., and S.J. supervised the study. S.S., L.C., and S.J. wrote the initial draft and all authors contributed to the manuscript.

Competing interests

The authors declare no competing interests.
