25 Abstract:

The pyrenean orogen extended eastward, across the present-day Gulf of Lion margin. The 26 late or post-orogenic dismantling of this orogen segment, contemporaneous with ongoing 27 28 shortening in the Spanish Pyrenees, is still debated. Understanding the transition between the 29 two geodynamic events requires to document the precise timing of the succession of the 30 tectonic processes involved. We investigate the superposition of rifting structures over 31 pyrenean thrusts and folds in the onshore Languedoc. Compilation and reassessment of the regional chronostratigraphy, in the light of recent biostratigraphic dating and new mapping of 32 Paleogene basins, lead to date the transition to the Priabonian. Tectonic-sedimentation 33 34 relationship in the Eocene to Oligocene depocentres are analysed in surface exposures as 35 well as in seismic reflection surveys. Bed-to bed mapping allowed us to: i) characterise an intermediate sequence of Priabonian age, bounded at the base and the top by unconformities; 36 ii) evidence syn-depositional deformation within the Priabonian; iii) define the axes of 37 Priabonian deformation. Interpretation of seismic reflection profiles, across the onshore basins 38 covered by syn- and post-rift sequences, reveal the existence of an intermediate sequence 39 displaying similar features, and that is correlated to the Priabonian. Syn-depositional 40 deformation of some Priabonian basins correspond to extensional structure, whereas 41 neighbouring, contemporaneous basins, reveal compressional deformation. The distribution of 42 such apparently conflicting observations across the studied area provides evidence for left-43 44 lateral strike-slip deformation between two major regional faults (Cévennes and Nîmes faults). 45 Left-lateral strike-slip along NE-trending faults accommodates E-W extension of the West 46 European Rift (ECRIS) and part of the ongoing N-S shortening in the Central and Western 47 Pyrenees. Priabonian clastic sedimentation and deformation in Languedoc witness the initial stages of the dismantling of the Languedoc-Provence Pyrenees, prior to Oligocene-Aquitanian 48 49 back-arc rifting.

55 Résumé (français)

L'orogène pyrénéen s'étendait vers l'est à l'emplacement actuel du Golfe du Lion. Contemporain de la poursuite de la compression dans les Pyrénées franco-espagnoles, le démantèlement tardi- ou post-orogénique de ce segment de l'orogène est encore mal compris. La compréhension de la transition entre l'orogénèse Pyrénéo-Provençale et le rifting du Golfe du Lion nécessite de préciser le calendrier des évènements ainsi que la succession des différents processus tectoniques mis en jeu. Nous analysons la superposition des structures

du rifting sur les structures compressives Pyrénéennes exposées à terre, dans le Languedoc. 62 Tout d'abord, nous compilons et révisons la chronostratigraphie régionale, à la lumière de 63 datations postérieures à la publication des cartes au 1/50.000- du BRGM, et de la cartographie 64 65 de plusieurs bassins paléogènes. Nous datons cette transition du Priabonien. Nous analysons 66 les relations tectonique-sédimentation des dépocentres Eocène à Oligocène sur le terrain et 67 en sismique réflexion. La cartographie banc-par-banc permet de : i) caractériser une séguence 68 intermédiaire d'âge Priabonien encadrée par deux discordances, ii) mettre en évidence une déformation syn-dépôt dans le remplissage Priabonien, iii) définir les axes de la déformation 69 priabonienne. L'interprétation de profils de sismigue réflexion à travers les bassins paléogènes 70 à terre, recouverts par les séries syn-et post-rift, révèle l'existence d'une séquence 71 72 intermédiaire présentant des caractéristiques similaires et que nous corrélons avec le Priabonien. La déformation syn-dépôt de certains bassins est extensive, alors que dans des 73 bassins voisins contemporains, elle est compressive. La distribution régionale de ces 74 75 observations apparemment contradictoires est interprétée comme liée à un couloir de déformation en décrochement senestre entre les failles majeures des Cévennes et de Nîmes, 76 d'orientation NE-SW. Ce décrochement accommode l'extension EW des rifts ouest-européens 77 et contribue au raccourcissement N-S des Pyrénées franco-espagnoles, toujours actif au 78 Priabonien. La sédimentation syn-tectonique clastique du Priabonien du Languedoc enregistre 79 les premiers stades du démantèlement de la chaine pyrénéo-provençale, plusieurs millions 80 d'années avant l'initiation de l'extension d'arrière-arc. 81

89 The Pyrenean orogen results from the inversion of Mesozoic extensional basins, mostly 90 formed during Mid-Cretaceous rifting and mantle denudation (Chelalou et al., 2016; Cochelin et al., 2018; Lagabrielle and Bodinier, 2008; Lagabrielle et al., 2010; Ternois et al., 2019; 91 Tugend et al., 2014; Vergés and Garcia-Senz, 2001). The orogenic shortening was 92 93 accommodated in the upper crust by reactivation of the inherited Cretaceous extensional faults, as thrust faults (Debroas, 1990), while the middle crust and exhumed mantle were 94 subducted beneath the European crust (Teixell et al., 2018; Teixell et al., 2016). The orogen 95 extended eastwards (Ford and Vergés, 2020), in Corbières (Lamotte et al., 2002; Viallard, 96 97 1987), Languedoc (Arthaud and Laurent, 1995) and southern Provence (Bestani et al., 2015; Lacombe and Jolivet, 2005), across the present-day Gulf of Lion (Arthaud and Séguret, 1981; 98 Gorini et al., 1994). It was later dismantled in Oligocene time to give way to the Gulf of Lion 99 100 rifted margin (Arthaud et al., 1981; Arthaud and Séguret, 1981; Gorini et al., 1994; Guennoc et al., 2000; Lacombe and Jolivet, 2005; Mascle and Vially, 1999; Mauffret and Gorini, 1996; 101 Séranne, 1999; Séranne et al., 1995). In the onshore Corbières area, upper crust extension is 102 characterised by "negative inversion" of the Pyrenean thrusts, associated with deposition of 103 Oligocene-Aquitanian syn-rift sediments in the hanging-wall (Gorini et al., 1991). The crustal 104 roots of the Pyrenees disappear eastwards (Chevrot et al., 2018) and the orogen brutally gives 105 way to the Gulf of Lion rift and margin, within only tens of kilometres (Jolivet et al., 2020; 106 Mauffret et al., 2001). Although documented both onshore and offshore, tectonics and 107 kinematics of the superimposition of Pyrenean structures by later rifting (Fig. 1) remains 108 109 incompletely understood. Transition of the compression to extension could be driven by collapse of the elevated mountain range (Séranne et al., 1995), it could be related to the 110 southern propagation of the European Cenozoic Rift System (ECRIS) (Dèzes et al., 2004), or 111 to the onset of back-arc extension due to the NW-dipping subduction roll-back of the old 112 Tethyan lithosphere (Jolivet et al., 2020; Séranne, 1999). Better constraints on tectonics and 113 114 precise timing of the transition from the Pyrenean orogeny to the Gulf of Lion rifting are needed in order to better understand the origin and driving mechanism of the transition between the 115 two major geodynamics events. Such data are also needed to constrain paleotectonic 116 restorations (e.g. (Bestani et al., 2015; Christophoul et al., 2016), and kinematic 117 reconstructions of the Mediterranean (e.g. (Romagny et al., 2020). 118

Since most of the collapsed orogen is presently buried beneath the thick Neogene sequence of the Gulf of Lion margin, the onshore Languedoc provides the only geological outcrops that are relevant to address this question. There, the rare available stratigraphic data suggested that the Pyrenean orogeny lasted until "early Oligocene", as reported on the Saint-Martin-de-Londres 1/50.000-scale geological map (Philip et al., 1978), while rifting took place in the late

- Rupelian according to the Montpellier map (Andrieux et al., 1971). Consequences of such a short delay implies: i) that Pyrenean compression was polyphase, including a last compressive phase, following a Late Eocene period of tectonic quiescence, and ii) rifting interrupted folding and thrusting, with no transition.

134

In this paper, we examine five Paleogene basins located in Languedoc, which developed at 135 the front of the Eocene external thrusts of the Pyrenean belt and onshore of the Gulf of Lion 136 passive margin. The main objective of this contribution is to document, thanks to the revision 137 of available biostratigraphic data and to detailed sedimentological, tectonic and seismic 138 analyses, the key period of the transition between the last stages of Pyrenean orogenic 139 (mountain building) events and the earliest stages of rifting associated with the opening of the 140 141 Gulf of Lion. We aim at constraining the tectonic setting associated with the deposition of 142 Priabonian continental units by analysing the tectonic-sedimentation relationships in 5 distinctive basins (Fig. 2). Analyses are based on field observations (Guzargues, Les-Matelles, 143 144 Saint-Martin-de-Londres basins) and subsurface data (Hérault and Saint-Chaptes Gardon 145 basins). This study also relies on: i) new original investigation in the Guzargues basin, ii)

- 146 reappraisal of published works in Les-Matelles and Saint-Martin-de-Londres basins (the latter
- 147 involving additional mapping), and iii) the interpretation of ancient (1983-1992) seismic profiles
- tied to boreholes data in the Hérault and Saint-Chaptes Gardon basins.

Fig. 2: Simplified geological map of Languedoc, in the northern foreland of the Provence-Pyrenees fold and thrust belt. See location in the regional structural framework of Fig.1. Priabonian basins according to the present study, in some areas, stratigraphic attributions are different from the BRGM 1/50.000scale geological maps (see text for explanation). Subsurface data used in the study is indicated fine black lines (seismic) and open circles (boreholes); seismic profiles shown in this contribution are in bolder black line. Location of detailed maps and sections is shown with double black line frames.

159 **2-1** Location of the studied area within the Pyrenean orogen

160

Languedoc, in the south of France, is located between the Variscan basement of the Massif Central and the shores of the Mediterranean Sea; it links the Pyrenees (in the SW) to the Alps (to the NE), across the Rhône Valley (Fig. 1). Together with the Corbières, Languedoc forms

a segment of the north foreland of the Pyreneo-Provençal fold and thrust belt (Arthaud and 164 Séguret, 1981; Bestani et al., 2015). 165

The Paleozoic (Variscan) basement is exposed in the Massif Central to the NW, in the Maure 166 167 and Esterel massifs to the east. To the south, the basement has been reactivated during the 168 Late Cretaceous to Eocene Pyrenean orogeny. It is exposed in the Pyrenees and buried 169 beneath the thick Neogene sequences of the Gulf of Lion margin (Arthaud and Séguret, 1981; 170 Gorini et al., 1994; Guennoc et al., 2000) (Fig. 1). Onshore, the Variscan basement is unconformably covered by Mesozoic sequence, including at the base variable amounts of 171 Triassic detritals and evaporites (Debrand-Passard and Courbouleix, 1984), which have been 172 used as decollement level during later tectonic phases. The Jurassic through to Neocomian 173 174 marine marls and carbonates were deposited during the Tethyan rifting and subsequent thermal subsidence, controlled by NE-trending normal faults such as the Cévennes, Nîmes 175 and Durance faults. Thickness of the Jurassic increases southeastwards from the Cévennes 176 fault (less than 1,5km), and maximum subsidence is recorded in the hanging-wall of the Nîmes 177 Fault, where seismic profiles show up to 10km of Trias to Neocomian sequences (Le Pichon 178 179 et al., 2010; Séguret et al., 1997).

This Mesozoic sedimentary cover has been folded and thrusted in the Pyrenean foreland, 180 detached over Triassic decollement. Thick-skinned thrusting presumably occurred close to the 181 present day shoreline (Arthaud and Séguret, 1981; Lacombe and Jolivet, 2005; Séranne et al., 182 183 1995), The style of the thrust and fold belt is mostly controlled by the thickness of the detached 184 Mesozoic sedimentary cover (Arthaud and Laurent, 1995): north-verging, EW-oriented thrusts dominate areas of thin cover (≤ 2,5 to 3 km) whereas thicker cover developed series of E-W 185 186 folds. Combined thin- and thick-skinned shortening exceed 20km in the Languedoc (Arthaud 187 and Laurent, 1995) and 40km in the Provence segment of the orogen (Bestani et al., 2016; Bestani et al., 2015). The Pyrenees-Provence fold and thrust belt is segmented by NE- to NNE-188 trending faults which separate areas of distinct structural styles and amounts of shortening. 189 190 Left-lateral strike-slip along the Cévennes Fault accommodated shortening of its hanging-wall 191 while the NW footwall remained mostly undeformed during the Pyrenean orogeny (Arthaud and Laurent, 1995). In Provence, the Durance Fault separates thin- and thick-skinned 192 193 Pyrenean deformation (Bestani, 2015; Bestani et al., 2016).

194

195 2-2. Location of the studied area within the Gulf of Lion rift and passive margin 196

The studied area is affected by NE-trending normal faults bounding syn-rift Oligocene basins 197 198 (Fig. 2). At least, some of these faults - if not all - are reactivated previous Pyrenean left-lateral strike-slips faults (i.e. the Cévennes fault, Matelles Fault (Mattauer, 2002). Seismic reflection 199 profiling has shown that, during Oligocene rifting, such faults detached in the Triassic 200

decollement (Benedicto, 1996; Benedicto et al., 1999; Husson, 2013; Sanchis and Séranne,
2000). The onshore syn-rift basins NW of the Nîmes Fault were formed by thin-skinned
extensional tectonics (Séranne, 1999). The basement-cover decollement ramps down in the
Nîmes basement fault (Benedicto et al., 1996) and into the basement ramp of the Montpellier
thrust to the south and southeast of the study area.

206

207 **3. Revised chronology of events**

208

The chronology of the transition between Pyrenean orogeny and the Gulf of Lion rifting is still discussed. The stratigraphy of the 1/50.000-scale geological maps of the study area is confusing: all maps are consistent in identifying the Bartonian (e6) as a Pyrenean syn-tectonic sequence, but they greatly diverge in dating the end of the orogeny and the onset of the rifting. The comparison of stratigraphy of the adjacent maps of the study area reveals contradicting ages for identical and spatially continuous formations (Fig. 3 a).

Another unconsistency arises from the outstanding question: what was the geodynamic context during the time interval between the Pyrenean syn-orogenic deposits and the syn-rift formations? Adjacent maps carry contradicting interpretations: the « g1 » is a continuity of the syn-orogenic Bartonian on the Saint-Martin-de-Londres map (Philip et al., 1978), whereas the Montpellier map correlates the « g1 » with the early stages of the Gulf of Lion rifting (Andrieux et al., 1971).

The mammalian reference levels developed for the Paleogene continental record of Europe (Sigé and Legendre, 1997), allowed to improve the stratigraphy and to revise the tectonic agenda of the area, especially around the transition from orogeny to rifting. Figure 3b uses chronology of (Vandenberghe et al., 2012) and mammal reference levels of (Aguilar et al., 1997).

The age of the lacustrine limestone was defined as Lutetian or slightly older. In the Pic-Saint-226 Loup foreland, fauna allowed to place this formation between MP12 and MP13 reference levels 227 of the mammal reference levels (Crochet et al., 1988). In different localities of Les-Matelles 228 basin, several lignite beds provided a diversified fauna, which correlates with the Lutetian 229 (MP13) (Crochet et al., 1997). A distinctive marly facies including 1 to 20cm diametre 230 oncolithes, occurs at the top. It has yielded fauna ascribed to the MP14 reference level 231 (Crochet et al., 1997) of latest Lutetian age. This facies passes southwards and upwards to 232 the Bartonian syn-orogenic breccia, exposed along the Montpellier thrust (Andrieux et al., 233 1971). In the Sommières and Saint-Chaptes basins the reference sites of Robiac provided a 234 late Bartonian age for the latest Pyrenean syn-tectonic formations (Remy, 2015). 235

237 Fig. 3 a: Correlation chart of the Eocene to Oligocene interval, and inferred ages, according to the 238 BRGM 1/50.000-scale geological maps of the study area. The inset in the lower part gives the position of the BRGM 1/50.000-scale geological maps. b: Revised chronostratigraphy of the basins north of 239 Montpellier (covered by the geological maps of Montpellier, St Martin-de-Londres and part of Sommières 240 241 and Anduze) and of the St Chaptes-Gardon basins (maps of Alès and part of Anduze and Uzès). This 242 is based on new mapping of the Paleogene basins (this study) and on the compilation of biostratigraphy 243 data, including recent discoveries of mammal fossils (references in the figure and in the text). 244 Biostratigraphy scale according to mammal reference levels (M.Z.). Black stars and black hexagons correspond to mammal and charophyte sites, respectively. Simplified lithology of the formations is 245 246 indicated. Colour code as in the following maps and sections of the Paleogene basins analysed in this study. White areas corresponds to non-depositional and erosional hiatuses; the Priabonian interval from 247 St Chaptes-Gardon-Alès basins is documented in (Lettéron et al., 2018). 248

249

They pass upward to continental marls and limestones dated to the Bartonian-Priabonian transition (MP17) (Remy, 2015; Rémy and Lesage, 2005). In the Saint-Martin-de-Londres basin, similar lithologies correspond to time equivalent, as suggested by charophytes (Feist in (Philip et al., 1978).

The overlying formation mapped as « g1 » in Les-Matelles basin, displays polygenic 254 255 conglomerates and sandstones within yellow marls and silts, including several lignite beds. They are interpreted as alluvial plain deposits (Benedicto et al., 1999; Egerton, 1996). The age 256 of this formation was subjected to discussion due to the controversial location of the discovery 257 by Gervais, in the late XIXth Century, of a *Lophiodon* skull (see review in (Hartenberger et al., 258 1969). Reappraisal of the specimen, exhumed from Lyon university collections by J. A. Remy 259 (personal communication), relates the specimen to MP 18 (middle Priabonian). Another 260 Lophiodon specimen has recently been discovered in the correlative « g1 » formation in the 261 Guzarques basin, and has been related to the MP19 reference level (R. Tabuce and F. 262 263 Lihoreau, personal communication). The age of this conglomerate formation is therefore attributed to the Priabonian. As first suggested by (Andrieux et al., 1971), it is correlated with 264 the detrital continental formation « Grès de Célas » of upper Priabonian, in the Sommières and 265 Saint-Chaptes - Gardon basins, northeast of the study area, which spans the MP18 to MP19 266 (Rémy, 1985; Remy and Fournier, 2003; Rémy and Lesage, 2005). 267

At Les-Matelles and Saint-Vincent-de-Barbeyrargues localities, yellow to orange marls interfingering with syn-rift breccia, contain charophytes (Grambast, 1962), teeth of small mammals (Thaler, 1962) and gastropods (Rey, 1962) that yielded mid- to late- *«Stampian»* age, which corresponds to the Late Rupelian. This age was later confirmed by the discovery of small mammals in Les-Matelles half-graben, that relate to MP25 mammal scale (Crochet, 1984). In addition, breccia pipes and dykes of intracontinental alcaline basalt, that intrude Lutetian and Priabonian formations, were dated 24 to 28 Ma (Gastaud et al., 1983), and have been related to the Late Rupelian rifting event (Dautria et al., 2010; Séranne, 1999). In the
northern basins, this unconformable formation has not yet provided mammal remains, but
Charophytes from the alluvial environments of Saint-André-de-Cruzières in the north of Alès
Basin yielded an Oligocene age (Feist-Castel, 1971).

279 Reappraisal of ancient specimens and new discoveries thus indicate that the sequence made 280 of marls, sandstones beds and polygenic channelized conglomerates, which is exposed in 281 separated basins across the study area, belongs to the same interval, dated to the Priabonian. In particular, the fluvial conglomerate and yellow sandy marls (reported on the published maps 282 as "g1", Fig. 3a), correlate with, and are the proximal equivalent of the lacustrine delta 283 sandstones "Grés de Célas" of the Alès Basin (Lettéron et al., 2018). This formation is 284 285 intermediate between the syn-orogenic Pyrenean (Bartonian) and the syn-rift (Late Rupelian) deposits. Furthermore, it is bounded by two marked angular unconformities, the upper one 286 corresponding to a several-million-years hiatus. 287

In the following, we examine key field evidence in the north-Montpellier area (Guzargues, Les-Matelles and St-Martin-de-Londres basins, respectively) where the tectonic sedimentation relationships allow to characterise this intermediate formation. It can be interpreted as the record of the transition between the Pyrenean orogeny to the Gulf of Lion rifting.

292

4. Tectonic and sedimentation in the Guzargues Basin

294

4-1. *Lithostratigraphy of Eocene deposits in the Guzargues area*

296

The Guzargues basin (Fig. 2) has not been the topic of any specific study and remains poorly documented. The Paleogene sedimentary succession contains 4 main lithological units representative of the regional geodynamic history since the early stages of the Pyrenean compression to the main rifting phase (Fig. 4). When possible, all of them were precisely mapped to analyse the geometrical relationships of Priabonian deposits with under- and overlying units.

(1) Paleocene to Lower Eocene facies are represented by fluvial marls with interbedded
sandstones and palustrine limestones (*"Marnes infra-lutétiennes"*), only few tens of metres
thick in the Guzargues area. They are usually correlated to alluvial fan syn-tectonic breccias,
reworking the Jurassic succession at the front of the Montpellier thrust, and thus deposited
during the early stages of the Pyrenean compression.

308

Fig. 4: Generalised lithostratigraphy of the Late Mesozoic and Paleogene in the Guzargues Basin and
 immediate surrounding.

312

(2) Massive whitish Lutetian limestones, up to 100m thick in the area, form an easily
 recognised, continuous unit displaying folds produced by late stages of the Pyrenean
 compression.

(3) Lutetian limestones are conformably capped by a singular unit, up to 30m thick, made of
 lacustrine to shallow marine, marly facies containing oncoliths and calcarenitic layers,
 Bartonian in age.

(4) Topmost deposits of the Paleogene succession in the Guzargues area correspond to
Priabonian fluvial deposits showing alternations of conglomerates, sandstones and marls, up
to 300 m thick. Pebbles are supplied both from distant Pyrenean sources and from local
Mesozoic carbonates. These deposits rest unconformably above the Pyrenean folds consisting
of Lutetian to Bartonian units.

One kilometre to the south, the northern edge of the neighbouring Assas basin shows a sedimentary unit of strong geodynamic significance, which is missing in the Guzargues basin. Close to the Assas village, Oligocene breccias and marls, usually interpreted as syn-rift

327 deposits, unconformably overlie Priabonian continental facies.

Thus, the Priabonian deposits of the Guzargues basin, bounded below and above by unequivocal syn-tectonic units, represent a key unit to study the transition between two main

330 regional geodynamic events.

4-2. Sedimentological features of Priabonian deposits in the Guzargues basin 332

333

340

334 As observed in the 10 sections studied in the Guzargues basin, Priabonian deposits are 335 basically made of eight lithofacies units distinguished by their lithology and sedimentary structures. Each lithofacies is described and interpreted in terms of depositional processes 336 337 (Table 1), and most are illustrated on Figure 5.

Lithofacies units are often associated together, defining three main facies associations (FA1, 338 FA2, and FA3), the distribution of which varies depending on the spatial location in the 339 Guzargues basin and on the vertical position into the Priabonian stratigraphic succession.

341 FA1 is represented by the alternations of (i) channel-shaped, poorly to weakly sorted conglomerates (Gu, Gt; Table 1), (ii) matrix-rich, stratified conglomerates (Gm; Table 1), and 342 (iii) medium- to coarse-grained, cross-bedded sandstones (Sp; Table 1). A general trend in the 343 vertical evolution of FA1 facies units is recognised through most of the studied sections. In the 344 lower part of sections, predominant Gu/Gt conglomeratic channels, up to 3m thick and 3 to 5m 345 wide, contain heterometric, sub-rounded to well-rounded clasts, mainly composed of local 346 Mesozoic (Upper Jurassic to Lower Cretaceous) carbonates. In some places, they also show 347 abundant oncoliths (as fragments or complete specimens) probably originated from the 348 underlying Bartonian formation. In the upper part of sections, conglomeratic bodies in Gm 349 facies unit are thinner (< 1m) and more laterally continuous (usually more than 10 metres in 350 351 width) than in the lower part. In addition to local Mesozoic carbonates, guartz and lydite, originated from Cévennes and/or Montagne Noire Paleozoic peripheral units, and ginger 352 (Aptian?) sandstones represent a significant proportion of clasts in channel fillings. 353

Gu conglomerates can be interpreted as channel lag (Miall, 1977, 1978; Nemec and Postma, 354 1993). The Gm and Gt facies units present strong similarities with gravel bars in braided 355 streams (Mack and Leeder, 1999; Miall, 1977; Nemec and Postma, 1993). Sp cross-bedded 356 sandstones are typical of megaripples deposited by a unidirectional upper to lower flow regime 357 (Simons et al., 1965; Southard, 1991) produced by subaerial to subaqueous, stream and/or 358 sheet flows (Hampton and Horton, 2007; Mack and Leeder, 1999). Inferred FA1 depositional 359 360 environments are thought to belong to an alluvial fan setting, first supplied by a local catchment area (lower part of sections), and then by a regional catchment area (upper part of sections). 361 362

364 Fig. 5: Photographs of outcrops illustrating some typical facies observed in the Priabonian deposits of 365 the Guzargues basin. A: Facies Gu with carbonate clast alignment underlining tenuous cross-beddings. 366 Note scours at the base of the channel (arrows). B: Facies Gt showing progressive transition between (base) unsorted, highly heterometric massive, stratified conglomerates, and (top) weakly sorted, cross-367 368 bedded conglomerates. C: Alternations between (Sst) cross-stratified sandstones with lenses of scattered subrounded gravels and pebbles, and (Gm) matrix-rich, graded, stratified conglomerates with 369 weakly sorted pebbles mainly made of Mesozoic carbonates. D: Reddish to yellowish laminated silty 370 371 claystones (facies Fm) with intercalation of a decimetric layer of massive fine-grained sandstones (facies 372 Sr). E: Medium- to coarse-grained cross-bedded sandstones typical of facies Sp. F: 50cm-thick 373 carbonated horizon showing well-preserved, vertical root casts, probably derived from vegetalization on 374 top of massive fine-grained sandstones (Sr). 375 Note the occurrence of several pedogenetic carbonate nodules above the irregular top surface of the

376 carbonated sandy horizon.

Facies code. Facies name	Lithological features	Sedimentary structures	Inferred depositional processes
Gu. Poorly sorted, massive, channel-shaped conglomerates (Fig. 7A)	Poorty sorted, massive, locally normally graded conglomerates. Highly heterometric, sub- rounded to well-rounded cleats (pebbies to small bouldens), mainly composed of local Mesozoic carbonates	Well-defined basal erosional surfaces with gutter/scour structures. Channels displaying few clast imbrications, 50cm up to 3 meters in depth, 3 to 5 meters in width	Channel-lag deposits under subaerial flashy braided-stream flows (Barrier et al., 2010)
Gt. Weakly sorted, cross-bedded, stratified conglomerates with coarse-grained sand lenses (Fig. 78)	Clast-supported, stratified conglomerates. Weakly sorted, heterometric, sub-rounded clasts (granules to small boulders of Mesozoic carbonates). Occurrences of poorly sorted lenses of coarse-grained sand matrix surround- ing individual pebbles	Fining upward infil. Trough cross-bedding	Minor channel fills (Miail, 1978). Transverse- or diagonal-bar depos- its under subaerial perennial braid- ed-stream flows (Barrier et al., 2010)
Gen. Matrix-rich, normally grad- ded, stratified conglomerates (Fig. 7C)	Matrix-rich, normally graded, stratified con- giomerates. Poorly sorted, subangular to sub- rounded clasts (granules to cobbles) made of local Mesozoic carbonates and some siliceous elements	Some beds with horizontal alignment of clasts. Few clast imbrications into horizontal foreset strata. "Gradual" basal surfaces	Longitudinal-bar deposits under subaerial competent and perenni- al braided-stream flows (Barrier et al., 2010)
Set. Moderately sorted, medium- to coarse-grained, cross-stratified sandstones with lenses of sub- rounded gravels and pebbles (Fig. 7C)	Moderately sorted, medium- to coarse-grained sandstones. Layers (and lenses) of well-sorted subrounded clasts (granules to pebbels) com- posed of Meeozoic carbonates, some Lutetian mudsiones and common Bartonian oncoliths (as fragments or complete specimens)	Fining-up trend. Cross-stratification with grad- ing foresets. Well-defined internal erosional surfaces	Bar deposits under subaerial sheet flows or stream flows
Sp. Medium- to coarse-grained, cross-bedded sandstones (Fig. 7E)	Weakly sorted, medium- to coarse-grained sandstones which can contain scattered granules at the base	Cross-stratification. Internal erosional surfaces. Few small scour structures	Megaripple deposits under subaerial sheet flows or stream flows
Sr. Massive, pedoturbated, well- sorted, fine-grained sandstones (Fig. 7D)	Massive, well-sorted, fine-grained sandstones	Pedoturbation (root sleeves, destructuration of primary sedimentary structures by root growth). Locally few asymmetrical ripples at the top	Ripple deposits under subaerial sheet flows or stream flows
Fm. Massive, sity claystones with planar sitistone to fine-grained sandstone layers (Fig. 7D)	Reddish to yellowish (also purplish red in some horizons of plastic texture), massive, sity claystones with few thin (mm to cm) layers of well-sorted sittstones and very fine-grained sandstones	Fining-up grading in sitistone to fine-grained sandstone layers	Deposits from suspension fallout in a floodplain. Overbank or wan- ing flood deposits (sitistones and very fine-grained sandstones)
P. Pedogenetic carbonate nodules (Fig. 7F)	Indurated, om to dm carbonate nodules, often scattered within plastic claystones, sometimes coalescent to form continuous carbonate hori- zons	Vertical root casts	Soil (Miall, 1978) or temporary vegetalized surface

³⁷⁷

Table 1: Summary of the main facies features observed in the Priabonian deposits of the Guzargues basin, and interpretations in terms of depositional processes. Gm, Gt, Sp, Sr, Fm and P, are abbreviations from the facies code provided by (Miall, 1978). Gu and Sst are abbreviations defined by (Barrier et al., 2010).

382

FA2 corresponds to the alternation between (i) moderately sorted, medium- to coarse-grained 383 384 sandstones with sub-rounded clast lenses (Sst; Table 1), and (ii) medium- to coarse-grained cross-bedded sandstones (Sp; Table 1). If local (Mesozoic but also Lutetian) calcareous 385 386 elements still represent an important proportion of clasts (granules, gravels, pebbles), siliceous 387 component (quartz and lydite gravels) is more abundant than in FA1. FA2 depositional 388 processes are dominated by tractional transport under a unidirectional upper flow regime, with 389 episodic sheet flows. Inferred depositional environments correspond to the proximal part of a subaqueous alluvial fan to fan delta, with sediment supplied from both local and regional 390 391 catchment areas.

FA3 is mainly represented by yellowish, greenish or reddish silty clays, with plastic texture at some places, in which are interbedded thin layers of well-sorted siltstones and fine-grained sandstones (**Fm**; Table 1). Carbonate pedogenic nodules locally form scarce, up to 1m thick, distinctive layers (**P**; Table 1). Interbedded massive fine-grained sandstones (**Sr**; Table 1) usually show vertical root traces and more rarely asymmetrical ripple cross-laminations several centimetres thick at the top. FA3 deposition must be the result of vertical settling from detrital suspensions in standing water (Horton and Schmitt, 1996; Miall, 1977). Fine-grained sandstones showing asymmetrical ripples and interbedded silty and sandy layers suggest episodic flow regime, related to sheet flood events. The occurrence of carbonate nodules records occasional pedogenic processes and temporary aerial exposure. Assuming these depositional processes, FA3 should have been deposited in the distal part of a subaqueous to subaerial alluvial fan, or in a floodplain laterally to major braided distributaries.

Fig. 6: Detailed stratigraphic correlation of Priabonian deposits along a 2km-long N-S transect at the southeastern border of the Guzargues basin, showing differential subsidence and onlap geometries induced by the syndepositional growth of the Lirou anticline. See Fig. 7 for location of logs. Horizontal correlation lines set at the maximum of progradation recorded by several meters-thick, stacked conglomeratic channels that closely rests on Lutetian limestones at the apex of the Lirou anticline.

411

The 10 studied sections show vertical variations in the FA succession (basically FA1-FA2 or FA2-FA3 alternations) forming elementary sequences between several metres and tens of metres thick (Fig. 6). As indicated by the various inferred depositional environments for FA, these elementary sequences, made up of alternatively proximal and distal deposits, are arranged into overall trends measuring several tens of metres thick, recording progradational and retrogradational evolutions.

418 At the scale of the Guzargues basin, the large FA alternations are describing a whole 419 progradational, then retrogrational, and finally progradational evolution, which is easily recognised on the field. These trends were used to correlate Priabonian deposits at basin scale
and, combined with aerial photograph interpretation, to produce a detailed geological map that
allows building cross-sections.

423

424

4-3. Tectonic-sedimentation relationships in the Guzargues basin

425

426 The detailed geological map (Fig.7) and cross-sections (Fig. 8) of Guzargues basin show sequences of Priabonian conglomerates interfingering with marls, that are involved in gentle 427 folding of complex geometry. To the south, the basin is separated from the contemporaneous 428 Assas Basin by a NW-SE anticline, cored by Valanginian (Fig.7 and Fig.8 - Section 1). North-429 430 south sections of Guzargues basin (Fig.8 - Sections 2, 3) display an asymmetrical syncline structure: the southern limb is steeply dipping north, whereas the northern limb extends over 431 3 to 4 km in a gently dipping or subhorizontal position. In addition, the basal part of the 432 Priabonian is affected by ENE-trending anticlines, while the youngest conglomeratic 433 Priabonian seals the anticline (Fig. 8 - Section 3). 434

The Lirou anticline - The Bartonian and the base of the Priabonian sequence (isolated 435 sandstone and conglomerate beds in marls) are wedging towards an anticline with an EW-436 oriented, W-plunging axis. Conglomerate beds isolated in the silt and marls are observed on-437 lapping both flanks of the anticline (Fig.6), and they display diverging bedding away from the 438 anticline (Fig. 7, Fig. 9a). The upper conglomeratic interval, corresponding to the final 439 440 progradational trend recorded by Priabonian deposits, progrades northwards across the whole 441 basin, over a silt and shale interval and seals the Lirou anticline (Fig. 6). Folding affects the 442 Lutetian lacustrine limestones, and the top of the Lutetian is eroded in the crest of the anticline. 443 Variable thickness of Latest Cretaceous to Early Eocene marks suggests a decollement with the underlying monocline Valanginian limestones. The latter is affected by a sub-vertical, NE-444 trending fault, which displays a left-lateral component of movement (Fig. 8 - Section 3). These 445 observations lead to the following points: i) folding was initiated during Pyrenean shortening, 446 and was still active during deposition of the early Priabonian; ii) folding of the Paleogene 447 sequences is detached above the Valanginian limestone, through a detachment within the Late 448 449 Cretaceous-Early Eocene marls; iii) folding is related with a NE-trending left lateral strike-slip.

Fig. 7: Detailed geological and structural map of the Guzargues basin (north of Highway D68, while
Assas sub-basin is located south of the highway). Location of the sedimentological logs 1 to 9 reported
on Fig. 6 are indicated by fine black rectangles. Position of the structural cross-sections extremities (Fig.
8 and 9) are given by black arrows.

of the Lirou anticline. Location on map Fig. 7. b: Penetrativve deformation of the Jurassic limestones
along the basin-bounding fault, indicating left-lateral kinematics. Serre de Moujes, location on maps Fig.
7.

463

The southeastern boundary - Figure 10 shows up to three stacked, angular unconformities, 464 which affect the lower Priabonian sequences along the southern flank of an EW syn-465 sedimentary syncline. These angular unconformities pass northwards to correlative 466 conformities, while they converge southwards, towards the basin boundary, corresponding to 467 an E-trending anticline of Lutetian limestone. This anticline is locally eroded by a present-day 468 transverse valley, but mapping reveals that sub-horizontal Priabonian conglomerates are 469 470 exposed within this valley and that they laterally onlap onto the incised carbonates (Fig. 7). Clasts imbrication within the fluvial conglomerates indicates a consistent northwards 471

472 paleocurrent in the paleo-valley. Very thin (several tens of metres) in the transverse valley, the 473 Priabonian formations thickens rapidly northward within 1 kilometre distance, from less than 474 300 m to 450 m, and it exceeds 600 m in the syncline axis. In addition, fluvial conglomerate 475 belts pass laterally and distally (northwards) to silts and marls of alluvial plain facies. These 476 observations clearly show that: i) the syncline was formed during deposition of the Priabonian ; 477 ii) the basin was fed by a north-flowing paleoriver, incised into the growing Lutetian limestone 478 E-W anticline.

Fig. 10: Detailed structural section in the south of Guzargues basin showing growth syncline and internal
 angular unconformities. See location of Section 5 on Fig. 7.

482

479

483 Serre de Moujes - The northern part of the basin corresponds to a syncline trending N020°, that involves Lutetian limestones and Priabonian conglomerates (Fig. 7). The conglomerates 484 are more developed on the steep western flank, where they unconformably rest over the 485 steeply dipping Lutetian limestones, and they grade eastwards to distal silts and marls (Fig. 8 486 487 - Section 4). Along the eastern flank of the syncline, Priabonian formations are onlapping onto 488 the Lutetian limestone; in addition, the Bartonian oncolith formation is transgressed towards 489 the north by the Priabonian. Onlapping surfaces point to a pre-existing synform of Lutetian 490 limestones prior to Priabonian deposition. The conglomerate belt is separated from that of the 491 main part of the basin, suggesting the presence of a smaller, northern, sub-basin with a distinct feeder that supplies clastic sediments across the western boundary (Fig.8 – Section 2). 492 Unfortunately, no clear evidence of paleocurrent were found. North-south correlations across 493 the entire Guzargues basins shows that the northern sub-basin represents the youngest 494 depocentre of the whole basin (Fig. 8 - Section 1). To the NW, Priabonian is directly in contact 495 with the Mesozoic carbonates through a sub-vertical faulted boundary. In the Serre de Moujes, 496 outcrop in the damage zone of the bordering fault reveals sets of associated fractures and 497 dissolution surfaces, consistent with a left-lateral strike-slip motion (Fig. 9b). Unfortunately, no 498 499 slickensides could be observed to constrain the respective vertical and horizontal components of slip. Saint-Bauzille-de-Montmel borehole (located 1.5 km north, along strike) constrains a 500 curved geometry for this fault and provides evidence for a 700m vertical offset (Fig. 8 - Section 501 4). Considering the fault geometry and the kinematic observations on the outcrop, a dominantly 502 strike-slip movement along this bordering fault is suggested during Priabonian and the 503 important vertical offset implies several kilometres of cumulated lateral offset. A significant part 504

of such offset may be inherited from earlier (Pyrenean) tectonic phases. These observations argue for i) deposition of Priabonian syn-tectonic sediments in a hanging-wall syncline, controlled by the activity of the N020°-trending bounding fault, and ii) accommodation of a significant amount a left-lateral strike-slip, by this inherited fault.

509

510 **4-4.** Tectonics - paleoenvironment relationships in the Guzargues basin

511

512

Fig. 11: a: Sketch map of the paleoenvironments in the Guzargues basin, in relation with the Priabonian tectonics. **b:** Conceptual tridimensional representation (no scale intended) of the interaction between Priabonian kinematics and sedimentation in the Guzargues basin. Braided fluvial conglomerates accumulate in the most subsiding parts, i.e. the actively deforming synclines that affect the Mesozoic-Lutetian cover, detached over the basement. See text for explanations.

518

Figure 11a provides a synthetic view of the paleoenvironment distribution across the 519 Guzargues Basin during Priabonian. Fluvial sediments were delivered through an incised 520 521 canyon across a growing anticline, which separates Assas (to the south) and Guzargues 522 basins. The belt of northward-flowing fluvial channels preferably occupied the most subsiding parts of the basin: i) in the south, parallel to the bordering growing anticline and, ii) in the overall 523 524 N-trending axis of the syn-depositional syncline. The latter was controlled by a set of NNEtrending faults which display map- and outcrop-scale evidences of normal faulting and left-525 lateral strike-slip. The secondary fluvial conglomerates depocenter of Serre de Moujes, in the 526 northern part of the basin, witnesses an additional fluvial input to the basin, across a relay or 527

a jog in the bordering fault system. The syn-depositional Priabonian sequence is therefore controlled by folding of the Mesozoic through the Lutetian cover detached over the Triassic decollement, corresponding to an overall transcurrent, left-lateral kinematics, along the NNEtrending faults (Fig. 11b). The kinematics documented in the Guzargues basin result from NS shortening combined with EW extension,

533

534 **5. Les-Matelles and Saint-Martin-de-Londres Priabonian basins**

535

536 **5-1. Les-Matelles basin**

537

538 The overall geometry of Les-Matelles basin (LMB) is that of an Oligocene syn-rift hanging-wall syncline, controlled by a NNE-trending normal fault (Fig. 2), known as the Matelles-Corconne 539 Fault (Benedicto et al., 1999). The Priabonian sequence mostly consists of marls and 540 siltstones with rare conglomerate beds. Paleocurrent measurements in the channelised fluvial 541 conglomerates indicate northwest to northeast flowing channels (Egerton, 1996). Detailed 542 mapping (Benedicto, 1996) revealed that the underlying Priabonian sequence also presents 543 growth structures in an asymmetric syncline, that displays a NW limb steeper ($\geq 40^{\circ}$) and 544 thinner than the SE limb (Fig. 12). Sequential tectonic restoration of transverse sections 545 indicates an extensional offset across Les-Matelles-Corconne Fault of some 375 m, during 546 547 Priabonian (Benedicto et al., 1999).

In the southernmost part of the basin, Priabonian unconformably overlies the syn-orogenic 548 549 breccia of Paleocene age, related to the activity of the Montpellier thrust (Andrieux et al., 1971). In the central segment of the basin, Priabonian is conformable over the distal syn-orogenic 550 marls and oncoliths of Bartonian age. Finally, in the northern extension of this basin, Priabonian 551 is unconformable over Neocomian marly limestones, which are deformed by EW-trending 552 compressional structures. Such folds and thrusts are correlated to the Pic-Saint-Loup thrust, 553 active during Bartonian (Philip et al., 1978). Considered at the scale of the basin, the 554 Priabonian is thus unconformable over pre-Pyrenean deformed series, as well as syn-orogenic 555 Pyrenean sedimentation. Finally, the syn-rift Late Rupelian breccia are unconformably 556 557 overlying the Priabonian (Crochet, 1984).

Fig. 12: Structural section across Les-Matelles basin (from surface data and seismic profile) showing
 syn-extension deposition of Priabonian units. Modified after (Benedicto et al., 1999).

558

562 5-2. Saint-Martin-de-Londres basin

563

Saint-Martin-de-Londres basin (SMLB) extends in an EW asymmetric syncline, immediately
north of the Pic-Saint-Loup thrust, a structure of the Pyrenean fold and thrust belt (Fig. 2).
Above an unconformity over the Neocomian, the basin sequence starts with continental marls
and thin beds of lacustrine limestones of latest Cretaceous to Paleocene age (Crochet, 1984;
Freytet, 1971; Philip et al., 1978), which are the distal correlative of the syntectonic *« Vitrollian »* breccia, deposited along the Montpellier thrust.

570 Lutetian lacustrine limestones, transgressive over Late Jurassic to Paleocene formations, form 571 an 80 m to 100 m-thick slab that designs a wide, low amplitude, EW-oriented syncline (Fig. 13). The overlying breccia, dated to the Bartonian (Philip et al., 1978), consists of local, late 572 Jurassic, Neocomian and Lutetian limestones, derived from erosion of the active Pic-Saint-573 Loup thrust front. They pass northwards to distal continental marls and silts, which present 574 syn-tectonic growth structures. The southern boundary of the basin has been intensely folded 575 and faulted in relation with the Pyrenean Pic-Saint-Loup thrust, during Bartonian time (Fig.14). 576 The Priabonian sequence unconformably overlies the Bartonian breccia; to the east, it seals 577 an intra-Bartonian thrust propagation fold (Fig.13), which requires erosion of the Pyrenean-578

579 related structure prior to Priabonian deposition.

Fig. 13: Detailed geological map of Saint-Martin-de-Londres basin. Position of sections Fig. 14 indicated
 as white line. The black dot and cross points to the churches of the villages.

584 Fig. 14: Structural section across St Martin-de-Londres basin: a - general ; b – detailed, showing syn-

⁵⁸⁵ depositional compression during Priabonian.

586

Fig. 15: a and **b:** general view of the eastern end of St-Martin-de-Londres Priabonian basin, an asymmetrical growth syncline, unconformable over the synorogenic Bartonian breccia, which were generated along the pyrenean Pic-St-Loup thrust. **c:** overturned Priabonian sandstone along the southern limb of the asymmetric syncline. **d;** detail of the previous outcrop displaying small scale reverse faults that provide evidence for N-S compressive deformation. *E:* deformed root traces, evidence for pre-lithification N-S compressive deformation of the Priabonian sandstone bed, prior to its folding. Outcrop location on Fig. 13.

Along the southern margin of the SMLB, the Priabonian sequence designs an asymmetric 595 syncline with sub-vertical to overturned southern limb (Fig. 15a,b.). The sequence starts with 596 a thin level of finely laminated limestone that contains bioclasts and charophytes characterising 597 598 a lacustrine / palustrine environment. Laterally, the limestone passes to thicker and more 599 massive beds of lacustrine mudstone. The thin basal limestone is correlated to the north of the 600 basin, with 10 m to 15 m thick marls and carbonates deposited in an arid, evaporitic 601 environment. Above the limestones, along the central southern margin only, are found grey marls including several thin beds of glauconitic sandstones with bioclasts and rare foraminifera 602 (Egerton, 1996). This shallow marine sandstone passes upwards to marls and siltsones 603 including thin bioturbated sandstone beds, deposited in a floodplain, similar to those described 604 605 in LMB. In the upright, southern limb of the syncline, these sandstone beds are affected by small scale reverse faults (Fig.15c). They also display soft penetrative deformation of initially 606 cylindrical root traces (Fig. 15d), which indicate an early, pre-lithification, N-S shortening prior 607 to folding. Finally, up to 50 m stacked, channelized conglomerates, are deposited in several-608 metres-thick levels, interbedded with siltstones and marls. The high ratio of channelized 609 conglomerates vs floodplain marls and siltstones is more in line with Guzargues than with Les-610 Matelles basins. Conglomerates are clast-supported and rather well-sorted. Clasts are 611 polygenic, including significant number of quartz veins and black cherts, derived from the 612 Paleozoic deformed basement. Distinctive clasts of glauconitic sandstones and calcarenites 613 614 containing Albian orbitolines cannot be related to any local source, as the Mesozoic sequence 615 is interrupted above the Valanginian due to the regional erosion of the Durancian Isthmus (Husson, 2013). Such clasts, also been identified in Les-Matelles and Montferrier Priabonian 616 outcrops are imbricated under the influences of north to northwestwards paleocurrents 617 (Egerton, 1996), and thus correspond to a southerly derived material (Freytet, 1971). 618

The Priabonian sequence of SMLB unconformable over Pyrenean structures, and containing
 clasts supplied by a southerly derived sedimentation was deposited in a N-S compressional
 setting, related to reactivation of the Pyrenean Pic-Saint-Loup Thrust.

622

623 6. Seismic sequence analysis of the Hérault Basin

624

The Hérault Basin (HB) is a NNE-SSW asymmetric half-graben developed along the Cévennes Fault, formed in relation with the rifting of the Gulf of Lion (Arthaud et al., 1981; Maerten and Séranne, 1995; Séranne, 1999). It covers the western part of the Pyrenean Montpellier thrust (Fig. 2) and is filled by up to 1500m-thick succession of rift and post-rift sequences. The synrift and earlier Pyrenean structures are therefore mostly covered, which lead us to investigate the Pyrenean to syn-rift transition through subsurface data.

The basin sequence consists of (i) Rupelian to Aquitanian, continental and lacustrine

formations, and (ii) Burdigalian to Langhian, marine to fluvial post-rift deposits, forming syn-rift 632 and post-rift sequences separated by a major unconformity. The pre-rift substratum consists 633 of Permian to Jurassic sequence, as well as mid-Cretaceous bauxite deposits, which have 634 been sampled by several boreholes (Berger et al., 1981; Lajoinie and Laville, 1979). In 635 636 addition, syn-tectonic Pyrenean Paleocene to Eocene formations (poorly exposed along the 637 eastern margin of the basin) and Mesozoic carbonates deformed during Pyrenean 638 compression can be extrapolated beneath the basin, and several Pyrenean thrusts repeating parts of the Jurassic sequence are documented (Alabouvette et al., 1982; Berger et al., 1981). 639

Fig. 16: Seismic profiles representative of the Hérault basin (H84D, H84F, H84X). The purple sequence
 interpreted as Priabonian (see discussion in text) is intermediate between the Pyrenean synorogenic
 units and the Oligocene syn-rift sequence. See location on Fig. 2 and 18.

644

Two geophysical surveys acquired in 1983 and 1984, then reprocessed in 2005-2008 (Serrano and Hanot, 2005), provide a regular seismic coverage (Fig. 2) of sufficient quality to examine the seismic units underlying the syn-rift sequence (Fig. 16). Some of these seismic sections were already interpreted by (Maerten and Séranne, 1995) who focused their study on the geometry of syn- and post-rift units.

653

Fig. 17: Line drawings of parts of selected seismic profiles in the Hérault basin showing the lower and
 upper erosional boundaries of the intermediate sequence. See location on Fig.18.

Reinterpretation of the seismic profiles allows us to identify, in several parts of the basin, a 654 distinctive seismic unit below the syn-rift deposits (Fig.16). It is bounded by angular 655 unconformities both at the top and at the base and displays significant thickness variations and 656 complex internal geometries. Geometrical relationships with underlying and overlying seismic 657 sequences define its relative stratigraphy: (i) It is truncated by typical syn-rift sequences and 658 is affected by the extensional syn-rift faults; (ii) It unconformably rests on pre-rift units affected 659 660 by Pyrenean reverse faults (Fig. 17). This intermediate seismic unit, undrilled by any boreholes, does not correlate with surface exposures. However, comparison with field 661 observations in the GB, SMLB and LMB point out a similar structural and stratigraphic position 662 663 suggestive of a Priabonian age. Mapping of this intermediate interval, of proposed Priabonian

age, across the Hérault basin shows a discontinuous sequence including two main 664 depocentres (Fig. 18 a). One depocentre is located where the Cévennes Fault displays a 665 significant change from an overall NE-SE direction to a SSE-trending orientation. H84X profile 666 667 (Fig.16) shows evidence for Priabonian syn-depositional, dip-slip movement across the SSE-668 trending fault segment. Such a geometry suggests a left-lateral movement along the Cévennes 669 fault, associated with a dip-slip across the SSE segment which represents a releasing bend 670 (e.g. (Christie-Blick and Biddle, 1985; Cunningham and Mann, 2007) of the master fault. A second depocentre is located along the SE margin of the Hérault basin, controlled by NE-671 trending faults that offset the earlier Pyrenean Montpellier thrust. 672

6.

Fig. 18: Isopach maps of Priabonian (a) and of syn-rift (b) sequences in the Hérault basin, superimposed onto a simplified geological map (same legend as in Fig. 2, and location in Fig. 2). Contouring of depocenters in metres. The seismic profiles used in the study are represented in stippled green lines; plain green lines with labels correspond to the profiles shown in Fig. 16 and 17. Faults are represented in red.

Isobaths of the base syn-rift (Fig. 18 b) depict the depocentre of the syn- and post-rift Oligo Miocene basin. Comparing the two maps (Fig. 18 a and b) clearly shows that the successive
 sequences were controlled by two distinct tectonics settings and kinematics. The distribution

and NE-SW overall orientation of the Oligo-Miocene depocentre, and the presence of a
transfer zone (roughly parallel to H83E profile) are consistent with NW-SE extension across
the Cevennes-fault (Maerten and Séranne, 1995). Our data do not support such a transfer
zone active during the Priabonian.

687

7. Seismic sequence analysis in the Gardon - Saint-Chaptes basin

689

707

The Priabonian Gardon - Saint-Chaptes basin (GSCB) sits at the junction of an almost 690 continuous NE-trending strip of Priabonian outcrops from the foreland of the Montpellier thrust 691 (Fig. 2), to the large syn-rift Alès basin, parallel to the NE-trending Cévennes Fault. Syn-rift 692 693 Oligocene sediments are observed, unconformable over the Priabonian, in the Alès Basins (Sanchis and Séranne, 2000) and in a distinct outcrop in the southern part of the GSCB 694 (Lettéron et al., 2018). Transgression of the post-rift Burdigalian tidal sequences, restricted to 695 the E-W paleo-ria of Uzès basin (Reynaud et al., 2006), did not reached the Alès basin. The 696 Gardon segment, between Alès and Saint-Chaptes, consists of a large asymmetrical syncline, 697 with a distinctive NW-trend, contrasting with the general NE-trend of the contemporaneous 698 699 basins (Fig. 2).

Pyrenean structures in this area consist of a succession of E-W folds affecting the thick Triassic to Neocomian sequence (Arthaud and Laurent, 1995), dated with syn-tectonic Paleocene to Bartonien terrigenous sediments in the syncline axes. The later are buried to the west beneath Priabonian and Oligocene sequences, which provides a first-order evidence for a major post-Pyrenean discontinuity (Fig.2). Detailed mapping of the northeastern border of the GSCB also defines a marked angular unconformity of the Priabonian over the synpyrenean breccia sequences (Sanchis, 2000).

Fig.19: Interpreted line drawing of a seismic reflection profile across the Gardon Basin showing the syn depositional migration of the hanging-wall syncline. Modified after (Sanchis, 2000). Main markers are

identified; Priabonian interval in purple overlay; intra-Priabonian marker corresponds to the base of
 "Grès de Celas" Formation. Location on Fig. 2 and 21.

712

Chronostratigraphy is rather well constrained due to numerous mammalian fossils (Fig. 3) 713 714 reviewed in (Lettéron et al., 2018). Priabonian deposits form a wide asymmetric syncline, including a thick NE and reduced SW limbs, respectively. Seismic reflection survey of the Alès 715 basin included a southern profile (85LGC11), which reveals the structure and mode of 716 formation of this syncline (Sanchis, 2000) (Fig. 19). In section, the GSCB displays Priabonian 717 growth syncline migrating WNW-ward, which characterises dip-slip movement of a hanging-718 719 wall flat made of Mesozoic sequence detached above an eastward, low-dipping, decollement, above the Paleozoic basement. Such low-dipping decollement, the "Alès Fault", has been 720 identified in the neighbouring Alès basin and beneath the Mesozoic sequence, folded during 721 the Pyrenean (Benedicto, 1996; Sanchis, 2000; Sanchis and Séranne, 2000). This 722 decollement at the basement-cover interface is distinct from the Cévennes basement fault, 723 although both the Cévennes and Alès faults emerge along the same trace. This seismic profile 724 (Fig. 19) also provides evidence for 4km E-SE migration of the depocentre, therefore 725 suggesting similar displacement of the hanging-wall across the Alès Fault, in this direction, 726 727 during Priabonian.

728

733

Fig. 20: Seismic reflection profile and corresponding line drawing in the Gardon - Saint-Chaptes basin
 showing evidence for syn-depositional (Priabonian) extensional faulting sealed by the Rupelian
 sequence. Maisonnette borehole allows to interpret and to date the sequence. Modified after (Baral,
 2018). Location on Fig. 2 and 21.

The Saint-Chaptes part of the GSCB has been investigated by seismic reflection profiling, 734 aiming at hydrogeological exploration of the covered Barremian Urgonian karst (Josnin, 2001). 735 The sections tied to 4 wells sampling the Oligocene and Priabonian interval (Fig. 2) (Baral, 736 737 2018; Baral et al., 2018) and correlated with surface exposures providing sedimentology and stratigraphy controls (Lettéron et al., 2018), allowed to identify, date and map the major seismic 738 739 markers across the basin (Fig. 20). In borehole, the Priabonian sequence consists of lacustrine 740 marls and carbonates, that pass upward to sandstones. It rests on a thin interval of undated detrital continental sediment, which can be tentatively correlated with the syn-tectonic 741 Bartonian observed in outcrops north of the borehole. Priabonian displays growth structures 742 generated by extensional faults which ramp down into the Barremian (Urgonian facies) 743 744 massive limestones. Such faults belong to the N-NE trending fault-network that truncates the Pyrenean folds, and is sealed by the Rupelian syn-rift sequence (Fig. 2). The dip-slip 745 component of such faults observed in seismic, is not associated with any significant horizontal 746 747 displacement, since the pyrenean fold axes (Berger et al., 1978) are not laterally offset (Fig. 2). 748

Fig. 21: Isopach maps of Priabonian (a) and Rupelian (b) sequences in the Gardon – Saint-Chaptes
 basin. Note the different orientation of the Rupelian depocentre axis with respect to the previous
 Priabonian subsidence axis. Location in Fig. 2.

753

Time-depth conversion was achieved using velocities stack provided with the seismic profiles and controlled with the borehole data (Baral, 2018), in order to make an isopach maps of the

Priabonian depocentre Fig. 21a). It provides evidence for Priabonian tectonics across N-NE-756 trending active faults, observed north of the basin, and southward, parallel to the Sommières 757 basin (Fig. 2). The Gardon segment of the depocentre, although less well constrained by 758 759 subsurface data, designs the NNW-trending asymmetrical syncline imaged in seismic (Fig. 760 19). The overlying Oligocene (syn-rift) depocentre (Fig.21b) is restricted to the Saint-Chaptes 761 part of the GSCB and it is not affected by the earlier faults, nor controlled by any active 762 boundary faults. It designs a wide depocentre, whose subsidence axis strikes N050, oblique with respect with the Priabonian depocentre. This suggests a Rupelian syn-rift basin formed 763 as a hanging-wall syncline (Benedicto et al., 1999) above a detachment, which we interpret to 764 be the Paleozoic basement-Mesozoic cover interface, i.e. the Alès Fault in this area. The 765 766 structural relationships in the GSCB and the contrasted orientation of the Priabonian and Rupelian depocentres indicate two distinct events with different extension directions. 767

768

769 8. Regional synthesis and discussion

770

Field observations show that the GB, LMB and SMLB display similar Paleogene successions 771 and stratigraphic settings. In all exposed basins, the syn-tectonic pyrenean continental 772 formations consist of breccia along the active thrusts that pass distally, i.e. northwards, to fine 773 continental silts and marls, or lacustrine/palustrine limestones. They are overlain by Priabonian 774 continental sediments, which were deposited in alluvial floodplains, including channelized 775 776 polygenic, sub-rounded, conglomerates. Proximal-distal facies distributions, paleocurrents and some distinctive clast lithologies are consistent with a southern source for the clastic 777 778 sediments. This is related with a remaining pyrenean topography that extended in the present-779 day Gulf of Lion, until the Priabonian. Priabonian formations are preserved in distinct basins or 780 sub-basins corresponding to subsiding depocentres, which display significant thickness variations and syn-tectonic growth structures. The lower boundary is an unconformity over the 781 pyrenean syn-orogenic formations and structures, although it can locally be observed 782 783 conformable at outcrop scale. The angular unconformity is better expressed where pyrenean tectonics was more developed: i.e. close to the Montpellier and Pic-Saint-Loup thrusts and 784 around the anticlines. Priabonian sequences are eroded and unconformably overlain by Late 785 Rupelian continental alluvial fans and lacustrine deposits, in relation with the rifting of the Gulf 786 of Lion margin, except in the SMLB, where the stratigraphic record ends with Priabonian. The 787 Priabonian sequences of the GSCB, observed in seismic profile and tied to borehole data, and 788 those from the HB (although not precisely dated) provides evidence for similar structural and 789 790 stratigraphic relationships, as observed in the field. Pyrenean structures and syn-orogenic sequences are unconformably overlain by a seismic sequence of highly variable thickness, 791 792 which is also truncated by younger sequences displaying syn-rift growth structures against the

- basin bounding normal faults. We correlate this intermediate seismic sequence with the
 Priabonian interval described in the field in GB, LMB and SMLB.
- 795 At variance with the observed similar structural relationship with underlying and overlying
- sequences, the Priabonian deposits display contrasting structures in the different basins
- 797 investigated (Fig. 22):
- 798 Priabonian basins Pyrenean syn-orogenic formations Priabonian tectonics extensional fault strike-slip or undifferentiated fault thrust fold axis syndepositional syncline Pyrenean Thrust (inactive during Priabonian) Fig. 22 7.
- **Fig. 22:** Synthetic regional map of Priabonian structures and kinematics in Languedoc. For location of specific features and localities, please refer to Fig. 2, which shares the same frame. The study area corresponds to a zone of sinistral shearing between the Cévennes and Nîmes faults, with a minimal value of 5 km (grey overlay symbolises the simple shear).
- 804
- LMB: Syn-tectonic growth-structures are consistent with a hanging-wall syncline,
 resulting from extensional faulting along the NNE-striking bounding normal fault.
- SMLB: Structures are related to syn-depositional compressional folding across the E trending Pic-Saint-Loup thrust.

- GB: The tectonic sketch derived from the detailed geological map Fig.7 displays syn-809 depositional folding, which characterises both NE-SW compression and EW extension; 810 in addition, there is evidence of left-lateral strike-slip along NNE-trending faults (Fig. 811 812 11b).
- HB: Depocentre distribution with respect with controlling faults suggests left-lateral 813 -814 motion along the NNE-trending Cévennes Fault, which accommodates normal faulting 815 across N-trending splays (Fig. 22).

GSCB: The Priabonian sequence was deposited as a hanging-wall syncline controlled by a SE-trending extensional low-angle decollement of the Mesozoic cover over the 817 Paleozoic basement. 818

819 Such apparently contradicting kinematics can be understood in an overall left-lateral deformation along the regional NNE-trending faults, such as the Cevennes, Les-Matelles-820 821 Corconne and the Nîmes faults (Fig.22). When submitted to a stress regime characterised by a horizontal, N-S, maximum principal stress σ 1 and a horizontal E-W minimum principal stress 822 823 σ 3, inherited faults oriented NNE are reactivated as left-lateral strike-slip faults, with restraining bends (Christie-Blick and Biddle, 1985) along more northerly oriented segments, as in LMB, 824 HB, GSCB. East-west oriented fault splays such as the Pic-Saint-Loup correspond to 825 restraining bends. Syn-tectonic deposition in the syncline north of Uzès (Fig.2, Fig.22) also 826 provide additional evidence for N-S shortening across EW oriented structures, during 827 828 Priabonian.

The amount of left-lateral displacement during Priabonian is poorly constrained, as it 829 reactivates, and is superimposed, onto Pyrenean left-lateral ramps, resulting in a combined 830 finite strain, which hampers the distinction of the two contributions to the strike-slip offset. In 831 addition, our study shows that i) the strain was distributed across the whole area between the 832 833 Cévennes and Nîmes faults and ii) possible discrepancies between the amount of deformation recorded in the Mesozoic cover and the basement may occur. However, the Priabonian 834 835 tectonic-sedimentation relationships recorded in some of the studied basins provide minimum values for the offset. The extensional growth structure in the Hérault basin (Fig. 16 c) suggests 836 837 a minimum extension of some 3 km, corresponding to the minimum value of Priabonian leftlateral offset across this segment of the Cévennes fault. The migration of the Priabonian 838 hanging-wall syncline in the GSCB (Fig. 19) indicates NE-ward displacement of 4 km. 839 840 Restoration of the LMB points to 375m Priabonian extension (Benedicto et al., 1999) across a releasing bend of the Matelles-Corconne Fault. This could represent the order of magnitude of 841 displacement across the other identified NE-trending faults that bound the Guzargues and 842 Sommières basins (Fig. 2). We thus suggest that the Priabonian cumulated left-lateral motion 843 distributed across the 40 km wide NE-trending wrenching zone remained moderate, with a 844 minimal value of 4 to 5 kilometres. Even though some wrenching may have occurred without 845

- any syn-tectonic deposits recorded, the cumulated Priabonian movement unlikely exceeded
- 10km. There is no data to document the offset across the major Nîmes fault.

Fig. 23: Evolution of stress regime from mid-Eocene Pyrenean shortening, through Priabonian strikeslip regime, to Rupelian rifting.

851

852 The transition from Pyrenean compressional mountain building to rifting of the Gulf of Lion in 853 Languedoc was achieved by a specific evolution of the stress regime (Fig. 23). From latest 854 Cretaceous to Bartonian the N-S convergence of Sardinia and associated continental block with southern Europe was accommodated by E-W folds and thrusts, while the inherited 855 regional NE-trending faults were activated as lateral-ramps. Such deformation results from a 856 horizontal σ 1 oriented N-S and a vertical σ 3 (Arthaud and Laurent, 1995). During Priabonian, 857 the stress regime evolved by permutation of σ^2 and σ^3 axes, σ^1 remaining horizontal and 858 859 oriented N-S. Such stress regime activated the inherited NE-trending faults as left-lateral strike-slip faults. This fault network inherited from the Late Cretaceous-Bartonian Pyrenean 860 orogeny included restraining and releasing relays, the later correspond to Priabonian 861 depocentres, where σ^1 and σ^2 permuted. The restraining bend, where compression occurred 862 (σ 1 N-S horizontal and σ 3 vertical) is illustrated by the Saint-Martin de Londres basins. 863 Contemporaneous releasing bend and relay, where local extension occurred (σ 1 vertical) is 864 examplified by the northern part of the Hérault basin, Les-Matelles basin, or Gardon Saint-865 Chaptes basin. (Fig. 22). Permanence of N-S horizontal σ 1 from Late Cretaceous through to 866 Late Eocene was also documented in southern Provence, defined by both strike-slip or reverse 867 868 faults (Lacombe et al., 1992). N-S shortening along the regional NE-trending faults accommodated transpression of the oblique Africa-Eurasia convergence in the Languedoc-869 Provence-Corsica domain (Lacombe and Jolivet, 2005) and lasted until Priabonian. During 870 Late Rupelian, the stress regime rotated clockwise around the vertical σ 1, by 30°(Séranne, 871

1999), which activated the inherited NE-trending strike-slip faults as extensional faults. This 872 Rupelian change in stress orientation reflects a change at plate boundaries, which we relate 873 to the onset of subduction roll-back and back-arc rifting above the Apennine subduction (Jolivet 874 875 and Faccenna, 2000; Jolivet et al., 2015; Réhault et al., 1984; Romagny et al., 2020; Séranne, 876 1999). Southeast-trending transfer faults zones are a distinctive feature of the rifting of the Gulf 877 of Lion (Canva et al., 2020; Gorini et al., 1993; Guennoc et al., 2000; Maillard et al., 2020; 878 Mauffret et al., 2001). However, there is no evidence of active SE-oriented structure in the onshore study area, until the Oligocene rifting episode (Maerten and Séranne, 1995; Sanchis 879 and Séranne, 2000). The Priabonian strike-slip deformation documented in the present study 880 therefore constitutes a distinct tectonic phase, corresponding to different kinematics and 881 882 driving forces than the rifting of the Gulf of Lion (Séranne, 1999). We suggest that the development of SE trending transfer zones in the back-arc basin, as from the Rupelian, dates 883 the initiation of slab tearing in the underlying subduction zone (Romagny et al., 2020). 884

886 Fig. 24: Simplified map Pyrenees / European Cenozoic Rift System /Alps during Priabonian.

Paleogeographic reconstruction at 35 Ma from (Romagny et al., 2020); Position of the North Alpine
foreland from (Dumont et al., 2012; Ford and Lickorish, 2004) and of the ECRIS from (Dèzes et al.,
2004).

890

Priabonian left-lateral wrenching in Languedoc links the active Pyrenean orogen to the E-W 891 rifting of the European Cenozoic Rift System (ECRIS) (Dèzes et al., 2004) and the North Alpine 892 Foreland Basin (Ford and Lickorish, 2004). Such left-lateral wrenching during Priabonian most 893 probably extended southward in the Corbières (Fig. 1); however, lack of Priabonian 894 sedimentary record in this area does not allow to confirm this. Eocene northward motion of the 895 Adriatic plate was accommodated by left-lateral oblique convergence along the SW Alps until 896 continental collision in Oligocene (Dumont et al., 2012; Ford et al., 2006) (Fig. 24). 897 898 Convergence between the Iberia and Europe respectively lasted until early Miocene in the 899 Pyrenees e.g. (Mouthereau et al., 2014; Teixell et al., 2018) and circa 85km shortening is computed for the Late Eocene to Early Oligocene interval (Teixell et al., 2016). Pyrenean 900 shortening in Corbières, Languedoc and Provence terminated during the Bartonian 901 (Alabouvette et al., 2001; Bestani et al., 2015; Séguret and Benedicto, 1999). Northward 902 903 flowing clastic sedimentation pattern in Languedoc, Provence and the SE Alps shows that this segment of the orogen, located in the present-day Gulf of Lion, was being dismantled at that 904 905 time (Egerton, 1996; Guieu and Roussel, 1990; Joseph and Lomas, 2004).

The left-lateral movement along the Nîmes and Cévennes fault system extended northward to the Jura region where sinistral strike-slip is well documented during Eocene (Homberg et al., 2002). It is also consistent with the transfer zone between Rhine and Bresse grabens (Bergerat et al., 1990; Lacombe et al., 1993; Madritsch et al., 2009), which both record a distinctive Priabonian pulse of sedimentation predating a mid-Oligocene extensional tectonics (Sissingh, 1998). Crustal extension across these rift basin amounts to 7 km (Ziegler and Dèzes, 2005), a value in agreement with the offset measured across the strike-slip faults.

During the Priabonian, the Languedoc-Provence segment of the Pyrenean orogen was thus surrounded by two active convergence zones, while it was undergoing collapse. This different behaviour may be due to the interaction with the west-European rifting (Dèzes et al., 2004), which propagated southward beneath the Languedoc-Provence-Pyrenees.

917

918 9. Conclusion

919

The transition from the Pyrenean orogeny to the Gulf of Lion rifting in onshore Languedoc occurred during Priabonian. Prior to Priabonian time, every structural and tectonicsedimentation evidence argue for pyrenean compressional deformation. In contrast, after

Priabonian, all structures indicate NW-SE extension related to the Gulf of Lion rifting. This 923 makes the Priabonian interval a key intermediate period of kinematic change. Reassessment 924 of the chronostratigraphic evolution of the area allowed us to constrain the calendar of events. 925 926 This period is recorded by deposition of a distinctive sedimentary sequence, which is 927 documented both by surface analyses and seismic profiling of Priabonian basins. Such 928 intermediate sequence is bounded at the base by an angular unconformity over the Pyrenean 929 structures, and at the top by the Oligocene syn-rift unconformity, respectively. Continental sedimentation ranges from lacustrine/ palustrine limestone and evaporitic marls at the base, 930 to marls and silts of alluvial plain, including variable proportion of sandstone sheets and 931 932 channelised fluvial conglomerates, toward the top. The Priabonian series progrades north- or 933 northeastward and is derived from a southern source, presently located offshore, which indicates the existence of a remaining pyrenean topography in the present-day Gulf of Lion. 934

Mapping and seismic analyses of the tectonic-sedimentation relationships in the Priabonian 935 basins give evidence for syn-depositional deformation against bounding faults and in growth 936 synclines. Contrasted modes of deformation are observed, within short distance, in the 937 Priabonian basins: i) controlled by extensional movement of NNE to NNW-trending faults or 938 segments of faults or ii) controlled by E-W-oriented thrusts and folds. Regional mapping of 939 940 these structures shows a distribution of the compressional and extensional structures which 941 are consistent with a left-lateral shearing of the area comprised between the major, NE-942 trending, Cévennes and Nîmes faults. Such sinistral strike-slip of moderate offset (± 5 km) 943 accommodates the E-W extension of the West European rifts basins that are located to the north of the study area. To the south, the strike-slip faults are connected to the ongoing 944 shortening in the Spanish Pyrenees. Priabonian deformation and sedimentation records the 945 946 initial stages of the dismantling of the Languedoc-Provence segment of Pyrenees, located 947 between two active orogens: the Spanish Pyrenees and the Western Alps. The late orogenic dismantling of the eastern Pyrenees (Jolivet et al., 2020) therefore started up to 5 My earlier 948 than the Rupelian onset of Apennine subduction retreat and associated back-arc NW-SE 949 950 extension.
