Key Points:

- Annual glacier mass balance for Central Asia (1999/00–2017/18) is derived by combining transient snowlines, geodetic surveys and modelling.
- Strong spatio-temporal heterogeneity with contrasting patterns of mass gain and loss are found.
- Hot spots of heterogeneous mass balance variability are associated with highly variable glacier melt water runoff.

Abstract

The Tien Shan and Pamir mountains host over 28,000 glaciers, providing essential water resources for increasing water demand in Central Asia. A disequilibrium between glaciers and climate affects meltwater release to Central Asian rivers, challenging the region's water availability. Previous research has neglected temporal variability. We present glacier mass balance estimates based on transient snowline and geodetic surveys with unprecedented spatio-temporal resolution from 1999/00–2017/18. Our results reveal spatio-temporal heterogeneity characterised by two mass balance clusters: (i) positive, low variability, and (ii) negative, high variability. This translates into variable glacial meltwater release ($\approx 1\%$ to 16%) of annual river runoff for two watersheds. Our study reveals more complex climate forcing-runoff responses and importance of glacial meltwater variability for the region than suggested previously.

Plain Language Summary

Glaciers in Central Asia act as water towers for millions of people by storing and releasing water in response to climate. Monitoring glaciers is difficult due to their often very remote locations. Satellite remote sensing has emerged as a powerful method but a drawback is their (semi-)decadal resolution for glacier mass change surveys. We present a methodology, combining multi-year elevation change maps with frequent snowline observations to estimate mass changes and variability at annual scale, which allows us identifying so-far unrecognised regions of contrasting trends for the Tien Shan and Pamir mountains. These “hot spots” reveal a far more complex climate-glacier interplay than previously known. The additional meltwater released from the retreating glaciers varies considerably and contributes to the river flow for warm dry years by twice as much as for cold wet years. Our findings will help to better understand the impact of climate change on Central Asian glaciers and their meltwater release.

1 Introduction

Most glaciers around the world are retreating (IPCC, 2013). During past decades, mass loss has accelerated (Zemp et al., 2019). Glacier responses in High Mountain Asia, including Tien Shan and Pamir, are very heterogeneous spatially (Scherler et al., 2011; Kääb et al., 2012; Farinotti et al., 2015; Brun et al., 2017; Q. Wang et al., 2017; Kraaijenbrink et al., 2017; Shean et al., 2020). Ongoing glacier retreat will have profound consequences on fresh water resources for Central Asia, in particular under high-emission scenarios (Huss & Hock, 2018; Marzeion et al., 2020; Rounce et al., 2020).

Glacier melt contribution represents up to 40–60% during the late summer months (Aizen et al., 1995, 1997; Armstrong et al., 2019), serving a crucial buffer during droughts (Pohl et al., 2017; Pritchard, 2019). The major Central Asian river basins Syr Darya, Amu Darya and Tarim will reach maximum glacier meltwater input within the next decades (Huss & Hock, 2018; Rounce et al., 2020). In combination with rapidly growing economies, this poses the risk of freshwater scarcity (Varis, 2014) and might trigger conflicts (Munia et al., 2016; Krasznai, 2019).

The synthesis of regional mass balance dynamics on annual to seasonal time scales for Tien Shan and Pamir is challenging because glaciological datasets are sparse (Unger-Shayesteh et al., 2013; Hoelzle et al., 2019; Barandun et al., 2020). Therefore, most hydrological models for glacier melt quantification are calibrated on auxiliary datasets rather than actual measurements, hampering their reliability (Pritchard, 2019).

We apply the approach developed in Barandun et al. (2018) for the period 1999/00–2017/18 to all 1,995 glaciers larger than 2 km^2 ($\approx 60\%$ glacierised area of Tien Shan and Pamir), providing for the first time, an annually resolved and consistent mass balance time-series. Our results extends the analysis of spatially heterogeneous glacier responses to the spatio-temporal dimension, and characterise the discharge variability for two medium-

78 size watersheds in Tien Shan (Naryn River) and Pamir (Gunt River) over the past two
79 decades. This provides first insights into changing year-to-year variability in glacier mass
80 change and highlights mountain ranges where important shifts in glacial excess meltwater,
81 i.e. additional water input from glacial water storage reduction (Shean et al., 2020;
82 Rounce et al., 2020) to total river runoff, can be expected.

83 2 Data and Methods

84 Our methodology combines (i) transient snowlines (transition between ice and snow
85 surfaces approximating the zero-mass-balance-line of the glacier; Dyurgerov et al. (1992)),
86 (ii) geodetic estimates, and (iii) distributed mass balance modelling to provide annual
87 mass balance time-series (Barandun et al., 2018). The snowlines are used to calibrate
88 a temperature-index and distributed accumulation model (Braithwaite, 1995) for each
89 glacier and year separately. Geodetic mass balances then constrain the modelled multi-
90 year mass balances to reach agreement between the two observational datasets.

91 2.1 Automatic snowline mapping

92 Over 3000 Landsat Reflectance Level-2 science products (Masek et al., 2006; Claverie
93 et al., 2015; Vermote et al., 2016) with cloud cover <50% were collected over ablation
94 seasons (June to September) from 2000–2018. We derived spatially distributed short-
95 wave broadband albedo for the glacierised area (Liang, 2001) and removed cloud-affected
96 pixels (Supplementary Material). We differentiated snow-covered and bare-ice surfaces
97 using an automated multi-step classification scheme based on the albedo threshold for
98 *certainly snow* ($\alpha > 0.50$) and *certainly ice* ($\alpha < 0.22$) proposed by Naegeli et al. (2019).
99 Ambiguous pixels ($0.22 \leq \alpha \leq 0.50$) were evaluated according to their spatial distri-
100 bution (Supplementary Material). We derived snow-covered area fractions (SCAFs), i.e.
101 ratio of area above current snowline to total area of the glacier, and filtered for misin-
102 terpreted SCAF's according to their seasonal evolution (Supplementary Material). Compar-
103 ison to manually delineated snowlines in the region result in a root mean square er-
104 ror of <10%.

105 2.2 Geodetic volume change

106 We produced Advanced Spaceborne Thermal Emission and Reflection Radiome-
107 ter (ASTER)-derived digital elevation models (DEMs) using MicMacASTER (Girod et
108 al., 2017). We selected 1201 ASTER DEMs and used 1852 High Mountain Asia DEMs
109 (Shean, 2017) for differencing based on at least five-year separation and 40% scene over-
110 lap, resulting in 4243 DEM-pairs providing data for 902 out of 969 glaciers $>2 \text{ km}^2$ in
111 Tien Shan and 848 out of 1004 $>2 \text{ km}^2$ in Pamir. Before differencing, we co-registered
112 DEMs Nuth and Kääb (2011). We calculated ice volume change using a local hypsomet-
113 ric approach (McNabb et al., 2019), converted it into mass change assuming a bulk den-
114 sity $\rho_{\Delta V}$ of 850 kg m^{-3} (Huss, 2013) and followed the uncertainty calculations in McNabb
115 et al. (2019) for random errors (Supplementary Materials).

116 For comparison with transient snowline-constrained mass balances, all geodetic mass
117 changes per glacier were homogenised to represent a reference period (1999/00–2017/18).
118 We temporally adjusted geodetic surveys to the common reference period using glacio-
119 logical measurements (Zemp et al., 2019). Thereby, we calculated the mean annual de-
120 viation between each geodetic estimate and the selected glaciological time-series over a
121 common time period (Fig. S1) and added this deviation to the glaciological measure-
122 ments for the reference period (Supplementary Material). Two glaciological time-series
123 covering the entire study period are available: Tuyuksu and Urumqi. Based on expert
124 knowledge and recent measurements (2010/11–2017/18), we chose Tuyuksu for Dzhun-
125 garsky Alatau, Western/Northern Tien Shan, Pamir-Alay and Western Pamir, and Urumqi
126 series Eastern and Central Tien Shan and Eastern Pamir. All homogenised mean annual

127 mass balances per glacier were weighted according to their uncertainty. The median of
 128 all weighted estimates was interpreted as reference geodetic mass balance of the corre-
 129 sponding glacier and compared with literature (Supplementary Material). For glaciers
 130 missing geodetic mass balances, the arithmetic mean of all geodetic surveys within the
 131 sub-region is used.

132 2.3 Transient snowline-constrained mass balance model

133 We used the model by Barandun et al. (2018) to infer glacier-specific surface mass
 134 balances using the Shuttle Radar Topography Mission (SRTM, Jarvis et al. (2008)) DEM
 135 for topography and a distributed accumulation and temperature-index melt model (Braithwaite,
 136 1995) with daily temporal and 30 m spatial resolution. RGI 6.0 outlines (RGI Consor-
 137 tium, 2017) were kept unchanged. Daily total precipitation and 2 m-air temperature from
 138 ERA-interim Reanalysis (0.75° resolution) are used to initiate the model. ERA-interim
 139 was chosen because, unlike other reanalysis products *in situ* observations in mountain
 140 regions are assimilated (Orsolini et al., 2019). To calculate melt M , a linear relation with
 141 positive daily mean air temperature $T_{\text{air}}(x, y, t)$ is applied for each grid cell x, y and time
 142 step t :

$$M_{x,y,t} = \begin{cases} DDF_{\text{ice/snow}} \cdot T_{\text{air}(x,y,t)} & T_{\text{air}} > 0^\circ \\ 0 & T_{\text{air}} \leq 0^\circ \end{cases} \quad (1)$$

143 We use two different degree-day factors for snow DDF_{snow} and ice DDF_{ice} and at
 144 first hold their ratio R_{DDF} constant over time.

145 The snow accumulation C is simulated for each grid cell x, y and t by

$$C_{(x,y,t)} = P_{\text{ERA}}(x, y, t) \cdot C_{\text{prec}} \cdot (1 + (z_{(x,y)} - z_{\text{ERA}}) \cdot \delta P / \delta z). \quad (2)$$

146 Solid precipitation occurs at $T_{\text{air}} \leq 1.5^\circ\text{C}$ with a linear transition range of $\pm 1^\circ\text{C}$
 147 (Hock, 1999). P_{ERA} is the daily precipitation sum of the ERA-interim grid cell closest
 148 to the glacier adjusted to its median elevation $z(\text{ERA})$. $z(x, y)$ gives the elevation of each
 149 pixel. To correct Reanalysis precipitation data to the specific location of each glacier,
 150 P_{ERA} is scaled with a correction factor C_{prec} (Huss et al., 2008, 2009). C_{prec} is assumed
 151 to be 25% lower for liquid precipitation (Sevruk (1981)). A constant temperature lapse
 152 rate $\delta T / \delta z$ and a linear precipitation gradient $\delta P / \delta z$ (Table S2) are applied for extrap-
 153 olating the temperature and precipitation to each grid cell. Above a critical elevation
 154 Z_{crit} precipitation is held constant. The constant model parameters (Table S2) are based
 155 on Barandun et al. (2018).

156 For a first-order calibration, we use SCAFs to constrain model parameters for ac-
 157 cumulation (C_{prec}) and melt (DDF_{snow}) for each glacier and year (Supplementary Ma-
 158 terials). Barandun et al. (2018)'s calibration procedure is adjusted to limit computation
 159 time. A start value for DDF_{snow} and C_{prec} is iteratively narrowed down until no improve-
 160 ment of the model is observed (Figs. S6 and S7). Barandun et al. (2018) found an un-
 161 certainty of $\approx 0.10 \text{ m w.e. yr}^{-1}$ related to an over- and underestimation of the mapped
 162 snowlines, showing the model sensitivity to a single snowline delineation to be relatively
 163 small, provided that enough and temporally well-distributed snowline observations are
 164 available.

165 C_{prec} and DDF_{snow} are calibrated annually and for each glacier separately to cor-
 166 rectly represent winter snow accumulation and melt rates for each year (Figs. S6, S8,
 167 Barandun et al. (2018)). The model is run from 1999/00–2017/18 for every year with
 168 at least two available snowline observations (Barandun et al., 2018). Calibrated param-
 169 eters obtained for years with good data availability were averaged for remaining years.
 170 113 glaciers had fewer than 16 out of 18 years with sufficient snowline maps and were
 171 removed.

172 In contrast to conventional modelling, our results are tied to sub-seasonal snow-
 173 line observations for each glacier and year, as well as multi-annual geodetic surveys. This
 174 reduces the model sensitivity to input variables (Barandun et al., 2018). Using transient
 175 snowline observations for model calibration reproduced year-to-year mass balance vari-
 176 ability close to observations (Table S3), improving conventional modelling.

177 For the second-order calibration, we constrain annual mass balances by compar-
 178 ison with geodetic surveys of each glacier for the reference period. The relation between
 179 initially constant degree day factors of snow and ice R_{DDF} (first-order calibration) are
 180 adjusted within a plausible range (1.2–2.9, Hock (2003)), and then the first-order cal-
 181 ibration is repeated (Fig. S6) in case the snowline-constrained mass balance series ex-
 182 ceeds the error range of the geodetic approach. When no agreement is found but the plau-
 183 sibility limit for R_{DDF} reached, the precipitation gradient ($\delta P/\delta z$) is adjusted within re-
 184 alistic bounds (0.5–20% 100 m^{-1} , Immerzeel et al. (2015)) and previous calibration steps
 185 repeated. These literature-based parameters are spatially highly variable and not well
 186 constrained for individual glaciers. The final parameter range is summarised in Figure
 187 S8 and Table S2.

188 The second-order calibration is repeated until the absolute difference between the
 189 two approaches is smaller than the uncertainty of the geodetic method or both param-
 190 eters reach their plausibility limits. After this step, 283 (14%) glaciers were omitted. Fi-
 191 nally, we filtered the time-series for outliers by removing all annual mass balances un-
 192 realistically high or low (two standard deviations beyond the mean, 377 glaciers removed)
 193 and only include the resulting series if still in agreement with the geodetic survey.

194 We adopt the mean uncertainties ($\pm 0.32\text{ m w.e. yr}^{-1}$) associated with the snowline-
 195 constrained mass balance model from Barandun et al. (2018) and combine it with the
 196 error estimate from the geodetic surveys. This conservative estimate of $\pm 0.37\text{ m w.e. yr}^{-1}$
 197 does not assume independence of the errors from year to year.

198 2.4 Glacier meltwater excess

199 The effect of glacier mass balance on river discharge is assessed using two discharge
 200 datasets of Naryn (Tien Shan) and Gunt (Pamir) rivers (Fig. 1a). For each catchment,
 201 three monthly time-series were obtained (Table S4): long-term average discharge, one
 202 extremely negative (2009 for Gunt, 2003 for Naryn) and one positive (2008 for Gunt, 2006
 203 for Naryn) mass balance year. The long-term discharge is the periods 1999/00–2017/18
 204 (Naryn) and 1999/00–2012/13 (Gunt). The Naryn and Gunt catchments have 8% and
 205 5% glacier cover. Discharge estimates are based on annually calibrated stage-discharge
 206 rating curves and stage readings. Both catchments drain higher parts of the respective
 207 mountain ranges so that runoff is not impacted by water resource management (e.g. dams,
 208 agriculture).

209 We calculate excess glacier meltwater contributions to river runoff due to decreas-
 210 ing water storage for negative glacier mass balances according to Shean et al. (2020) at
 211 annual time scale, and at monthly time scale for some extreme years to highlight strong
 212 variability. All annual mass balances $> 0\text{ m w.e. yr}^{-1}$ are set to zero, and mass balances
 213 of all glaciers $< 2\text{ km}^2$ and non-modelled glaciers are assigned the mean mass balance of
 214 the catchment (Shean et al., 2020). The smallest glaciers ($< 0.2\text{ km}^2$), which might de-
 215 viate strongly from this assumption (Shean et al., 2020), make up 9 and 7% of the to-
 216 tal glacierised area in the Gunt and Naryn catchments, respectively and contribute lit-
 217 tle to the overall uncertainty. However, we stress that our results are a first-order esti-
 218 mate. We use the monthly glacier mass change constrained with the transient snowline
 219 observations during the summer season (June to September) to calculate the monthly
 220 anomalies for a very negative and very positive mass balance year from the average monthly
 221 mass balance for each catchment. We assume mass balance and glacier melt to scale lin-
 222 early (Gao et al., 2010).

3 Annual glacier mass balance for the Tien Shan and Pamir

Our mass balance calculations, tied to transient snowline observations, provided annual values for 1,222 (61%) glaciers $>2\text{ km}^2$ (Table S5). The remaining 773 (39%) were excluded due to insufficient transient snowline observations or disagreement with geodetic surveys.

According to our multi-data assessment, we found an area-weighted average glacier mass balance of $-0.23\pm 0.37\text{ m w.e. yr}^{-1}$ from 1999/00–2017/18 for Tien Shan and Pamir. Glaciers in Eastern Tien Shan and Dzhungarsky Alatau showed the most negative mass balance rates at almost $-0.50\pm 0.37\text{ m w.e. yr}^{-1}$ (Fig. 1a). Glaciers in Northern/Western Tien Shan, Pamir-Alay and Western Pamir showed mass balance rates between $-0.25\pm 0.37\text{ m w.e. yr}^{-1}$ and $-0.32\pm 0.37\text{ m w.e. yr}^{-1}$. A moderately negative mass balance rate of roughly $-0.13\pm 0.37\text{ m w.e. yr}^{-1}$ was observed for Central Tien Shan and Eastern Pamir. Spatially contrasting mass balances within the sub-regions, and partly for glaciers in close vicinity, challenge regional averaging and question existing standard regional divisions (Fig. 1a).

Our results highlight that several glaciers of the existing international monitoring network represent the regional averages fairly well (Fig. 1b) but some deviate. The observation network is so far unable to capture the spread within their sub-regions (e.g. Western Pamir; Fig. S9) or no observations at all are available (e.g. Dzhungarsky Alatau).

4 Spatio-temporally heterogeneous glacier response

From 1999/00–2017/18, we found negative trends in annual mass balance for Tien Shan, significant for Northern/Western and Central Tien Shan ($p\text{-value} < 0.05$) but not for Eastern Tien Shan and Dzhungarsky Alatau. No clear temporal trend over this period was found for Western Pamir, but significant negative trends were observed for Pamir-Alay and Eastern Pamir. While at the southeastern part of Tien Shan and Pamir over 60% of the glacierised area remained above the equilibrium-line-altitude (ELA), less than 40% did at the northwestern margin, suggesting substantial glacier mass loss under current climatic conditions for the latter (Fig. 2a).

Prior to 2005, many glaciers had close-to-zero or slightly positive mass balances and ELAs below the 1999/00–2017/18 average (Figs. S10 and 2b). Subsequently, mass balance became more negative, and ELA increased gradually in most sub-regions until 2018. In Eastern Tien Shan and Western Pamir, the ELA remained close to the average from 1999/00–2017/18, and only non-significant negative trends in mass balance were revealed. “Hot spots” of nearly balanced conditions in Western Pamir contrasted with a significant negative mass balance in Eastern Tien Shan (Fig. S10). A similar “hot spot” was found in Central Tien Shan. Eastern Tien Shan was the only region where the ELA stayed below median glacier elevations (Table S5).

Previous studies (Shean et al., 2020; Brun et al., 2017, 2019) highlighted spatially heterogeneous glacier responses of High Mountain Asia. Our results show this heterogeneity to be pronounced down to sub-region-scale of Tien Shan and Pamir, revealing heterogeneous mass changes over time (Fig. 2c). Between a first (1999/00–2010/11) and a second (2006/07–2017/18) period chosen to overlap to avoid leverage effects of potential extreme years, overall mass balances became more negative. However, glaciers with less negative mass balance for the second period are apparent, often where mass loss from 1999/00–2017/18 was high (Fig. 2c).

In the three sub-regions of Pamir, glaciers with low median elevations ($<4500\text{ m a.s.l.}$) experienced accelerated mass loss in the second period (Fig. 2c). With higher median elevations (i.e. $>4500\text{ m a.s.l.}$), the signal weakened or even inverted to unchanged or slightly positive mass changes. Considering 500 m elevation bins for Tien Shan, almost all elevation classes had more negative mass balances for the second period (inset Fig. 2c).

The spread in glacier mass balances was generally similar or higher within the different classes for Tien Shan sub-regions, while generally decreased within individual classes

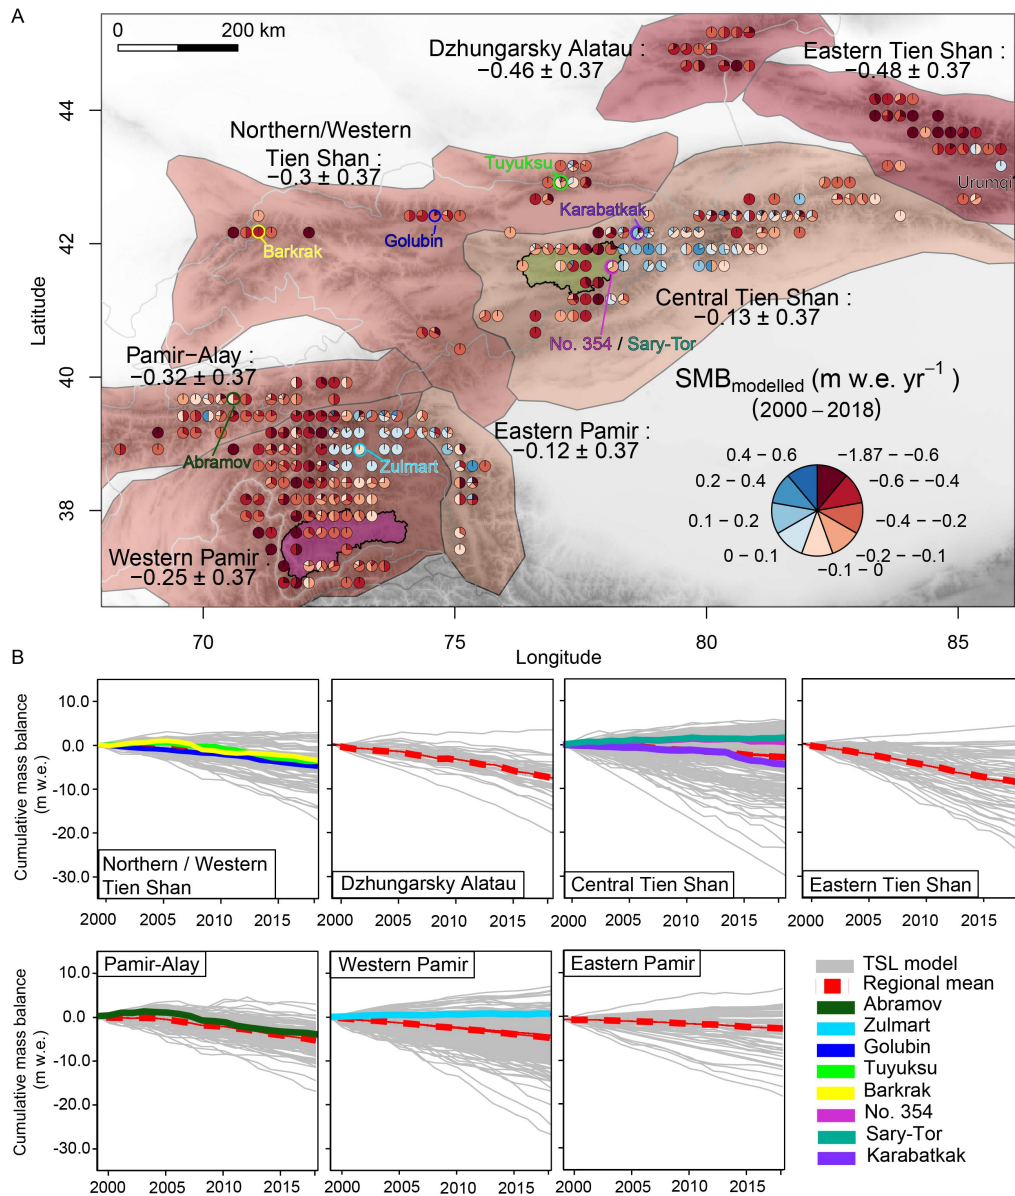

Figure 1. **A.** Mean annual mass balances (1999/00–2017/18) for different sub-regions. Pie slice sizes representing percentage of glaciers in each category (binned to 0.25-degree grid cells using glacier centroids provided in the RGI) not scaled to total number of glaciers per grid cell (Figure S11: pies scaled to number of glaciers on 0.75° ERA-Interim grid). Regional mass balances are area-weighted means of glacier values. Coloured circles indicating location of monitored glaciers. Magenta polygon showing Gunt (Western Pamir) catchment, and green polygon Naryn River (Central Tien Shan) catchment. **B.** Reconstructed cumulative mass balance series (grey lines) compared with regional mean (red dashed lines) and reconstructed mass balances of monitored glaciers (coloured continuous lines) per sub-region.

in Pamir for the second period (Fig. 2c). A declining regional variability (i.e. mean of the standard deviation of all mass balances within a region per year for either time pe-

277
278

riod) in Pamir (Fig. 3b) adds to a spatially homogeneous character. In contrast, increased spatio-temporal heterogeneity is present for Tien Shan from 1999/00–2017/18 (Fig. 3a,b).

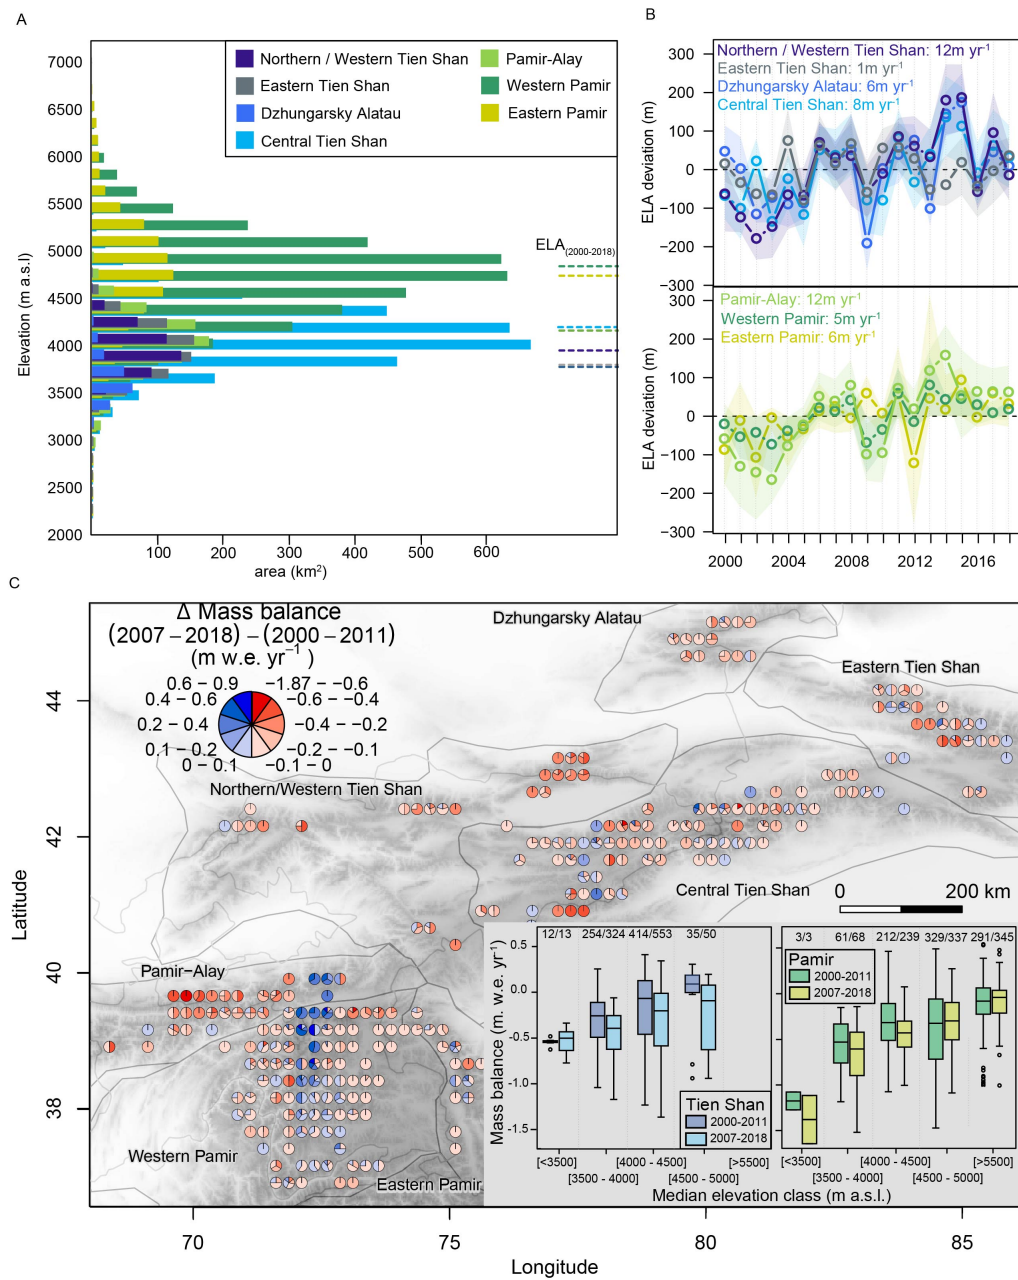

Figure 2. A. Area-elevation distribution (Bolch et al., 2019) and mean reconstructed ELA (dashed lines) per sub-region (1999/00–2017/18). B. Annual ELA anomalies per sub-region for Tien Shan (blue colours) and Pamir (green colours). C. Pie charts showing difference in mass balance between second (2006/07–2017/18) and first (1999/00–2010/11) period binned in 0.25-degree grid cells. Pie slice sizes representing percentage of glaciers in given class of mass balance change (δ Mass balance). Boxplots in inset show mean annual mass balances per median elevation class for both periods. Top of boxes numbers indicate number of considered glaciers vs total number of glaciers per class according to RGI 6.0.

5 Changing mass balance variability

Typically, Tien Shan and Pamir are classified into subcontinental (i.e. Western/Northern Tien Shan, Pamir-Alay) to continental (i.e. Central Tien Shan, Western and Eastern Pamir) regimes (R. Wang et al., 2019). We observed lower annual mass balance variability for more continental parts of Central Tien Shan and Central and Eastern Pamir. Higher variability dominates towards the subcontinental western margin, generally accompanied with higher mass loss (Figs. S12 and 1a). We found lowest year-to-year variability for Central Tien Shan (standard deviation $\sigma = 0.29$ m w.e.) and for Western and Eastern Pamir ($\sigma = 0.29$ and 0.21 m w.e., respectively) (Fig. S12). These high-elevation continental glaciers (Table S5) previously showed higher sensitivity to precipitation changes and non-uniform mass-balance sensitivity with elevation (R. Wang et al., 2019). Low mass balance sensitivity and variability and more gentle mass balance gradients relate typically to dryer and colder environments (Oerlemans, 2001). Within more subcontinental sub-regions, a higher year-to-year variability (greater $\sigma = 0.39$ m w.e., Fig. S12) is in agreement with previously shown elevated sensitivity to changing atmospheric conditions, especially air temperature (R. Wang et al., 2019). Stark contrasts within the sub-regions, especially for Western Pamir and Central Tien Shan, show that the “hot spots” of spatially heterogeneous glacier response (Fig. 1) are accompanied by a strong year-to-year variability (Fig. S12) and correspond only partially to proposed regional continental/sub-continental classifications.

We compared the standard deviations in annual mass balances (Fig. 3a) between the periods of 1999/00–2010/11 and 2006/07–2017/18. In Tien Shan, increasingly negative mass balances tend to be mirrored in slightly increased annual variability ($\Delta\sigma$: 0.03 m w.e. yr^{-1}). However, some areas in Central Tien Shan with high mass loss rates showed less negative mass balances but increased variability in the 2007–2018 period (Fig. 3b & Fig. 2c). Changes in Pamir are also diverse (Fig. 2c). For example, the year-to-year variability strongly decreased in parts of Western Pamir, where mass balances were less negative for the second period (Fig. 3a). Our data show that a decrease in mass balances from 1999/00–2010/11 and 2006/07–2017/18 was not always accompanied with an increase in year-to-year variability and vice versa (Fig. 2c). Still, areas with the smallest reduction in year-to-year variability were generally those with more positive mass balances from 1999/00 to 2017/18, and largest changes in variability were related to more pronounced mass loss.

Anticipated climate change in Tien Shan and Pamir (Haag et al., 2019; Aizen et al., 1997) is expected to continuously alter glacier sensitivities to air temperature and precipitation (Dyurgerov et al., 1994) and enhance spatio-temporal heterogeneity. Despite local differences, mass balance variability is on average higher ($\sigma = 0.43$ m w.e. yr^{-1}) for glaciers with more negative mass balances than for glaciers with above-average mass balances ($\sigma = 0.15$ m w.e. yr^{-1}). Under ongoing climate change, mass balances are expected to become increasingly negative and more variable in space and time, ultimately increasing the variability of glacier meltwater contributions with more pronounced extremes and changes in glacier runoff dynamics with important socio-hydrological consequences in the future (Nüsser, 2017).

Climatic forcing has been previously identified as dominant driver for the heterogeneous mass balance sensitivity over High Mountain Asia, explaining up to 60% of its spatially contrasting glacier response (Sakai & Fujita, 2017). Glacier morphology was found to explain up to 36% of the spatial mass balance variability for Tien Shan and 20% for Pamir-Alay, but only 8% for Western and Eastern Pamir (Brun et al., 2019). The influence of glacier surge activity is so far poorly understood (Goerlich et al., 2020). Although our results provide new estimates to revisit these analyses, prevailing large uncertainties in current meteorological datasets (Zandler et al., 2019) require a more detailed approach than can be provided here.

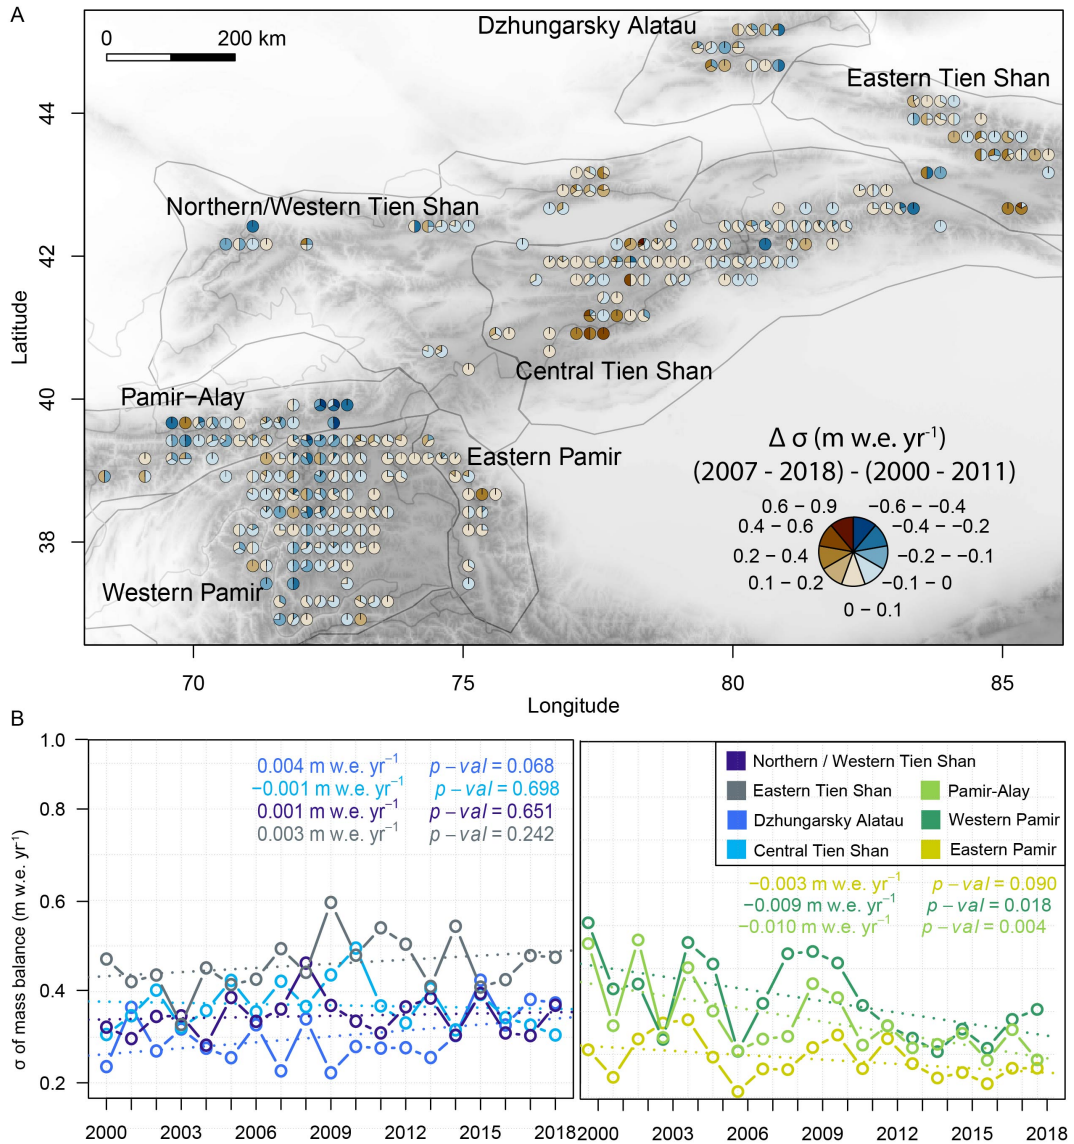

Figure 3. **A.** Differences in mean standard deviation (σ) between periods 2006/07–2017/18 and 1999/00–2010/11 for each glacier binned for 0.25-degree grid cells. Pie slice sizes representing percentage of glaciers in a σ change category. **B.** Mean annual σ for all glaciers within a sub-region (1999/00–2017/18) for Tien Shan (blue) and Pamir (green).

6 Relevance of glacier mass loss to river runoff

The most important impact of changing glacier runoff dynamics for Central Asia is the uncertain timing and duration of high or low meltwater contributions to river systems during dry summer months (Varis, 2014; Chen et al., 2018; Immerzeel et al., 2020). Glacier melt can mitigate extreme water shortages on seasonal to decadal timescales (Pritchard, 2019; Pohl et al., 2017).

337 The monthly observations of the summer (Naryn) and winter (Gunt) precipitation-
338 dominated catchment (Figs. 1 and S13; Table S4) provide insights for two representa-
339 tive watersheds for the headwaters of Central Tien Shan (Aizen et al., 1995) and Pamir
340 (Pohl et al., 2017). The average additional water released due to annual excess glacier
341 melt runoff is $\approx 9\%$ for Naryn and $\approx 5\%$ for Gunt. The annual excess meltwater con-
342 tribution increases to $\approx 16\%$ and $\approx 7\%$ for most negative mass balance years (Fig. 4a
343 & b). Despite a relatively low annual contribution, melt water excess can become cru-
344 cial during dry summer months (Armstrong et al., 2019; Pritchard, 2019; Barandun et
345 al., 2020). Glacier melt from June to September can increase by $\approx 90\%$ (Naryn) and
346 $\approx 40\%$ (Gunt) above average monthly melt production during an extreme negative mass
347 balance year (Naryn: 2001/02; Gunt: 2007/08, Fig. 4c). The largest relative increases
348 in glacier melt are observed in June due to differences in snow-cover depletion, partic-
349 ularly pronounced for Gunt (Figs. 4c, d & and S13). For Naryn, the importance of glacier
350 melt in August 2002 is almost doubled compared with an average year, probably related
351 to increased air temperatures (Fig. S13). Summer glacier melt for very negative mass
352 balance years can be twice as high as for extremely positive mass balance years (e.g. 2002/03,
353 2008/09), when meltwater production decreases by 20-50%. Highly glacierised catchments
354 (10-30%) show larger compensating effects in Pamir, i.e. lack in precipitation and sub-
355 sequent snow-cover results in higher glacier melt contribution to total runoff, and vice
356 versa (Pohl et al., 2017). However, for the Gunt catchment, containing less glacierised
357 area, a direct response of discharge to snow-cover changes is revealed (Fig. 4b, e).

358 Increasing year-to-year mass balance variability profoundly influences the excess
359 glacier meltwater contribution to total river runoff at the end of summer. This might
360 become especially visible for dry periods with reduced snow-cover (Aizen et al., 1995,
361 2007). We expect the most precarious changes in fresh water release variability through
362 glacier melt for highly glaciated, subcontinental mountain ranges [e.g. Dzhungarsky Alatau,
363 Western / Northern Tien Shan, Pamir-Alay], where strongly negative mass balances are
364 associated with large increasing year-to-year variability (Fig. 3).

365 7 Conclusions

366 We provide annual mass balance time-series with low sensitivity to meteorologi-
367 cal input, closely tied to transient snowline and multi-annual geodetic surveys for the
368 data-sparse mountain ranges in Central Asia. Our results show strong variability in mass
369 balance between successive years across Tien Shan and Pamir. The transient snowline
370 approach reveals spatio-temporal heterogeneity in which positive and negative glacier
371 mass balances stand in stark contrast. These “hot spots” extend the Karakorum anomaly
372 to other sub-regions in Central Asia. Whilst our findings show signs of spatio-temporally
373 more homogeneous glacier responses in Pamir, glacier mass balances in Tien Shan have
374 become increasingly heterogeneous. The derived clusters and the annually resolved mass
375 balances provide a new basis to investigate possible importance of meteorological and
376 morphological drivers and their variability in unprecedented temporal and spatial res-
377 olution.

378 The excess glacier meltwater release for two catchments representative for Central
379 Asia can highly vary between years (1-16%). The difference in meltwater production can
380 relate strongly to early summer snow depletion (up to six times more melt than aver-
381 age) or follow air temperature changes during the end of summer (up to three times more
382 melt than average).

383 Large uncertainties in meteorological datasets remain a major hurdle for our un-
384 derstanding of processes governing changes at the climate-glacier-runoff nexus. Ongo-
385 ing monitoring efforts coupled with mass balance and runoff models are essential to un-
386 derstand the impact of climate upon future glacier mass balance and discharge patterns,
387 and in turn, to develop policy responses to rapidly increasing water demands in Central
388 Asia.

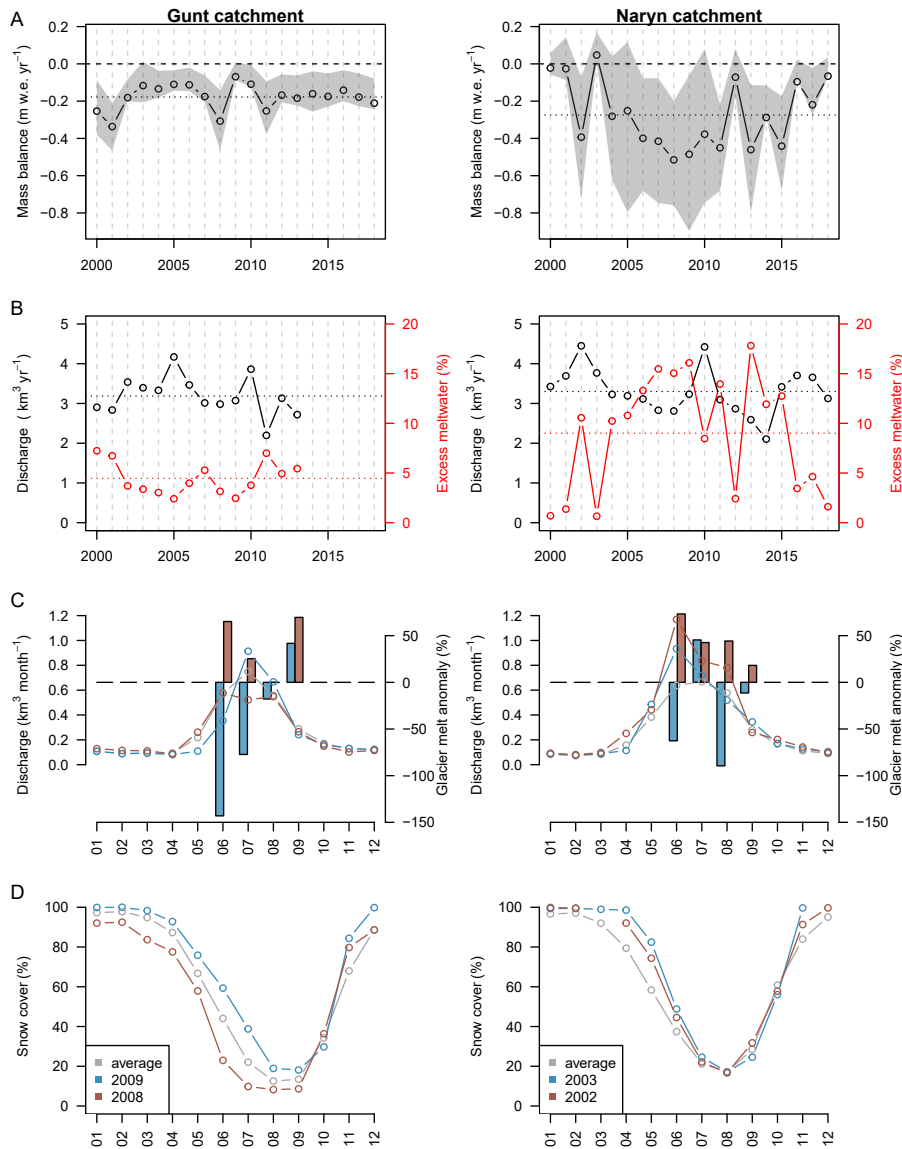

Figure 4. **A.** Mean annual mass balances for Gunt and Naryn catchments (1999/00–2017/18). Shaded grey area indicating spread between individual glaciers within a catchment. **B.** Annual river discharge measured (black) in comparison to excess glacier meltwater runoff contribution (red) to total river discharge. **C.** Monthly discharge (lines) as long-term average (1999/00–2017/18, grey), for below-average (red: 2002/03, 2008/09), and above-average (blue: 2001/02, 2007/08) mass balance years. Monthly melt anomalies with respect to average melt for each month (bars). Melt anomalies lower than -100% representing positive mass balances. **D.** Monthly snow-cover from MODIS10CM (D. K. Hall & Riggs, 2015) for both catchments.

Data Availability Statement

ERA-Interim Reanalysis data is available at <https://apps.ecmwf.int/datasets/data/interim-full-daily/> (last access:11.12.2020). Landsat imagery and SRTM is available at <https://earthexplorer.usgs.gov/> (last access: 11.12.2020). High Mountain

Asia DEMs are available at <https://nsidc.org/the-drift/data-set/hma/> (last access: 11.12.2020). ASTER imagery is available at <https://earthdata.nasa.gov/> (last access: 11.12.2020). MODIS MOD10CM data is available at <https://nsidc.org/data/mod10cm> (last access: 11.12.2020). High Asia Refined Reanalysis data is available at <https://www.klima.tu-berlin.de/HAR> (last access: 11.12.2020). Discharge data used in this study are available in the Supplementary material of the study. These data were obtained from the Tajik Hydromet <http://www.meteo.tj/> as part of the BMBF (Federal Ministry of Education and Research) research programme PAMIR (FKZ 03G0815) for the Gunt River, and from the Kyrgyz Hydromet <http://meteo.kg> for the Naryn River. Due to the hydromet institutions' data policies, the data are not readily available for download from the respective websites but can be requested through the contact links. Annual mass balance time-series are provided via zenodo open-access repository (<https://doi.org/10.5281/zenodo.4782116>).

Acknowledgments

We thank to the project CICADA (Cryospheric Climate Services for improved Adaptation), with contract no. 81049674 between Swiss Agency for Development and Cooperation and the University of Fribourg. The CAWa (Central Asian Water) project (<http://www.cawa-project.net>) was supported by the German Federal Foreign Office (contract no. AA7090002) as a part of the Berlin Process. This study was also supported by the Swiss National Science Foundation (SNSF) by the following two projects: Snowline observations to remotely derive seasonal to sub-seasonal glacier mass balance in the Tien Shan and Pamir Mountains, grant 155903, and Changing glacier firn in Central Asia and its impact on glacier mass balance, grant 169453. Funding for parts of this work comes from the BMBF (Federal Ministry of Education and Research) research programme PAMIR (FKZ 03G0815) within the CAME (Central Asia and Tibet: Monsoon dynamics and geo-ecosystems) project. KN acknowledges support from the SNSF Mobility Fellowship Grant (P2FRP2/174888). RM acknowledges support from the European Space Agency through Glaciers_CCI and CCI+ (4000109873/14/I-NB, 4000127593/19/I-NS), and by the European Research Council under the European Unions Seventh Framework Programme (FP/2007–2013) / ERC grant agreement no. 320816. EB acknowledges support from the French Space Agency (CNES). We thank A. Rodriguez Crespo for the proof reading and typesetting of the manuscript. We thank the reviewers and editor of the paper for the constructive reviews that helped to greatly improve the paper.
