31 plot databases they manage. Last but not least, we thank all the people who collected the plot data
32 on grassland vegetation in the field.
33
34

35
36 Author Contributions:
37
38 MC and IA conceived the research idea. Co-authors from the EVA database contributed the data. IA
39 prepared the data, performed statistical analyses, together with VK and JD compiled the final
40 neophyte lists, with MV prepared the maps and led the writing. All co-authors helped with species
41 status assignment and commented on the manuscript.

172 Abstract

2

373 Questions

4

5
674 The human-related spread of alien plants has serious environmental and socioeconomic impacts, and therefore it is
7 important to know which habitats are most threatened and why. We studied a wide range of European grasslands to
8
976 assess: (i) how invasion levels differ across European countries; (ii) which habitat types are the most invaded; and (iii)
10
177 which alien species are the most successful invaders.

12 Location

14

159 Europe

16

170 Methods

18

19 To address our questions, we selected 97,417 grassland vegetation plots from the European Vegetation Archive (EVA).
20

21 We assigned a native or alien status to each of the 8,212 vascular plant species, considering only neophytes (alien
22 species introduced after 1500 AD), which we further divided according to their origin. We compared the levels of
23 invasions using relative frequency of neophytes in the species lists, relative neophyte richness and cover per plots, and
24 percentages of invaded plots among regions and habitats.
25
26

28 Results

29

30 Only 536 species, representing 6.5% of all grassland vascular plant species, were classified as neophytes. Most
31 neophytes in grasslands were present in very few plots, while only three species were recorded in more than 1% of all
32 plots, namely *Onobrychis viciifolia*, *Erigeron annuus* and *E. canadensis*. We found a comparable total number of
33 neophytes from Europe ($n = 251$) and from outside Europe ($n = 249$), with therophytes and hemicryptophytes being the
34 most predominant life forms. We found no pronounced geographical patterns in the distribution of neophytes across
35 European grasslands but differences among habitat types. The most invaded habitat types were sandy grasslands, while
36 the least invaded were alpine and oromediterranean grasslands.
37
38

42 Conclusions

43

44 In general, natural or semi-natural European grassland habitats have relatively low levels of neophyte invasions
45 compared to human-made habitats or alluvial forests, or grasslands on other continents. The most typical neophytes
46 invading European grasslands are therophytes with broad ecological niches.

101 Introduction

2
3 The human-related spread of alien plants is an important issue worldwide (van Kleunen *et al.*, 2015; Pyšek *et al.*, 2017)
4 as many alien plant invasions have serious environmental and socioeconomic impacts (Vilà *et al.*, 2011; Pyšek *et al.*,
5 2020). However, there appears to be significant differences in the levels of alien invasion among regions (Chytrý *et al.*,
6 2008b; Kalusová *et al.*, 2015) and among habitats (Chytrý *et al.*, 2008a; Pyšek *et al.*, 2012a; Kalusová *et al.*, 2014). To
7 apply proper risk-assessment schemes and effective management, we need to identify the most vulnerable habitats
8 and the factors responsible for their high levels of alien plant invasion.
9

10 Europe is an important source of numerous neophytes (i.e. alien plants introduced to a region after 1500 AD) for other
11 continents, but also receives many neophytes from elsewhere (Kalusová *et al.*, 2015; van Kleunen *et al.*, 2015; 2019).
12 The first overviews of alien plants across European countries were based on the data from national and regional floras
13 and additional plant distribution data (Weber *et al.*, 1997; Lambdon *et al.*, 2008). These efforts recently continued with
14 the assessment of naturalized neophytes at the global scale (van Kleunen *et al.*, 2015; 2019). However, the data based
15 on regional floras do not necessarily reflect the frequency of neophyte species in different habitats. Therefore,
16 vegetation researchers focused on fine-scale data related to habitat types to get a different point of view of the invasion
17 levels (see Pyšek and Chytrý, 2014, for a review). The first comparisons among regions based on vegetation-plot data
18 showed that the same broadly defined habitats had comparable levels of neophyte invasions (Chytrý *et al.*, 2008b).
19 Despite different absolute invasion levels, the most and least invaded habitats were the same when comparing
20 European and North American regions (Kalusová *et al.*, 2015), suggesting that habitat typologies are a key factor to
21 understand plant invasions. Generally, the most invaded habitats seem to be human-made habitats (e.g. arable fields,
22 wastelands), while natural vegetation such as high-altitude grasslands or mires are less invaded (Chytrý *et al.*, 2008b;
23 Lambdon *et al.*, 2008). The recently compiled European Vegetation Archive (EVA; Chytrý *et al.*, 2016) enabled even
24 deeper insights into the neophyte invasion patterns at the level of fine-scale habitats, already reported for European
25 woodlands (Wagner *et al.*, 2017) and coastal dunes (Giulio *et al.*, 2020). However, neophyte invasions across grassland
26 habitats have not been studied so far at the European extent.
27

28 After forests, grasslands represent the second most widespread broad vegetation type in Europe, occurring across large
29 gradients of soil moisture and pH, nutrient availability and climate. Grassland habitats also bear the imprint of the past,
30 not only glacial-interglacial cycles and postglacial migration, but also traditional management practices (Pärtel *et al.*,
31 2005; Feurdean *et al.*, 2018). All these factors shape current grassland vegetation and result in high variability of
32 vegetation types (Chytrý *et al.*, 2021).
33

34 Previous comparisons of broadly defined habitat types showed that different levels of alien plant invasion could be
35 explained by several factors, especially resource availability, propagule pressure and climate (Chytrý *et al.*, 2008a).
36 Another important aspect affecting alien plant invasions are disturbances (Hobbs and Huenneke, 1992; Lozon and
37 MacIsaac, 1997) and with them related fluctuations in resource availability (Davis *et al.*, 2000). While the highly invaded
38

134 human-made habitats and alluvial forests are generally occurring in the most fertile parts of the countries and are
135 subjected to repeated introductions of neophytes, grasslands are likely to be less exposed to alien plant propagule
136 pressure (Botham *et al.*, 2009). The type, frequency and intensity of disturbance in grasslands differ from those typical
137 of human-made habitats or forests. Consequently, also the geographic patterns of neophyte invasions in grasslands
138 and forests differ considerably (Divíšek and Chytrý, 2018). Therefore, in addition to the recent assessment of neophyte
139 invasions across European woodlands (Wagner *et al.*, 2017), a reliable assessment of neophyte invasions across
140 European grasslands is also needed. To meet this aim, we used an up-to-date version of the largest European
141 vegetation-plot database (EVA; Chytrý *et al.*, 2016) to provide a synthetic overview of neophyte invasions in European
142 grassland vegetation, asking the following questions: (i) How do invasion levels change across European countries? (ii)
143 Which grassland types are the most invaded? (iii) Which alien species are the most successful invaders of European
144 grasslands?

23
24 Methods

25

26
27
28 Region definitions

29

30
31
32
33 Regions used in our study mostly correspond to countries, but some large islands or archipelagoes with distinct
34
35 biogeographic position were treated as separate regions (Baleares, Corsica, Crete, Sardinia, and Sicily with Malta). We
36
37 also followed the region delimitation concept of the Euro+Med PlantBase (2006–2020), and divided European Russia
38 into seven regions (Russia North, Russia Northwest, Russia Kaliningrad, Russia Central, Russia South, Russia Caucasus
39 and Russia East). For the list of all 49 studied regions and the detailed number of plots per region, see Appendix S3.

40

41
4243
44
45 Dataset preparation and filtering

46

47
48
49 We used 465,629 grassland vegetation plots provided by the European Vegetation Archive (EVA; Chytrý *et al.*, 2016).
50
51 The plots were classified to European Nature Information System grassland habitat types at the third level of the
52
53 classification hierarchy (hereafter EUNIS habitats or habitats) using the EUNIS-ESy expert system (Chytrý *et al.*, 2021)
54 in the JUICE software (Tichý, 2002). Apart from grasslands in a narrow sense (EUNIS group R), we also included coastal
55
56 grasslands of grey dunes, which belong to EUNIS group N (coastal habitats). An overview of contributing databases and
57 numbers of plots assigned to particular EUNIS habitat types is available in Appendices S1 and S2 in the Supplementary
58 Materials. We also merged these habitats to broader habitat types (habitat groups, see Appendix S2 for details on
59 merging), enabling us to detect more general patterns in analyses and comparisons at a coarser scale. Data from the
60 National Vegetation Database of Denmark could not be classified by the EUNIS-ESy expert system, because they lack
records of cover-abundances of species. Therefore, we calculated the Bray-Curtis dissimilarity index to find the most
similar plots from other countries with known classification and assigned the Danish plots to the same habitat groups

(all plots with similarity lower than 15%, i.e., Bray-Curtis dissimilarity > 0.85 , were excluded; in total 1,885 vegetation plots were assigned to habitat groups).

For our analyses, we filtered vegetation plots using the following criteria. First, we removed: (i) plots that could not be assigned to any EUNIS grassland habitat type at the third level of classification (transitional between different grassland habitat types); (ii) plots with a cover of woody species (trees or shrubs taller than 0.5 m) higher than 10%; (iii) plots dominated by *Pteridium aquilinum* (classified as R54 in EUNIS habitat); and (iv) plots from forest clearings (R57). Second, we excluded plots without geographic coordinates or with a location uncertainty ≥ 7000 m. Third, we selected only plots with a surface area ranging between 10 and 100 m² to limit the area effect (85% of the plots in original selection were of this size). However, for Nordic countries we retained plots between 1 and 100 m², since the small-size plots traditionally prevail there. We also kept plots with unknown size (based on the plot size histogram, we assumed most of the unknown sizes were within the range of 10–100 m²). Fourth, we kept only the vegetation plots sampled between 1970 and 2018 to lower the effect of vegetation changes across time. Fifth, to limit potential pseudo-replication due to spatial autocorrelations, we used geographical position and compositional similarity to define group of plots that need resampling (we selected all plots with similarity of 80% or more, i.e. ≤ 0.2 of Bray-Curtiss dissimilarity index) sampled within a distance of less than 1 km). From each pair of plots with highest similarity, we randomly selected just one and if needed repeated the resampling. Sixth, to further reduce over-representation of some regions in the dataset, we calculated the density of plots belonging to each habitat type for each region. Subsequently, the corresponding density threshold defining outlier values (upper quartile + 1.5 × interquartile range) was calculated for each habitat type. This threshold was used as a limit for the maximum number of plots to be retained for a particular habitat in a given region. The plots to fit this limit were randomly selected. After filtering, the final dataset included 97,417 plots.

Species status assignment

We considered only vascular plants in our study, including trees and shrubs. The nomenclature was unified to follow Euro+Med (2006–2020) PlantBase concept, or The Plant List (TPL, 2013) if the taxon was not included in Euro+Med. We assigned the native, alien or uncertain status to all the plant taxa with respect to the region where they were recorded. We included archaeophytes among native species, hence the alien plants in our study corresponded to neophytes only (i.e., alien species that arrived in the region after 1500 AD, see Pyšek and Jarošík, 2005). Archaeophytes were not treated separately as their lists are lacking or incomplete in many countries, and in many cases their status as arquaeophyte or native in a given country or region is doubtful. If a species was considered native in at least one part of a region, we assigned its native status for that region. We assigned the native/alien status to species using the Euro+Med PlantBase (2006–2020), DAISIE (2009), the GLONAF database (van Kleunen *et al.*, 2019), national and regional species checklists and knowledge of local experts. All sources are listed in Appendix S4. Taxa for which we could not decide their status were excluded (mostly genus-level records). For a status assignment at the plot level, we

199 used intraspecific data, as sometimes one subspecies can be native while another subspecies is considered as neophyte.
200 For comparison between species lists of regions and habitats, we summarised the results at the species level
201 (considering the subspecies status assignment) to make our results comparable with recent studies of other European
5 habitats (e.g., Wagner *et al.*, 2017; Giulio *et al.*, 2020).
7

202 We further classified neophytes into groups according to their origin: A, neophyte species originating from outside of
9 Europe (Africa, America, Asia, Australia); E, species native to some parts of Europe but considered to be neophytes
204 elsewhere in Europe, C, other origins, i.e., anecophytes or species with hybrid origin (see also Wagner *et al.*, 2017 for
11 details). We also classified all neophytes with respect to their prevailing life form: phanerophytes, chamaephytes,
12 hemicryptophytes, geophytes, therophytes, hydrophytes and woody lianas. For the list of sources used for this
13 assignment, see Appendix S5.

22

23
241 We assessed the levels of invasions using different metrics (see also Catford *et al.*, 2012; Wagner *et al.*, 2017; Giulio *et*
252 *al.*, 2020): (1) percentage of neophytes in the grassland species list, (2) frequency of neophytes across all occurrences
26 (sum of individual plot records) of all species in a given subset, (3) relative frequency of invaded plots (i.e., plots with
27 at least one neophyte present), (4) mean and median of relative species richness of neophytes per plot in a given subset
28 (relative species richness of neophytes refers to the number of neophytes/all species in the plot *100), (5) relative
29 neophyte cover per plot in a given subset (relative to total cover in the plot).
30
31

32
34 To compare the species lists of habitat groups with different numbers of plots, we selected only neophytes represented
35 in at least 0.5% and in at least 1% of the plots of that habitat group. Note that we selected such low levels of threshold
36 because most of the plots were free of neophytes. The differences in relative neophyte richness and relative neophyte
37 cover among habitat groups were tested using the Kruskal-Wallis multiple comparison test in the package pgirmess
38 (Giraudeau, 2013) in the R software (R Core Team, 2012). Total plant cover and neophyte cover were calculated as a
39 sum of individual plant covers considering their possible overlap (Fischer, 2015).
40
41

42
43 To track geographical patterns in the level of invasions, we assigned vegetation plots into the UTM grid cells spanning
44 50 km × 50 km. For each grid, we calculated the relative frequency of invaded plots, i.e., what percentage of plots
45 within a given grid cell have at least one neophyte present. We prepared separate maps with respect to habitat groups
46 and different origin categories of neophytes using the R packages ‘raster’ (Hijmans *et al.*, 2020), ‘rgdal’ (Bivand *et al.*,
47 2020), ‘spatialEco’ (Evans *et al.*, 2020) and ‘berryFunctions’ (Boessenkool, 2020). We mapped only grid cells containing
48 more than ten plots, in order to avoid interpreting random patterns. The data were processed using the R software
49 v.3.6.0 (R Core Team, 2019).

231 Results

2 Our final grassland dataset included in total 8,212 species, out of which only 536 were classified as neophytes
3 (approximately 6.5% of all species) with almost the same number of neophytes originating from Europe (3.0%) and
4 outside of Europe (3.1%). Most neophytes in grasslands were present in very few plots (median of 2 plots), while only
5 three species, namely *Onobrychis vicifolia*, *Erigeron annuus* and *E. canadensis*, were recorded in more than 1% of all
6 plots (Table 1). When comparing the relative frequency of species occurrences in plots, European neophytes
7 correspond to 0.17% (4,259 of all 2,565,674 occurrences), while those from outside of Europe to 0.33% (8,473), which
8 is different from percentages based on the grassland species list (see above, or Figure 1). The prevailing life forms of
9 neophytes in our study were hemicryptophytes (32%) and therophytes (31%), followed by phanerophytes (21%) (Figure
10 2).

18 Most of the vegetation-plot records included only native species and archaeophytes, while invaded plots, i.e., plots
19 with at least one neophyte, represented only 11.9% of all plots (7.1% of plots if only non-European neophytes were
20 considered, Appendix S6). The proportion of invaded plots varied greatly among individual regions and habitat types.
21 The means of relative neophyte species richness per plot also differed, although the medians were close or equal to
22 zero, suggesting the prevalence of neophyte-free plots. Summary statistics can be found in Appendix S6 and S7 for
23 regions and in Appendix S8 and S9 for habitat groups and EUNIS habitats. A list of neophytes recorded per regions is
24 available in Appendix S10.

30 We did not reveal any distinct geographical pattern in the distribution of neophytes across Europe (see Figure 3 for
31 overall pattern and other maps in Appendix S12 for separate habitat groups or neophytes according to their origin).
32 Higher invasion levels can be seen in northern European countries, where this is mostly due to the higher number of
33 European neophytes (see also Appendix S6). In addition, there is a slightly higher tendency for invaded plots to occur
34 in coastal areas. When comparing only the relative frequency of non-European neophytes, the regions with the highest
35 representation of neophytes relative to all species were Poland (3.9%), Netherlands (3.8%), Lithuania (3.5%), Denmark
36 (3.0%) and Germany (3.0%), for more see Appendix S6.

43 Analyses at the third hierarchical level of EUNIS habitat classification show that sandy habitats (both inland and coastal)
44 have the highest frequency of invaded plots across different types and geographical regions (on average around 20%,
45 with a maximum of 31%). Comparable percentages of invaded plots were also found in lowland wet tall-herb
46 grasslands, in both temperate and Mediterranean types. In contrast, high-altitude grasslands, especially alpine and
47 oromediterranean, had the lowest percentages of invaded plots (Figure 4).

52 Comparison among the habitat groups revealed that most neophyte species (90% when considering only species
53 recorded in at least five plots) occur in more than one habitat group, indicating their low degree of specialization (see
54 Table 2 for the most frequent neophytes per habitat group). The highest numbers of neophyte species were recorded
55

in mesic, wet and dry grasslands, followed by sandy grasslands (Table 3). However, removing rare species with few occurrences (recorded in less than 0.5 or 1% of the plots from the respective habitat) from these counts lowers the number of neophyte species considerably (Figure 5a,c). After the exclusion of rare neophytes, sandy, wet and mesic habitats harboured the highest cumulative numbers of neophyte species, while the oromediterranean and alpine grasslands the lowest. A similar pattern can also be seen in the relative frequency of invaded plots per habitat group (Figure 5b,d). Note that in dry grasslands, the relative frequency of invaded plots reaches almost the same percentages as in mesic and wet grasslands, but the number of neophytes in dry grassland species list is much lower, suggesting their higher frequency in the plots. While rocky, dry and mesic habitat groups have a higher number of European neophytes than those of non-European origin, sandy, wet and saline habitats showed a reverse pattern. We revealed the highest prevalence of non-European neophytes in wet grasslands (Table 3). For mean relative neophyte richness and other summary statistics calculated across plots, see Table 4. Kruskal-Wallis multiple comparisons of both the mean relative neophyte richness and the mean relative neophyte cover per habitat groups confirmed the above described pattern (Table 4, Appendix S11).

280 Discussion**281 Geographical patterns**

282 We found a relatively low proportion of neophyte species in European grasslands (only 6.5% of all species in the
283 dataset). Such low levels of invasion are similar to values reported from European forests (Wagner *et al.*, 2017) and
284 coastal vegetation (Giulio *et al.*, 2020), but they are in contrast to those reported from North-American habitats
285 (Lonsdale 1999; Kalusová *et al.* 2015). The several times higher numbers of neophytes in North America, even when
286 comparing similar grasslands (15% reported from prairies by Stohlgren *et al.*, 1999), support the view that Europe is
287 donating more alien species than it is receiving in exchange (Seastedt & Pyšek, 2011; Stohlgren *et al.*, 2011; Hejda *et*
288 *al.*, 2015), which holds also specifically for grasses (Monnet *et al.*, 2020).

289 We did not find any distinct geographical pattern, although there were higher percentages of invaded plots in northern
290 Europe (mostly due to a higher abundance of neophytes of European origin there) and in coastal habitats. The
291 neophytes of European origin were mostly from the Mediterranean, i.e. native to southern Europe from where they
292 spread to suitable habitats in other regions. Depending on when they reached individual countries, the same species
293 can be classified as either an archaeophyte or neophyte (Pyšek *et al.*, 2005). Moreover, plant ranges do not reflect only
294 recent climate but also the landscape history, especially Pleistocene glaciations, as the possibilities of postglacial
295 migration towards the north were limited (Normand *et al.*, 2011). A large number of otherwise frequent European
296 species have probably been able to colonize northern countries only as a consequence of human-induced changes of
297 habitats (Lambdon *et al.*, 2008). The shares of non-European and European neophytes were almost equal in terms of
298 numbers of species occurring in grassland, but the latter group prevailed when considering the relative frequency of
299 occurrences across the plots (accounting for 58.6% of all neophyte occurrences, most of them from North America).
300 This is in agreement with greater representation of species from other continents reported by previous large-scale
301 European studies (Wagner *et al.*, 2017; Giulio *et al.*, 2020). Such pattern results mostly from the fact that there are
302 fewer regions in Europe where species of European origin can be recorded as neophytes, although alternative
303 explanations can also be raised (see Wagner *et al.*, 2017).

304 We found the highest levels of invasion (relative number of neophytes in the species list) in Poland, the Netherlands,
305 Lithuania, Denmark and Germany, where both European and non-European neophytes were present in relatively high
306 numbers. We expect that in these countries, there was both the effect of glaciation and at the same time the presence
307 of coastal habitats which are generally more invaded (Chytrý *et al.*, 2008b; Dawson *et al.* 2017; Giulio *et al.*, 2020).
308 Another important factor supporting higher invasion levels can also be the recent changes in traditional management
309 (e.g. Timmermann *et al.*, 2015). We note that natural factors such as grazing by wild herbivores also maintained a
310 presence of grasslands in temperate Europe before agriculture and pastoralism or even before the arrival of *Homo*
311 *sapiens* to the continent (Svenning, 2002; Feurdean *et al.*, 2018). However, nowadays many grasslands experience both

312 reduced wild grazing and reduced management, leading to secondary succession and vegetation changes that can
313 support the success of neophytes (e.g. Swacha *et al.*, 2018).

4
5
6

7 315 *Habitat comparison*

8

9 316 We confirmed that grasslands generally have low levels of invasion, which is in contrast to highly invaded human-made
10 habitats, alluvial forests and herb-dominated river fringes (Chytrý *et al.*, 2008b; Kalusová *et al.*, 2015). However,
11 although the overall frequency of invaded plots was rather low (less than 12% of all plots), EUNIS habitat types varied
12 from 0 to 31% invaded plots. The highest percentages of invaded plots were found in sandy habitats and in lowland
13 tall-herb wet meadows, while grasslands at high altitudes were almost free of any neophytes. Such pattern is in
14 accordance with conclusions of earlier studies that neophytes preferably invade habitats with sufficient resources,
15 under milder climate and that they benefit from disturbances that suppress native species (Chytrý *et al.*, 2008a; Pyšek
16 and Chytrý, 2014).

17 323

18 324 When comparing neophytes among habitat groups, we did not find any typical habitat specialists. Similarly, also Giulio
19 et al. (2020) concluded that most (94%) of the neophytes found in their study of coastal dunes were generalists
20 occurring also in other habitats. Chytrý *et al.* (2008b) revealed comparable habitat levels of invasions among regions,
21 although the species lists of neophytes were different, suggesting that the habitat properties are more important than
22 geographical position within Europe. Since sandy and wet grasslands differ in many habitat characteristics, we can also
23 expect different strategies of neophytes invading them. Life-form comparison of neophytes revealed relatively high
24 representation of two distinct groups in our grassland dataset species list, namely therophytes and hemicryptophytes
25 (each group represented around 30%), which supports our expectation of different strategies. Wet grasslands mostly
26 have high total cover, and gaps occur only rarely after disturbances; thus, competitive hemicryptophytes are more
27 successful. In contrast, the unstable soil in sandy habitats does not allow the formation of closed stands, and many
28 open gaps are available to support therophytes. The spread of these short-lived, ruderal species can be recently
29 detected also in other vegetation types, such as dry grasslands. As present weather fluctuations and drought events
30 are leading to decreased cover or even disappearance of some native species, new gaps emerge in the stands and
31 therefore also opportunities for new species to successfully germinate (Fischer *et al.*, 2020).

32

33 328 Although canopy openness seems to be important, it does not ensure the success of the neophytes alone. We can
34 expect that the rather open stands of alpine and oromediterranean habitats are so extreme and nutrient-poor that
35 only species adapted to such conditions can grow there, which limits the number of suitable neophytes (Chytrý *et al.*,
36 2008b). Compared to lowlands, grasslands in higher altitudes historically experienced lower human impact and
37 intensity of disturbances, thus suppressing or at least reducing success of neophytes (see also Medvecká *et al.*, 2014;
38 Lembrechts *et al.*, 2016).

39 57

40 58

41 59

42 60

344

2

345 *Successful neophytes*

4

5

346 Neophytes themselves significantly differ in their ability to overcome abiotic and reproductive barriers and establish
347 sustainable populations in new environments. Some species are able to invade only the same or similar habitat from
8 which they originated and to which they are adapted. Therefore, the more habitats the species occupies in its native
10 range, the higher are the chances that it will become a successful invader (Hejda et al., 2015; Kalusová et al., 2017),
11 and the most successful species that reach the invasion stage extend their habitat niche in the invaded regions,
13 compared to the region of origin (Hejda et al., 2009). The association with human-made habitats and disturbances in
15 the native range also seems to support invasion success (Kalusová et al., 2017). This is in agreement with our findings
18 that many neophytes in our grassland dataset were not habitat specialists but short-lived ruderal species, using
354 opportunities of establishing in open gaps after disturbances. Divíšek et al. (2018) suggested that while having similar
20 traits as other species within the community enables naturalization in that particular habitat, a difference in at least
21 some traits (such as plant height) allows the neophyte species to prevail in the community and become invasive. This
22 points at another neophyte group - species growing in relatively productive sites, with intense competition for
23 resources (e.g. *Solidago* spp., *Symphytum* spp.). Within our dataset, we found mostly neophytes with few
25 occurrences only. Despite being rare in semi-natural grasslands, it is probable that many of these species are more
27 abundant in more suitable, human-made habitats of the same regions. We also have to note that many neophytes are
28 relatively new in Europe, and longer residence time is probably needed for them to become more widespread (Pyšek
30 and Jarošík 2005).

362

33

363 The most frequent neophyte in our dataset was *Onobrychis viciifolia*, a perennial species native to southern and
35 southeastern Europe and western Asia, from where it was intentionally introduced to the rest of Europe (but also to
36 North America and Australia) as a forage crop (Mora-Ortiz and Smith, 2018). After the first introductions, it started to
38 spread spontaneously to suitable habitats. The second most frequent species was *Erigeron canadensis*, an annual or
39 overwintering species native to southern Canada and having a broad climatic tolerance. Although it is mostly found in
40 human-made habitats (orchards, vineyards, roadsides, arable fields, ruderal sites), it has broad climatic tolerance and
41 is adaptable to different environments. Thanks to very effective wind dispersal, it can quickly establish in open gaps
42 after disturbance and start to grow rapidly (Weaver, 2001). It was reported as the most successful alien species also in
43 European coastal dunes (Giulio et al., 2020) and across Europe in general (Lambdon et al., 2008). The third most
44 frequent species was *Erigeron annuus*, an annual species with prevailing apomictic reproduction, native to North-
45 American tall-grass prairies. This species also has effective wind dispersal and is widespread across Europe. Although it
46 has been shown that its frequency declines towards higher altitudes, growth performance and seed production are
47 comparable with lowland populations, and the reason for the decline is probably its greater winter mortality (Trtíková
48 et al. 2011). In contrast to *Onobrychis*, the spread of which was directly supported by humans, both *Erigeron* species
49

50

51

52

53

54

55

56

57

58

59

60

377 seem to be so successful mostly due to high seed production and long-distance seed dispersal (Weaver, 2001) as high
378 propagule pressure is one of the key factors in neophyte invasions (Pyšek and Chytrý, 2014).
379
380

Dataset limitations

381 There are several possible limitations of our data. Firstly, EVA database (Chytrý *et al.*, 2016) comprises data originally
382 sampled for phytosociological surveys; therefore, we can expect that they largely originate from preferential sampling
383 (Michalcová *et al.*, 2011), as scientists studying natural and semi-natural vegetation often show tendency to avoid plots
384 with alien plants. Therefore, only when the neophyte is more abundant in the landscape, it is also recorded in the plots.
385 Secondly, when analyzing these data, we cannot easily track the changes in vegetation following the abandonment of
386 traditional management, although this seems to be an important factor. For example, if a grassland site is severely
387 disturbed and the management is no longer applied, the succession might lead towards ruderal sites dominated by
388 invasive neophytes (such as *Solidago gigantea*), which are no longer classified as grasslands and included in our dataset.
389 Finally, yet importantly, the data coverage across regions is unequal, and although we stratified the dataset to avoid
390 oversampling of some regions, there were regions less well represented in the data. We would also like to point at the
391 questionable status of some species, which can affect the overall patterns (but see Courchamp *et al.*, 2020). As most
392 problematic we see grasses, which were traditionally supported by humans and are hard to distinguish in archaeological
393 findings, such as *Lolium multiflorum*, *Festuca brevipila*, but most notably *Arrhenatherum elatius*. Although some
394 sources suggest neophyte status of *Arrhenatherum* (see for example Poschlod 2015), based on previous archaeological
395 findings we accepted it as an archaeophyte (see Pyšek *et al.*, 2012b). In the opposite case, it would be one of the most
396 successful neophyte across Europe.
397
398

Conclusions

399 We provided the first overview of neophyte invasion patterns in grassland vegetation across Europe based on the most
400 comprehensive dataset of vegetation plots existing to date. Although we found generally low invasion levels, there
401 were distinct differences between individual habitat types. While sandy habitats and lowland wet grasslands were the
402 most invaded, high-altitude grasslands were almost free of neophytes. A high proportion of neophytes invading
403 grasslands are therophytes with broad habitat niches.
404

For Review Only

Table 1. A list of the most frequent neophyte species recorded in European grasslands assessed by **(a)** number of plots across all regions where the species is considered neophyte (from a total of 97,417 plots) and **(b)** number of regions where the species occurred as a neophyte (from a total of 49; for more details on regions, see Appendix S6, S7 and S10). E - species with origin within Europe (they are considered neophytes only in some European regions, and their occurrences in the regions with native status were not counted), A - non-European origin, C - other origin (anecophytes, hybrids).

| (a) | | | | (b) | | |
|-----------------------------------|--------|--------------|-----|--------------------------------|--------|--------------------------|
| Taxon | Origin | No. of plots | % | Taxon | Origin | No. of regions (max. 49) |
| <i>Onobrychis viciifolia</i> | E | 1442 | 1.5 | <i>Erigeron canadensis</i> | A | 27 |
| <i>Erigeron annuus*</i> | A | 1312 | 1.3 | <i>Medicago sativa*</i> | C | 22 |
| <i>Erigeron canadensis</i> | A | 1188 | 1.2 | <i>Oenothera biennis</i> agg. | A | 20 |
| <i>Trifolium hybridum*</i> | C | 794 | 0.8 | <i>Erigeron annuus*</i> | A | 19 |
| <i>Medicago sativa*</i> | C | 743 | 0.8 | <i>Matricaria discoidea</i> | A | 19 |
| <i>Solidago gigantea</i> | A | 609 | 0.6 | <i>Xanthium orientale*</i> | A | 19 |
| <i>Epilobium ciliatum*</i> | A | 408 | 0.4 | <i>Juncus tenuis</i> | A | 18 |
| <i>Matricaria discoidea</i> | A | 348 | 0.4 | <i>Bidens frondosus</i> | A | 17 |

| <i>Bidens frondosus</i> | A | 199 | 0.2 | <i>Solidago gigantea</i> | A | 14 |
| <i>Berteroia incana</i> | E | 186 | 0.2 | <i>Amaranthus retroflexus</i> | A | 13 |
| <i>Veronica persica</i> | A | 178 | 0.2 | <i>Galinsoga quadriradiata</i> | A | 12 |
| <i>Achillea ptarmica</i> | E | 171 | 0.2 | <i>Lolium multiflorum</i> | E | 12 |
| <i>Xanthium orientale*</i> | A | 167 | 0.2 | <i>Oxalis stricta</i> | A | 12 |

*Taxon names marked by asterisk include the following subspecies: *Epilobium ciliatum* (subsp. *ciliatum*, subsp. *adenocaulon*), *Erigeron annuus* (subsp. *annuus*, subsp. *septentrionalis*), *Medicago sativa* (subsp. *sativa*, nothosubsp. *varia*), *Senecio leucanthemifolius* subsp. *vernalis*, *Trifolium hybridum* (subsp. *hybridum*, subsp. *elegans*), *Xanthium orientale* (subsp. *orientale*, subsp. *californicum*, subsp. *italicum*, subsp. *riparium*). *Oenothera biennis* agg. refers to a group of taxa which are difficult to determine and usually not distinguished.

Table 2. A list of the most frequent neophyte species per habitat group assessed by **(a)** number of plots across all regions where the species is considered to be a neophyte and **(b)** number of regions where the species is considered to be a neophyte. The group of oromediterranean habitats (recorded in six regions) is excluded here due to the absence of neophytes. All the neophyte species in the group of alpine habitats were recorded in one region only; therefore, they cannot be sorted by the number of regions in **(b)**. Origin 'A' refers to non-European origin, 'E' to European origin and 'C' to another origin (anecophytes, hybrids). For details on included intraspecific taxa see Table 1.

| Habitat group (plots) | (a) | | | (b) | | | Origin | No. of regions (max) |
|--------------------------|----------------------------------|--------|--------------|------|---------------------------------|--|--------|-------------------------|
| | Taxon | Origin | No. of plots | % | Taxon | | | |

| % of invaded plots | 25.7 | 5.6 | 10.7 | 0 | 13.5 | 12.8 | 0.5 | 7.4 |
| % of plots invaded by at least one non-European neophyte | 21.8 | 2.3 | 3.9 | 0 | 7.5 | 10.2 | 0.2 | 6.4 |

Table 4. Summary statistics for habitat groups: mean, standard error of the mean (SEM) and median of species richness and relative abundance of neophyte species calculated across plots. Oromedit. refers to oromediterranean habitat group. Species richness refers to all species recorded in the plot. Neophytes include all neophyte species irrespective of their origin, while they are separated in the latter categories. Kruskal-Wallis test shows significant differences at the level of $p= 0.01$.

| | Sandy | Rocky | Dry | Oromedit. | Mesic | Wet | Alpine | Saline |

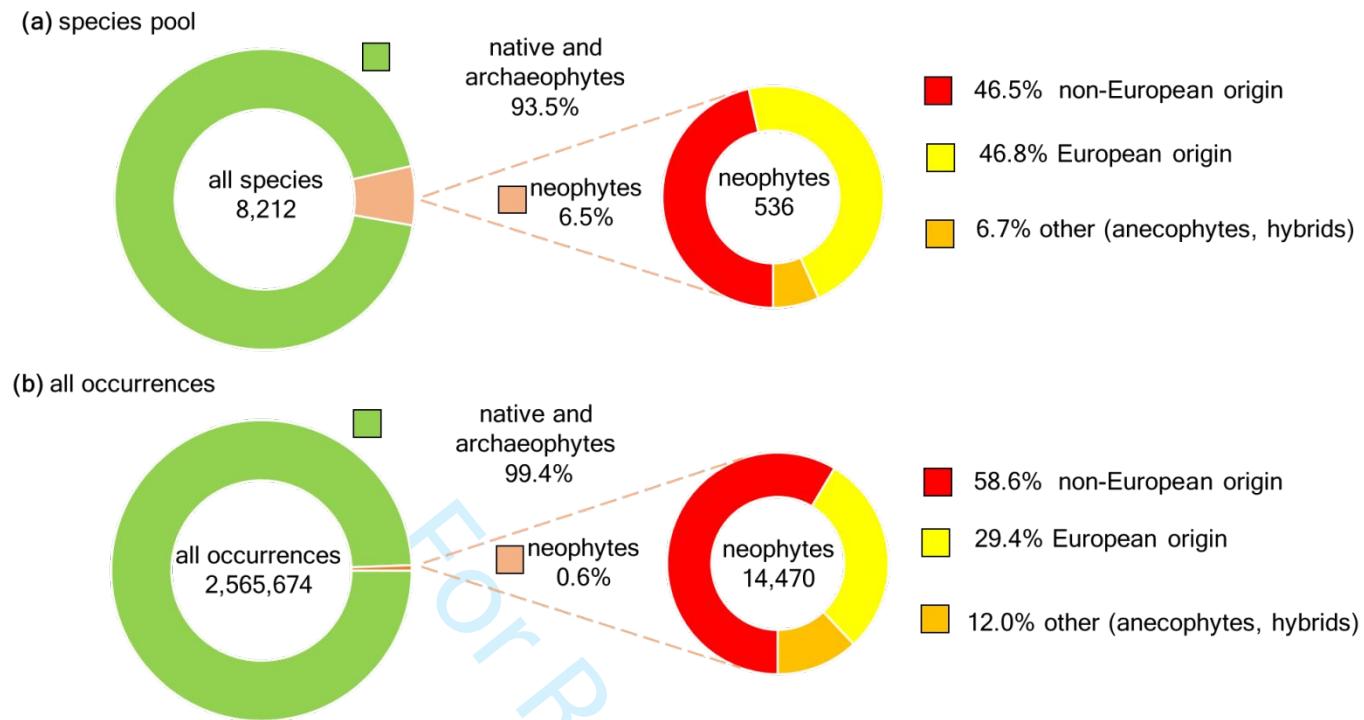

Figure 1. Absolute and relative numbers of native (including archaeophytes) and neophyte species in European grasslands. Representation in the grassland species list **(a)** considers native only those species that are in all countries included in the native category, while species of European origin considered as a neophyte in at least one country were included in the neophyte numbers. In total, 242 species had double status within Europe (approximately 2.9 %). Overview based on all occurrences **(b)** considers each record of plant species in a plot separately (see Appendix S10 for details).

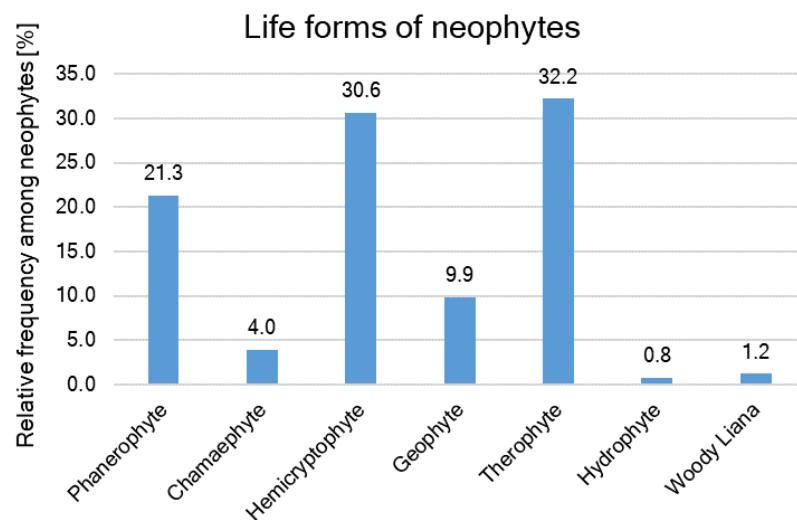

Figure 2. Life forms of neophytes in European grasslands.

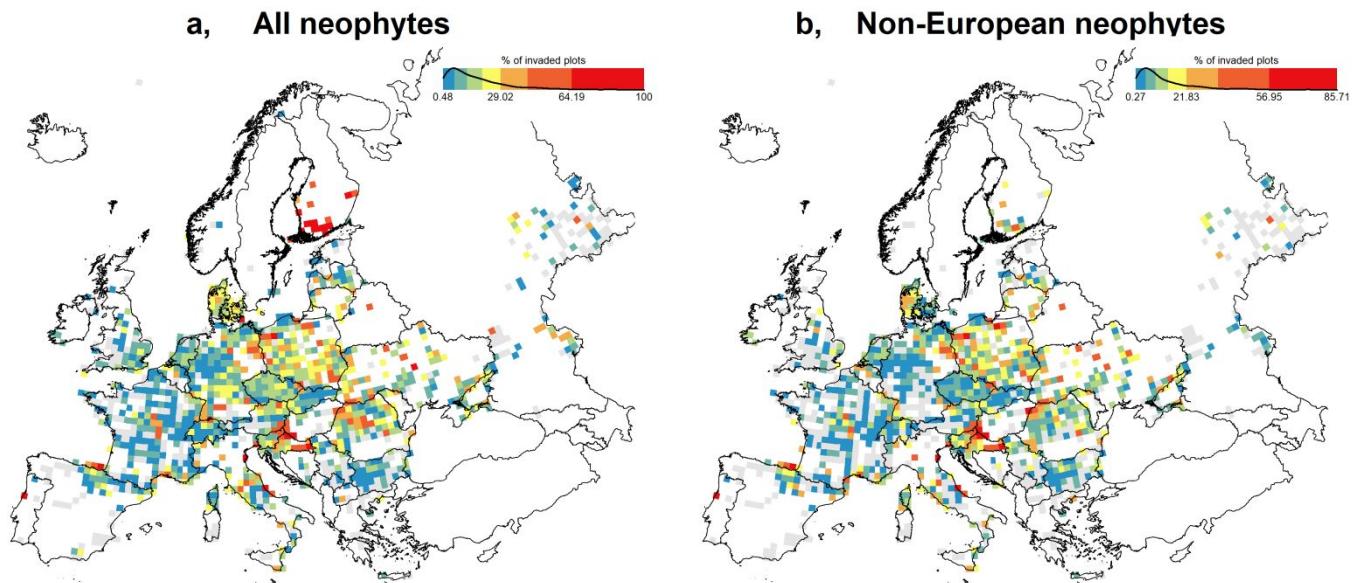

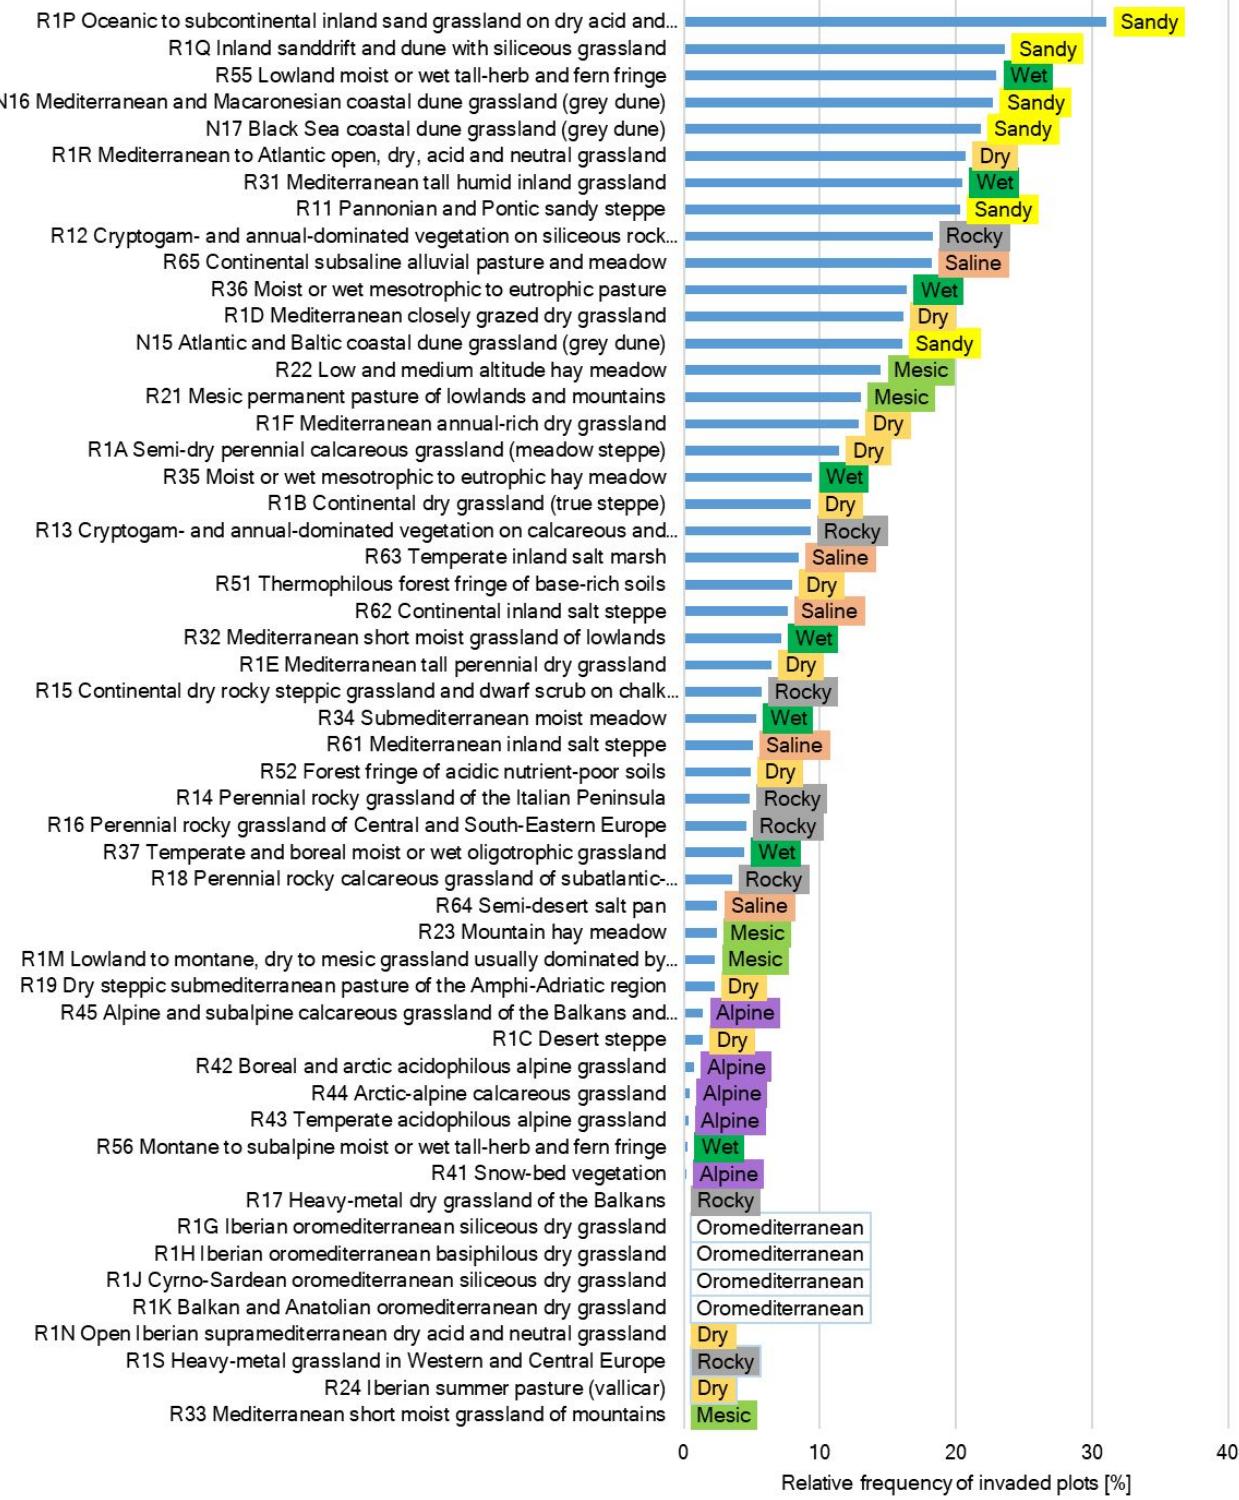

Figure 3. Relative frequency of invaded plots calculated per UTM 50 × 50 km grid cells. Colour-scale categories were defined to reflect the distribution of values (breaks calculated by k-means). Grey colour indicates cells with only not-invaded plots (0 %). Cells with less than ten plots are not mapped. Maps for habitat groups and neophyte origin categories are in Appendix S12.

1 EUNIS habitats: relative frequency of invaded plots
2

634 **Figure 4.** Relative frequency (%) of plots with neophytes in individual EUNIS habitats. Corresponding habitat groups are
 635 indicated by the labels to the right part of the bars. Note that last nine habitats (starting with R17) do not have any
 636 invaded plots and are sorted alphabetically by their EUNIS codes. For other statistics, see Appendix S8 and S9.
 637 Unclassified plots from Denmark are not included.

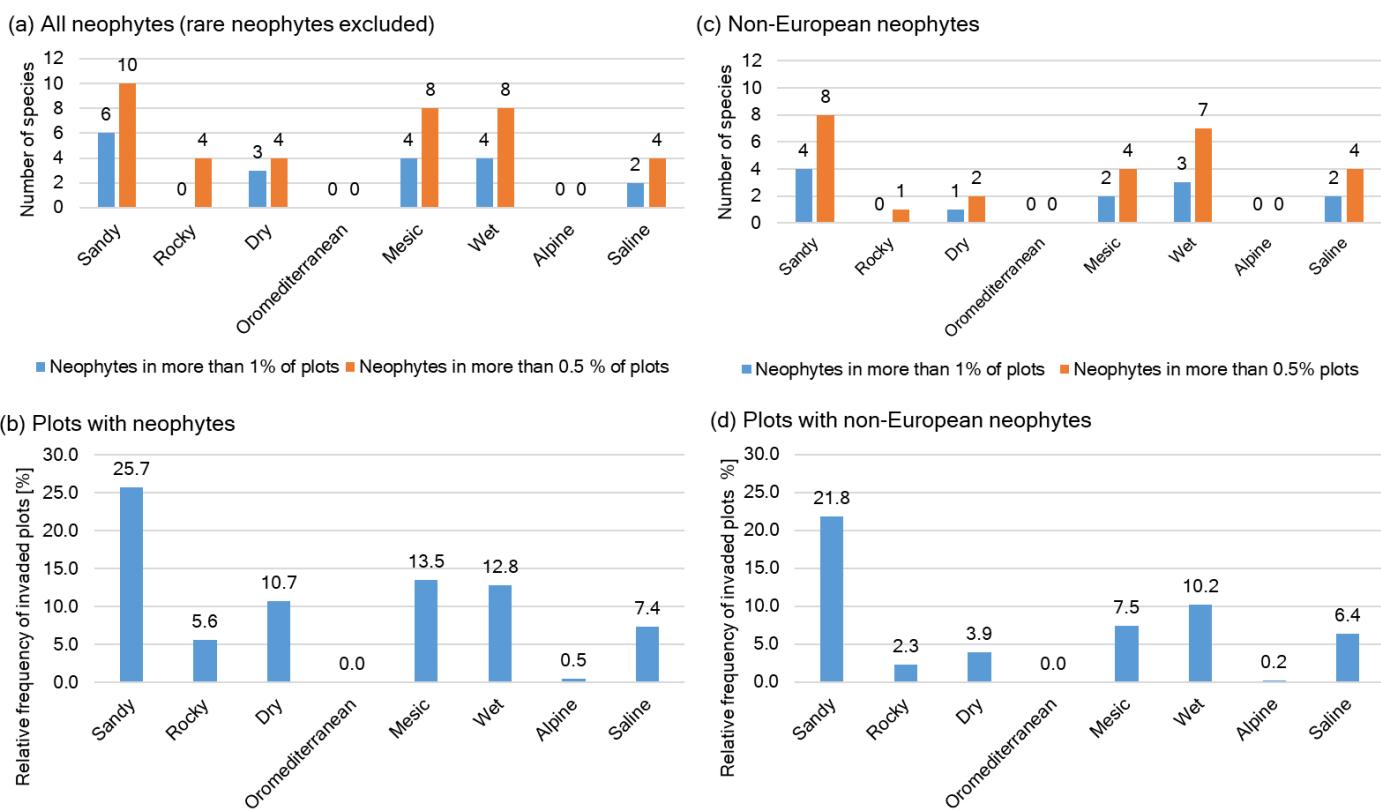

Figure 5. Overview of the species lists of neophytes by habitat groups. (a) Neophytes occurring in at least 0.5 or 1% of plots, respectively; (b) Relative frequency of plots invaded by neophytes; (c) Non-European neophytes occurring in at least 0.5 or 1% of plots; (d) Relative frequency of plots invaded by non-European neophytes.

25 **Appendix S2.** Overview of the classification of vegetation plots into habitat types according to the European Nature Information System (EUNIS) and their
 26 assignment into broad vegetation types. Habitat group combines vegetation types of similar ecology and vegetation characteristics. The total number of plots in
 27 the final dataset was 97,417. Asterisks indicate grassland plots from Denmark (National Vegetation Database of Denmark) that were not classified to EUNIS habitats
 28 but assigned into broad vegetation types based on their similarity in species composition (Bray-Curtis index) to plots from other countries (see Methods for details).
 29

250 Axmanová, I. et al. Neophyte invasions in European grasslands. *Journal of Vegetation Science*.
 2

251 **Appendix S6.** Overview of the species-pool data and relative frequency of invaded plots (plots with the presence of at least one neophyte) for Europe and individual
 252 countries. For Europe, we included into native category only species considered native in all regions, while species of European origin considered as a neophyte in
 253 at least one country were included in the neophyte numbers. Regions marked by an asterisk have less than 100 plots; therefore, statistics for these regions are
 254 less representative. The European part of the Russian Federation is divided into regions according to the Euro+Med PlantBase.

Supporting information to the paper

Axmanová, I. et al. Neophyte in European grasslands. *Journal of Vegetation Science*.

Appendix S8. Overview of the species-pool data and relative frequency of invaded plots (plots with the presence of at least one neophyte) for habitat groups and EUNIS habitats. Note that number of all species refers to taxa at the species level. EUNIS habitats marked by an asterisk have less than 100 plots; therefore, statistics for these habitats are less representative. Non-classified plots from Denmark are not included in the EUNIS habitat statistics (in total 1885 plots).

| Habitat | Number of all species | Number of native species | Number of neophytes | Non-European origin | European origin | Other (aneophytes, hybrids) | Relative frequency of all neophytes in the species pool [%] | Relative frequency of non-European neophytes [%] | All plots | Plots with only native taxa (no neophytes) | Plots with at least one neophyte present (invaded plots) | % of invaded plots | % of plots invaded by non-European neophytes |

Axmanová, I. et al. Neophyte invasions in European grasslands. *Journal of Vegetation Science*.

282 **Appendix S10.** List of neophyte species recorded in individual regions. Species are listed alphabetically and their frequency in regional subsets is shown under No.
 283 of plots in which the species was recorded. Subspecies were listed only if recorded in the vegetation plot and considered as neophytes for the given region. Russia
 284 refers to European part of Russia, which is in our study subdivided into seven regions. All the regions are delimited following the Euro+Med PlantBase. Note that
 285 some regions are considered separately due to their specific history or ecology (e.g. Crete). Regions with a low number of plots (less than 100) are marked by an
 286 asterisk. Origin 'A' refers to non-European origin, 'E' to European origin and 'C' to other origin (anecophytes, hybrids).

299 **Appendix S12.** Relative frequency of invaded plots in the whole dataset and individual habitat groups with respect to neophyte origin categories calculated per
300 UTM 50 × 50 km grid cells. Cells with less than 10 plots are not mapped. Colour scale categories were defined to reflect the distribution of values using the k-means
301 breaks (note different scaling in different maps). Grey colour indicates cells with only not-invaded plots. Oromediterranean habitat group had no invaded plots
302 and therefore it is not shown here.
