30 > The local ellipse of strains provided major orientations for extension needed for polygons to initiate
31 > Polygonal faults orientations are indicative of the modern strain state in the upper sedimentary column,
32 defining two major tectonic domains

33 **Abstract**

34 Based on an extensive seismic and multibeam dataset, 1-5 km wide giant polygons were identified at the
35 bottom of the Grenada basin, covering a total area of ~55000 km². They represent the top part of an active
36 underlying polygonal fault system due to the volumetric contraction of clay- and smectite-rich sediments
37 during burial. To date, this is the widest area of outcropping polygonal faults ever found on Earth. The seabed
38 polygons are bounded by rectilinear ~1000-1500 m wide and ~10-60 m deep furrows, depending on the

39 location in the basin. They are relatively regular in the north Grenada Basin, whereas they are getting longer
40 and more elongated in the south Grenada Basin. The polygonal faults consist in a set of discrete normal faults
41 affecting a 700 to 1200 m thick interval, initiated in the shallow sub-surface at the transition between Early to
42 Middle Pliocene and then having propagated both upward and downward during sedimentation. The centre-
43 to-centre method has been applied to determine the local ellipse of strains, providing a major orientation for
44 extension needed for polygons to initiate. In the north, the minor axes are oriented N40°, indicating a general
45 NE-SW extension of the upper part of the sedimentary cover consistent with the forearc/backarc regional
46 extension. In the south Grenada Basin, minor axes are progressively turning towards the south, pointing out
47 the actual maximum subsidence point. This implies that seabed polygonal faults could thus be indicative of
48 the present-day (or recent) strain state within the upper sedimentary column.

49 Introduction

50 Polygonal fault systems (PFS) have been recognised in many basins worldwide (Klitgord & Grow, 1980;
51 Clausen & Korstgård, 1993; Cartwright, 1994; Oldham & Gibbins, 1995; Lonergan & Cartwright, 1998;
52 Clausen et al., 1999; Gay et al., 2004; Hansen et al., 2004; Gay et al., 2007; Gay et al., 2009; He et al., 2010;
53 Sun et al., 2010; Cartwright, 2011, Laurent et al., 2012; Ghalayini & Eid, 2020). They are a special type of
54 non-tectonic normal faults forming polygons in plane view and prisms in 3D, similar to other environments,
55 such as thermal contraction of cooling lavas, ice-wedge polygons (Lachenbruch, 1962) or desiccation cracks
56 (Weinberger, 1999).

57 Four main hypotheses are proposed to explain the PFS formation: i) syneresis related to colloidal properties
58 of fine-grained sediments (Dewhurst et al., 1999), ii) density inversions and associated hydrofracturing
59 (Watterson et al., 2000), iii) smectite-rich clays causing residual friction at low burial depth (Gouly, 2002;
60 2008) and iv) grain dissolution in uncemented media inducing a decrease in horizontal stress that leads to shear
61 failure and shear strain localization (Shin et al., 2008; 2010). Other mechanisms different from lithology
62 variation have been referenced in the literature as responsible for polygonal fault initiation, propagation or
63 reactivation, such as sediment loading (Gay et al., 2007). In any case, this kind of shrinkage is due to diagenetic
64 reactions in the host-rock unit during early burial causing volumetric contraction of fine-grained clay-rich
65 sediments accommodated by small scale normal faults (Gay et al., 2004; Neagu et al., 2010; Ireland et al.,
66 2011; Davies et al., 2009; Wrona et al., 2017).

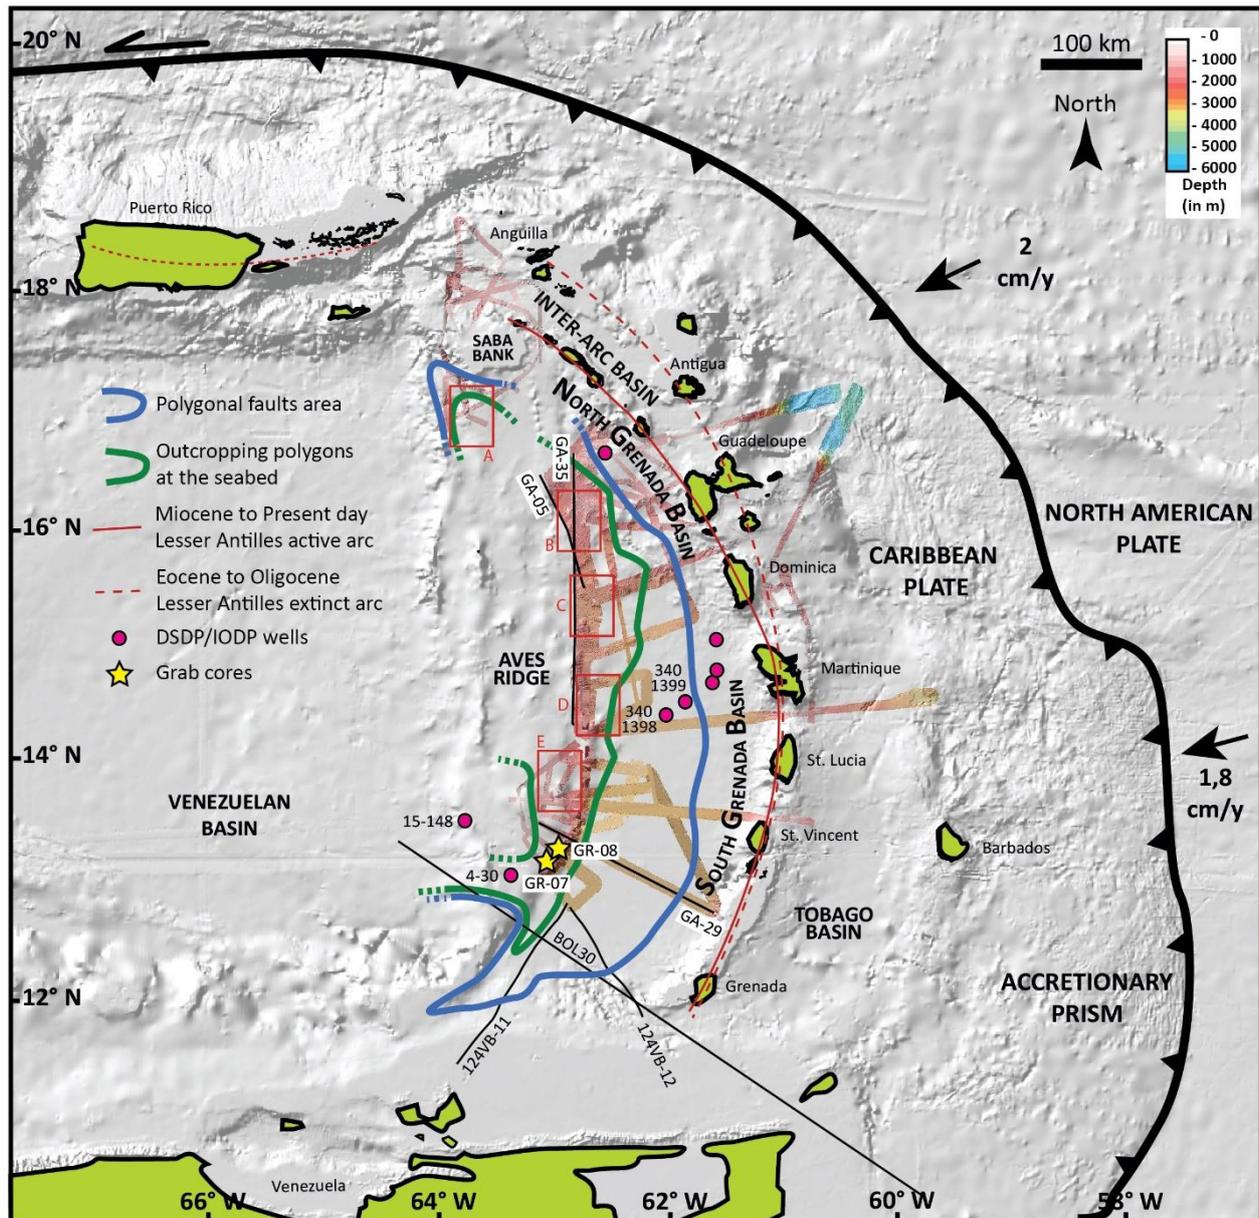

67 PFS are usually interpreted as layer-confined because they occur within sub-horizontal intervals, a few
68 hundreds of m thick, associated with lithological variations of the host sediments. They do not abruptly end at
69 a specific stratigraphical horizon and they can locally connect to major faults structuring the basin (Gay et al.,
70 2007). Some of these faults almost reach the modern seabed, thus representing the top of a modern or recently
71 active polygonal fault system (Hansen et al., 2005; Ireland et al., 2011). Even if a polygonal fault interval (PFI)
72 is generally buried from a few tens of meters to hundreds of meters, only a few examples have been reported
73 outcropping at the present-day seabed such as in the Hatton Basin (Berndt et al., 2012).

74 In the investigated area, extending from the Saba Bank southwest of Virgin Islands in the north Grenada
 75 Basin (NGB) to the south Grenada Basin (SGB) west off Grenada island, the Grenada Basin is in the backarc
 76 basin of the subducting North American Plate beneath the Caribbean Plate (**Fig. 1**). Giant polygons, 1 to 5 km
 77 wide, have been identified outcropping at the seabed during the GARANTI Cruise in May-June 2017. They
 78 cover the widest area of outcropping polygonal faults ever found on Earth, with a surface of ~55000 km². They
 79 are directly linked to a unique underlying 1000 m thick PFI that thins towards the modern volcanic arc where
 80 it abruptly ends and towards the North where sedimentary sequences are getting thinner. However, the PFI
 81 also extends towards the Venezuela Basin covering a total area of ~75000 km² in the study area, meaning that
 82 its total extent is probably much more.

83 Recent studies have attempted to link PFS with structural context using topology of the faults ([Morley &](#)
 84 [Binazirnejad, 2020 and references therein](#)) and/or rose diagram orientations ([Jimahantakul et al., 2020 and](#)
 85 [references therein](#)). Even if the fault pattern can be influenced by the slope of underlying units, causing different
 86 amounts of horizontal stress anisotropy within the faulted units ([Gay et al., 2004; Li et al., 2020](#)), the fault
 87 orientations are generally used as a direct marker of extension related to local paleo-stress fields during PFS
 88 formation ([Laurent et al., 2012, Ho et al., 2018](#)). The large extent of acquired data from north to south in the
 89 Grenada Basin gives the opportunity to investigate whether these polygonal faults are related to the current
 90 state of stress in the sedimentary cover by using a novel approach involving the centre-to-centre method. This
 91 method applied to adjacent polygons provided unexpected results with the evolving orientation of the
 92 sedimentary cover extension in the entire Grenada Basin.

93

94 **Figure 1:** Regional map of the eastern Caribbean Sea displaying the extension of giant seabed polygons (green
 95 line) and underlying polygonal faults (blue line) developing in the north Grenada Basin (NGB) and the south
 96 Grenada Basin (SGB). The multibeam bathymetry data and corresponding MCS profiles (noted GA-) were
 97 acquired during the GARANTI cruise in 2017. Additional seismic profiles (BOL30, 124VB-11 and 124VB-
 98 12) were used to extend the interpretation in the south. The grab cores GR-07 and GR-08 were collected within
 99 the area of seabed polygons. The shaded relief map is extracted from GEBCO datasets.

100

101 **Data and methods**

102 Deep-penetration multichannel seismic reflection (MCS) data were acquired onboard *R/V L'Atalante*
 103 during the GARANTI cruise in 2017 (Lebrun & Lallemand, 2017) (Fig. 1). MCS data were collected using a
 104 6473 in³ airgun array of 16 seismic sources emitting signals with a 9-40 Hz frequency range, and a 4.5 km
 105 long, 720-channel solid streamer. The data were quality-controlled and binned in common midpoint (CMP)
 106 gathers every 12.5 meters using the SolidQC software of IFREMER and they were processed using the
 107 Geovation Software. EM122 multibeam bathymetric data and high-resolution CHIRP profiles were also
 108 recorded along all seismic profiles. Additional profiles BOL30, 124VB-11 and 124VB-12 were used to connect
 109 our interpretation with previous studies in the SGB (Fig. 1).

110 Clay mineralogy of the core samples GR-07 and GR-08 collected during the GARANTI cruise (Fig. 1) was
 111 determined from X-ray diffractograms of oriented powder mounts of the bulk material and the less than 2 μm

112 granulometric fraction which is usually considered as representative of the clay fraction of sedimentary rocks.
 113 Oriented preparations are a prerequisite for a detailed characterization of the $d_{00\ell}$ reflections of phyllosilicates.
 114 The disaggregation of the bulk sediments and the dispersion of clay particles was made by ultrasonic treatment
 115 in distilled water without any preliminary grinding to strongly limit the contamination with fine grained
 116 fragments of detrital minerals. The less than 2 μm fraction was then extracted from the previous suspension
 117 by centrifugation. X-ray diffractograms were acquired on a Bruker D8 Advance diffractometer (40 kV and 40
 118 mA) coupled with a copper anticathode ($\text{Cu K}\alpha^{1+2}$ radiation) in the $2\text{-}30^\circ 2\theta$ angular range with $0.02^\circ 2\theta$ steps
 119 and a counting time of 2 seconds per step. Relative humidity was not controlled during data acquisition.

120 SEM observation of clay particles in sediments was performed on freshly broken fragments of core
 121 previously coated with a carbon film using a JEOL JSM IT500 scanning electron microscope equipped with
 122 Secondary Electron (SE), Backscatter Electron (BSE) detectors and coupled with a Bruker linxeye Energy
 123 Dispersive X-ray Spectrometer (EDX). The analytical conditions for quantitative EDX analysis of clay
 124 minerals were as follows: acceleration voltage 15 kV, current beam 1 nA, counting time 60 s, working distance
 125 11 mm, and analytical area of $\sim 2 \mu\text{m}$. The standards used for the EDX quantitative analysis consisted of albite
 126 (Na, Al, Si), almandine (Mg, Fe), diopside (Ca), orthoclase (K) and spessartite (Mn). Matrix corrections were
 127 performed using an integrated program called PhiRhoZ correction. The reproducibility of the standard analyses
 128 was 1.5% for all chemical elements, except Na, for which the reproducibility was 3%.

129 From north to south, five subzones (A to E) have been selected based on available data (seismic profiles,
 130 multibeam bathymetry and CHIRP profiles) in order to perform a statistical analysis on the length and
 131 orientation of polygon edges. The centre-to-centre distances between every pair of polygons were measured
 132 and plotted on a polar diagram using a sheet of tracing film repeatedly placed with its centre over an object,
 133 similar to the method of strain analysis (Ramsay, 1967). The relative positions of all surrounding objects are
 134 plotted until a central vacancy field emerges, defining well-defined fabric ellipses. The method requires the
 135 assumption of a statistically isotropic initial distribution of objects in which objects are unlikely to be closer
 136 than a minimum distance apart. It means that fabric ellipses are due to anisotropic conditions during polygon
 137 initiation, with a minor axis parallel the direction of the minimum horizontal stress.

138 **Geological settings**

139 The present-day crescent-shaped Grenada Basin (according to Mann, 1999 and Picard et al., 2006) results
 140 from the latter 56-Ma geodynamical evolution of the Caribbean plate movement forming the Greater Arc of
 141 the Caribbean (GAC) subduction zone (Ladd & Sheridan, 1987; Iturralde-Vinent & MacPhee, 1999;
 142 Audemard et al., 2009; Pindell et al., 2012; Boschman et al., 2014; Münch et al., 2014; Legendre et al., 2018).
 143 It is bounded to the west by the Aves Ridge, to the east by the Lesser Antilles Arc (LAA), to the south by the
 144 shallow Venezuelan continental shelf and to the north by the Saba Bank (Fig. 1). Currently, the American
 145 plates are subducting below the Caribbean plate at a mean rate of 2 cm/y (DeMets et al., 2000). The LAA
 146 subduction zone marks the eastern boundary of the Caribbean Plate, whereas the Aves Ridge corresponds to
 147 the southern part of the remnant GAC that was exposed between approximately 88 and 59 Ma (Fox et al.,

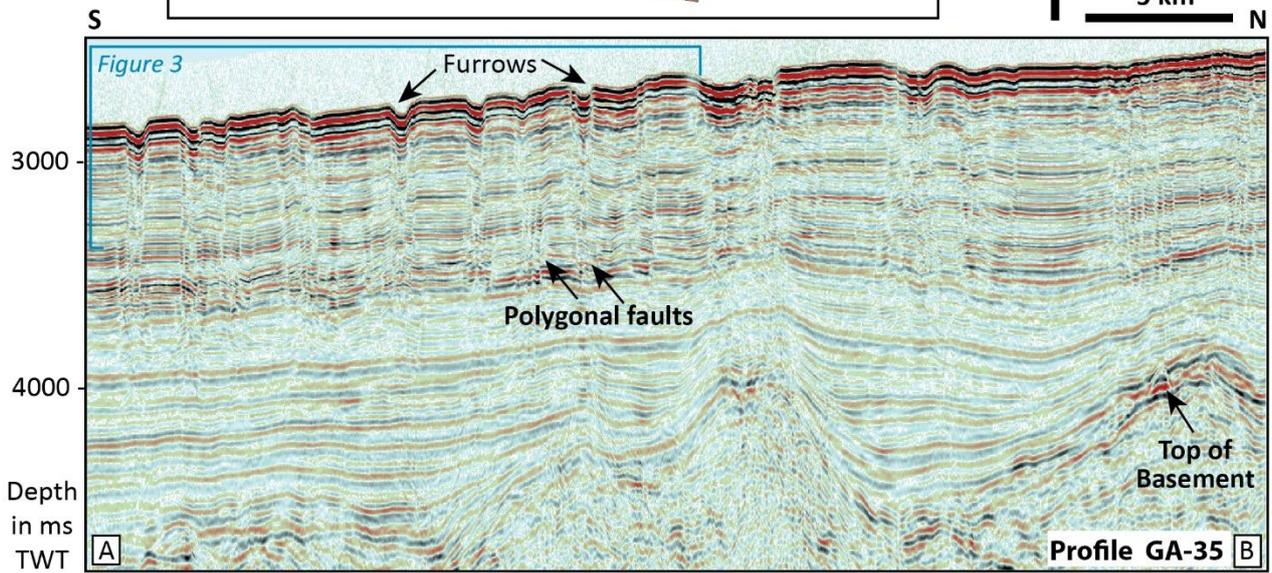

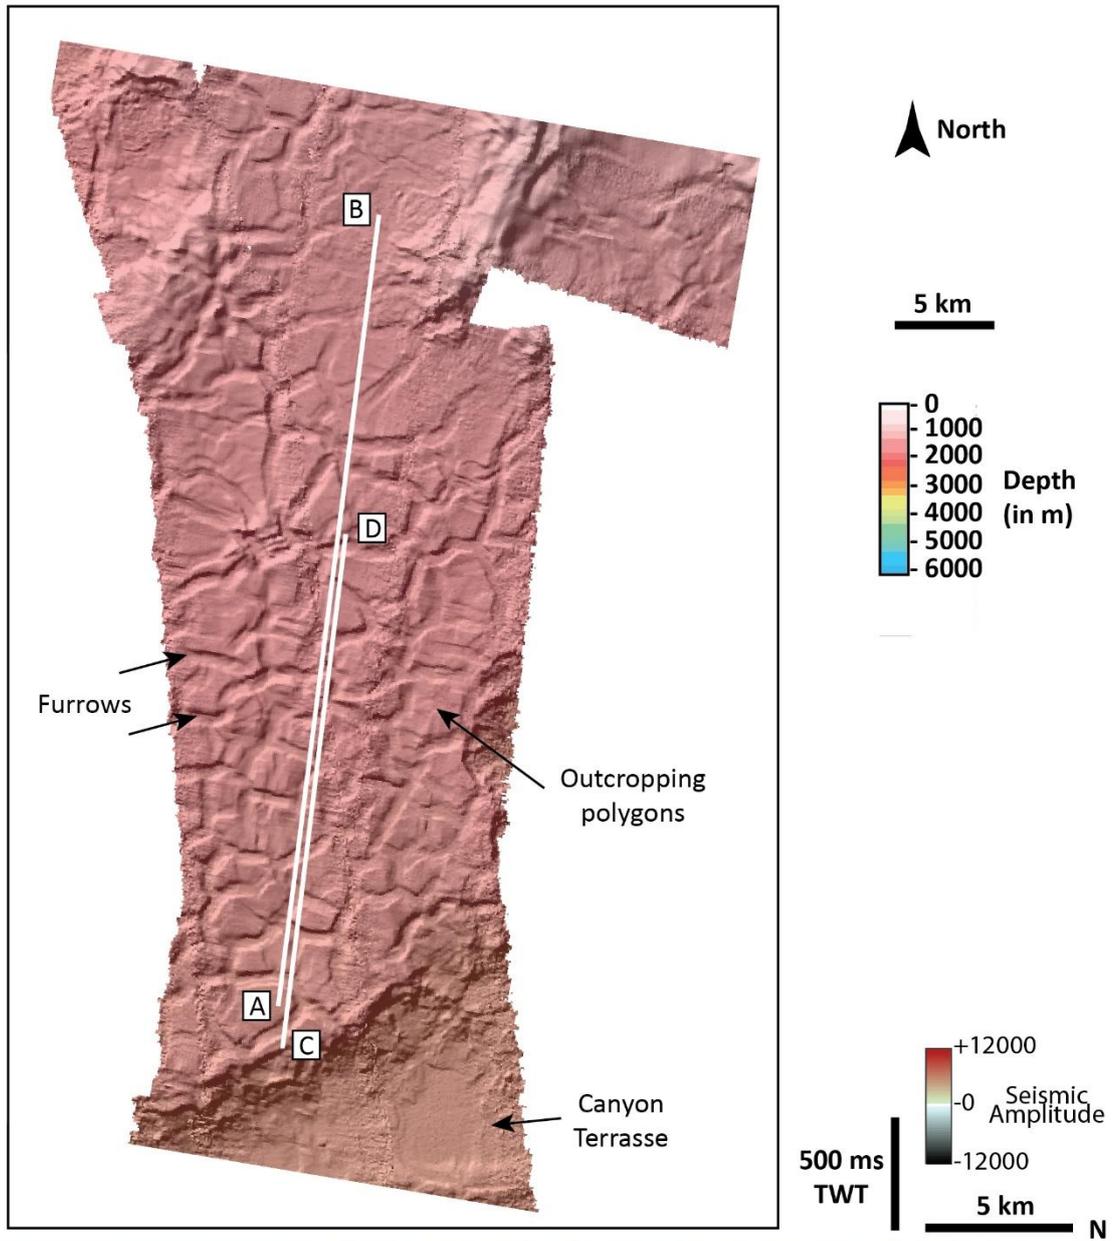

148 1971; Bouysse et al., 1985; Bouysse & Westercamp, 1990; Neill et al., 2011). The Grenada Basin has long
 149 been considered a typical backarc basin between the Aves Ridge and the LAA. However, its morphology varies
 150 from a rough ~1000-2000 m deep bathymetry and a Moho ~25 km deep in the North and a flat ~3100 m
 151 bathymetry and a ~10-15 km deep Moho in the South (Gómez-García et al., 2019; Padron et al., 2021). This
 152 is a marginal basin partly underlain by oceanic crust (Christeson et al., 2008; Allen et al., 2019; Padron et al.,
 153 2021), adjacent to an oceanic island arc, that receives volcanoclastic debris from the bordering volcanic arc
 154 and, to a lesser degree, the remnant arc (Carey & Sigurdsson, 1984; Parra et al., 1986; Murray et al. 2018).
 155 However, previous sedimentological and geochemical studies have indicated that Grenada Basin sediments
 156 are originated from two principal sources: volcanogenic material from the LAA, and terrigenous material
 157 eroded from the South American continent (Pautrizel & Pons, 1981; Kinder et al., 1985; Bowles & Fleischer,
 158 1985; Parra et al., 1986).

159 Seabed giant polygons and related polygonal faults

160 Seabed polygons are separated from the neighbouring polygons by 700-1500 m wide and 10-60 m deep
 161 furrows (compared to the regional seafloor) with a flat bottom (Fig. 2). The polygons are ranging from 2000
 162 to 3000 m on average. However, in the SGB the seabed polygons are much wider by a factor of 50-to-100%
 163 where they can reach 5000 m in length, suggesting that the size of polygons depends on the location within
 164 the basin.

165
 166 **Figure 2:** Top: Shaded relief map of seafloor along the seismic profile GA-35 showing 2 to 3 km wide
 167 polygons bounded by ~40 m deep furrows. Bottom: Seismic profile AB (GA-35 close-up view) displaying
 168 polygonal faults affecting a ~1000 ms TWT thick interval. The polygonal faults are organized in set of small-
 169 throw normal faults distributed beneath seafloor furrows. The furrows are the result of stacked depressions
 170 down to ~300 ms TWT below seafloor.

171

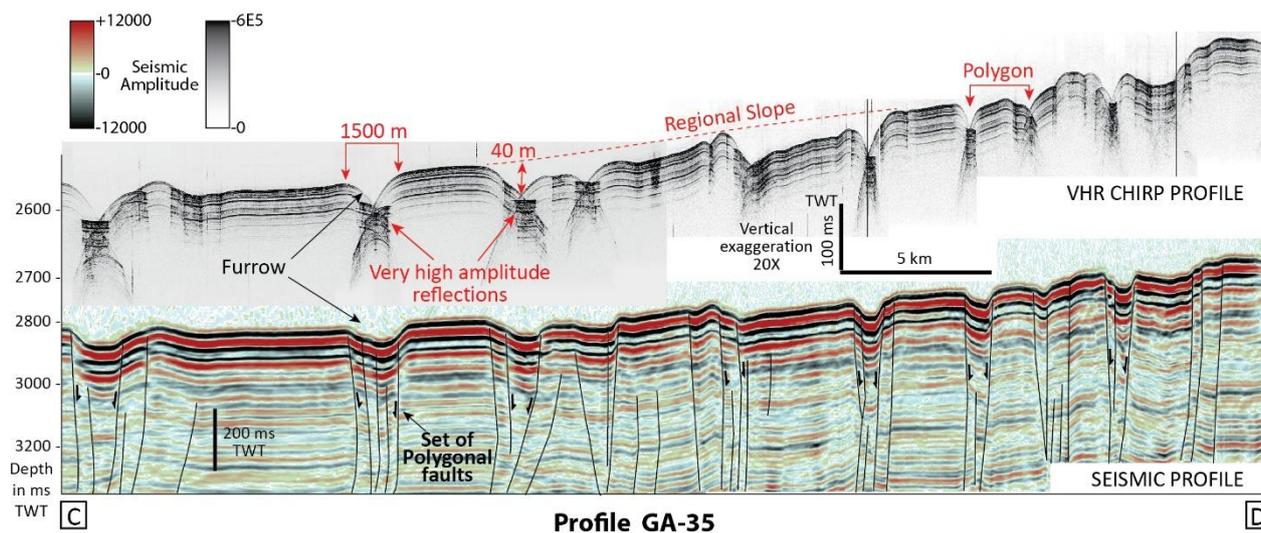

173 On profile AB (GA-35 close-up view in sub-zone B), seafloor furrows are generally seen as small
 174 depressions affecting underlying horizons down to 200-300 ms TWT below seafloor (**Fig. 2**). The vertically
 175 stacked furrows are consistently located above small-scale faults affecting an interval ranging from 700 to
 176 1200 ms TWT. The faults are characterized by various reflectors offsets, typically a few tens of ms TWT and
 177 they reach the seabed where they bound furrows. On high-resolution Chirp profiles, and despite a 20X vertical
 178 exaggeration, the polygons have very steep flanks ($\sim 3^\circ$), defining depressions (or furrows) that are 800-1500
 179 m wide and 40 m deep compared to the $0,3^\circ$ smooth regional slope (**Fig. 3**). Very high amplitude reflections
 180 occur right beneath the seabed creating large hyperbolae. A seismic profile displayed at the identical horizontal
 181 scale shows that each depression is bounded by faults reaching the seabed (**Fig. 3**). The polygonal faults are
 182 characterized on seismic profiles by an intense dimming of reflections on both edges of the fault planes
 183 suggesting that fluids are currently migrating upward.

184

185 **Figure 3:** Very high-resolution seismic profile (CHIRP) at the identical horizontal scale than the corresponding
 186 seismic profile GA-35. The furrows are affecting the present-day seafloor and they are ~ 1500 m wide and ~ 40
 187 m deep. The seabed furrows represent the top of an underlying polygonal fault system (PFS). The bottom of
 188 furrows is characterized by very high amplitude reflections compared to well-bedded horizons between
 189 furrows.

190

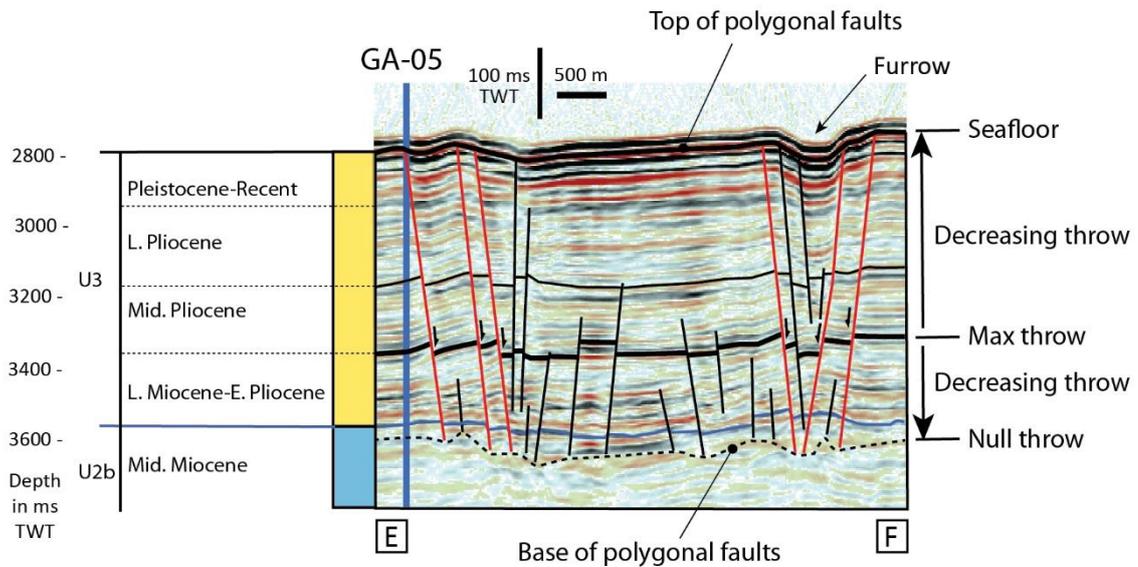

191

192

193 In more details all faults are normal and they are organised in set of 2-5 parallel faults (**Fig. 4**). Within the
 194 set of faults, the depressed reflections are vertically stacked and the offset along the fault plane is decreasing
 195 towards the seabed. At depth, the throw along a fault plane is progressively decreasing at the base of the
 196 polygonal fault interval where the lowest horizons do not appear affected (**Fig. 4**). The maximum throw along
 197 the fault planes has been identified at the transition between Early and Middle Pliocene (**Fig. 4**).

198

199 **Figure 4:** Detailed view of seismic profile GA-35 displaying decreasing offsets along fault planes both upward
 200 and downward from. The maximum throw is located at the transition between Early and Middle Pliocene all
 201 over the Grenada Basin. Units were correlated and described in [Garrocq et al. \(2021\)](#).

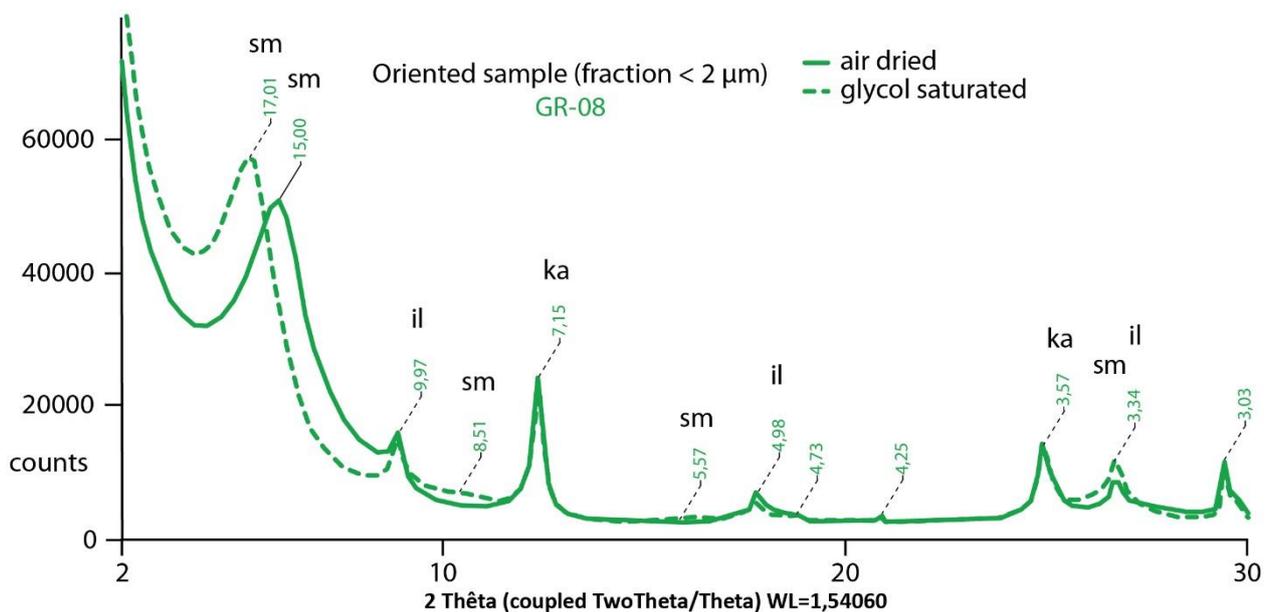

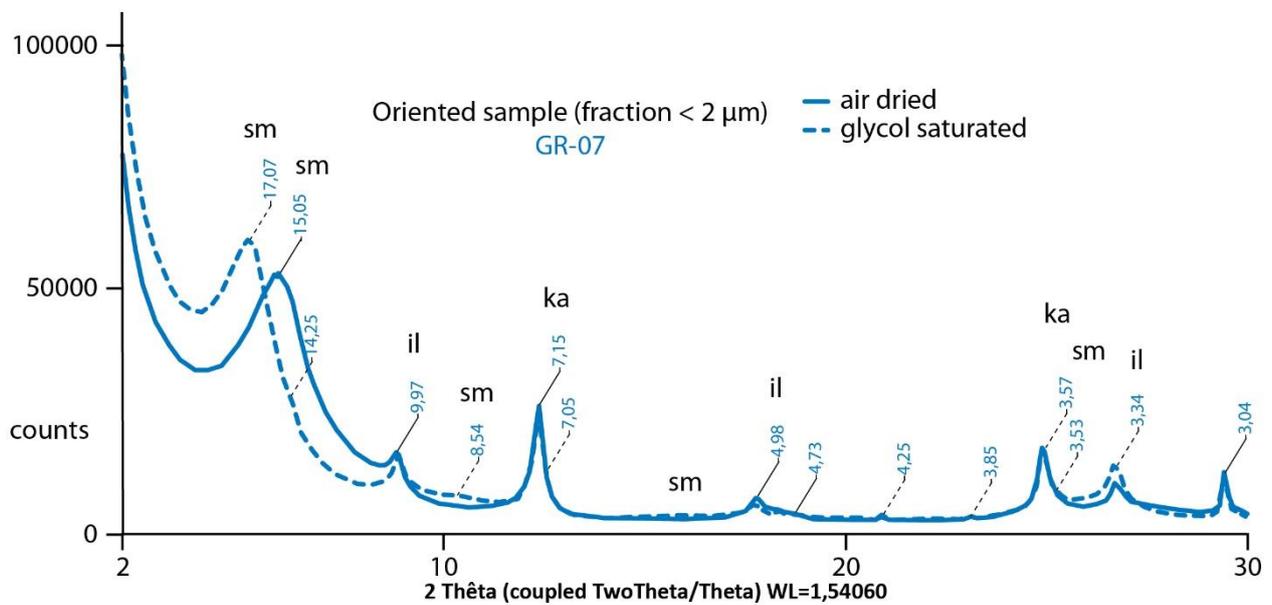

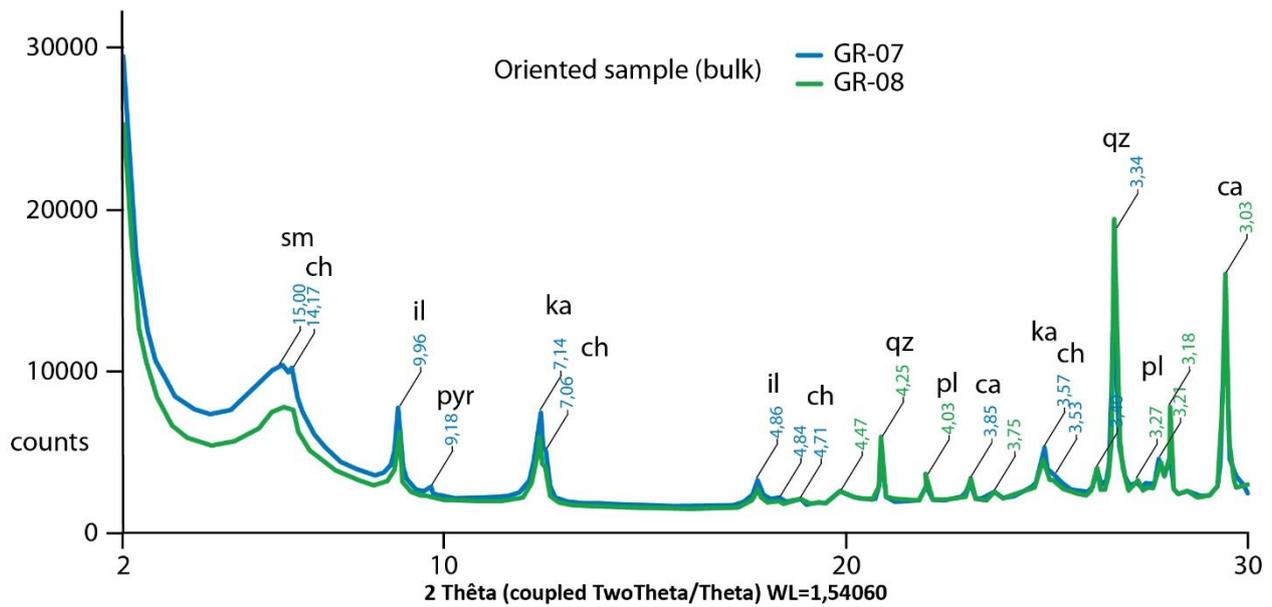

202

203 Nature of sediments

204 The present-day Antillean sediments are mainly of mafic-affinity, rich in pyroxenes and amphiboles but
 205 poor in quartz and biotite (in agreement with the andesitic composition of the volcanogenic material related to
 206 the LAA activity), whereas the South American supply is essentially of felsic-affinity, composed of quartz and
 207 phyllosilicate minerals, such as biotite, muscovite, and chlorite ([Pautrizel & Pons, 1981](#)). Clay mineralogy of
 208 two grab cores (GR-07 and GR-08) collected during the GARANTI cruise display very similar patterns. The
 209 bulk analysis shows a high clay content, mostly composed of smectite, illite/muscovite and kaolinite with
 210 subordinate chlorite and pyrophyllite, mixed with non-clay minerals such as pyroxenes, plagioclases, quartz
 211 and calcite (**Fig. 5**). The disappearance of chlorite and pyrophyllite X-ray reflections as well as the strong
 212 decrease in the peak intensity of illite/muscovite present in the XRD pattern of the fraction $<2 \mu\text{m}$ indicate that
 213 these minerals are coarse grained and probably related to clastic metamorphic-derived source (**Fig. 5**). The
 214 XRD patterns of the fraction $<2 \mu\text{m}$ are similar for both samples, with a very high smectite content and lower
 215 amounts of kaolinite and illite/muscovite. Based on cation exchange capacity measurement for the bulk
 216 material, the smectite content has been estimated to about 50% in both samples.

217

218 **Figure 5:** XRD analysis of grab cores GR-07 and GR-08. Top: bulk analysis displaying very similar patterns
 219 with a high clay content (smectite: sm, illite: Il, chlorite: ch and kaolinite: ka) and some other minerals
 220 (pyroxenes: py, plagioclases: pl, quartz: qz and calcite: ca). Bottom: analysis of the fraction $<2 \mu\text{m}$ for both
 221 samples GR-07 (blue curves) and GR-08 (green curve) displaying very high smectite content, high kaolinite
 222 peaks and low illite peaks.

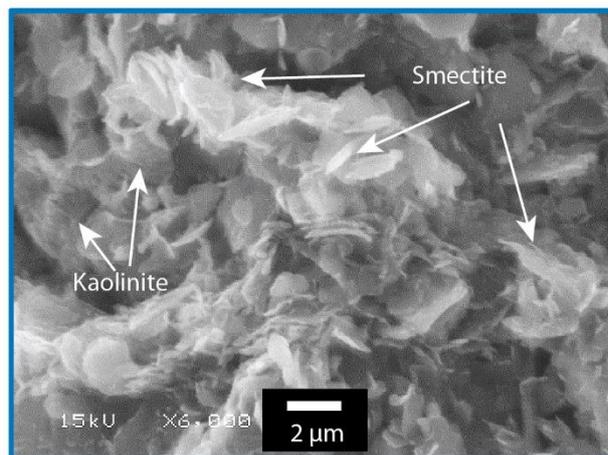

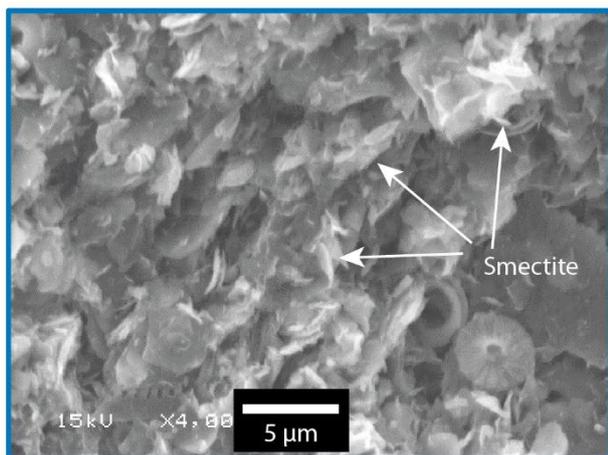

224 The SEM photographs shows that the sediments are dominated by smectite and kaolinite (**Fig. 6**). The
 225 calcite content is provided by the pelagic sedimentation of foraminifers although other minerals, such as
 226 feldspars (plagioclases), pyroxenes and quartz represent a minor contribution. The collected seabed sediments
 227 are primarily composed (>50%) of smectite at the grab cores location.

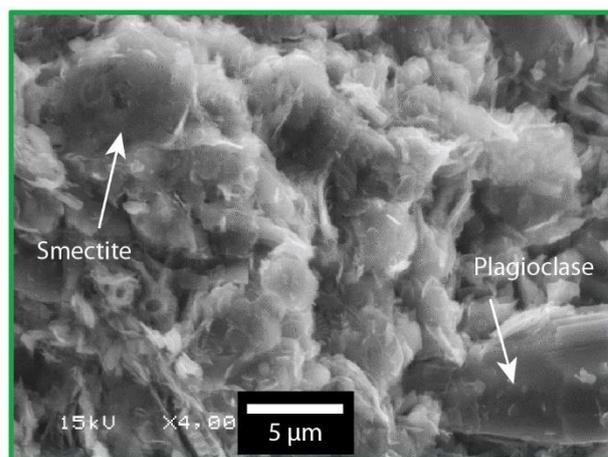

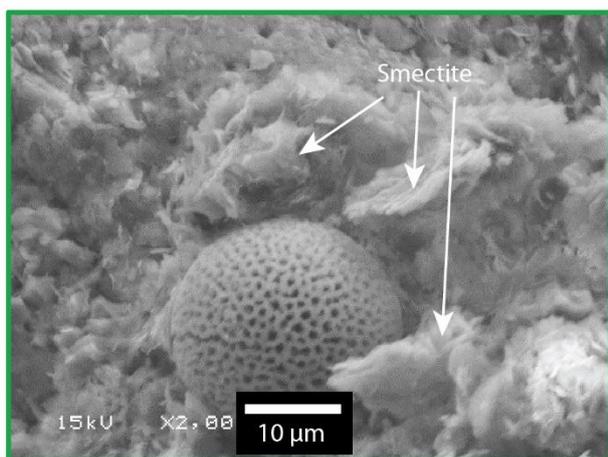

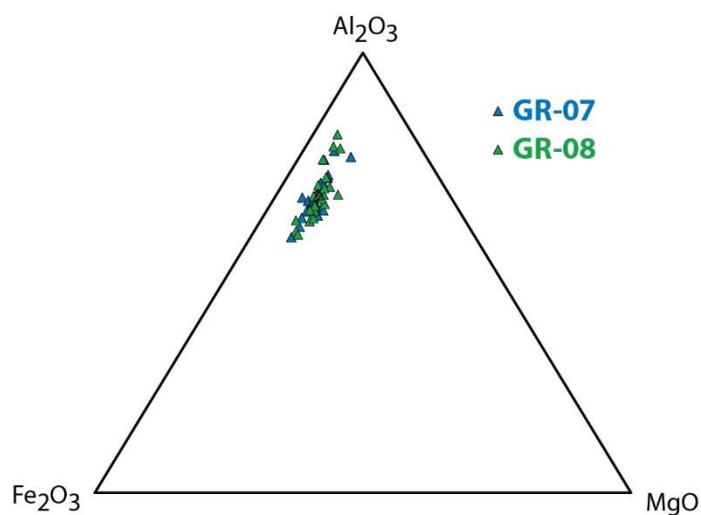

228 Chemical point analyses of the clay particles observed with SEM indicate that smectite is dioctahedral and
 229 is rich in Al and Fe with a layer charge mostly satisfied by K in interlayer position (**Fig. 6**). Such a chemical
 230 composition is similar to that of the potassic ferriiferous beidellites characterized in the volcanogenic clay
 231 material in recent marine sediments ([Desprairies and Bonnot-Courtois, 1980](#); [Parra et al., 1985](#)). In these
 232 sediments, smectite is generally derived from the diagenetic transformation of volcanogenic material
 233 (including volcanic ashes) into clay minerals. Conversely, kaolinite is usually derived from the weathering or
 234 the hydrothermal alteration of Al-bearing silicates in low pH environments and it is considered as a clastic
 235 material in marine sediments.

236

237 **Figure 6:** Top and bottom: SEM photographs of samples GR-07 (blue) and GR-08 (green). Both samples are
 238 dominated by smectite and kaolinite but smectite represents more than 50% of the bulk volume. The calcite
 239 peaks are derived from pelagic foraminifers; Middle left: Representative chemical analyses of smectites and
 240 the corresponding calculated structural formulae. Total iron was arbitrarily considered as Fe³⁺ ; Middle right:
 241 Al₂O₃-Fe₂O₃-MgO plots of the point chemical analyses of smectite particles from the two grab cores (GR-07
 242 and GR-08) collected during the GARANTI cruise.

	GR-07	GR-08

K	0.3	0.3

244 **Seabed polygon organization**

245 The polygons in the sub-zones A and B are very similar in size and shape (**Fig. 7**). However, they are 10-
 246 15 m deep in sub-zone A and 40 m deep in sub-zone B compared to the regional seafloor. They are
 247 characterized by 3 mains directions oriented N170-N10°, N30-50° and N90-110°, with lengths of 1260/1274,
 248 1190/1208 and 1345/1374 ±15 m respectively. The basic shape is a polygon with a major axis of ~2400/2500
 249 m in length in sub-zones A and B.

250 The sub-zone C is characterized by polygon edges oriented N170-10°, N30-50° and N70-90° with lengths
 251 of 1070, 1274 and 1047 ±15 m respectively. This defines polygons with a major axis of ~2250 m in length on
 252 average and 40-60 m deep bounding seafloor furrows.

253 The sub-zone D is characterized by polygon edges oriented N10-30°, N30-50° and N70-90° with lengths
 254 of 1245 m ±15 m for every direction. They define elongated polygons with a major axis of ~3100 m in length
 255 on average and 30 m deep bounding seafloor furrows.

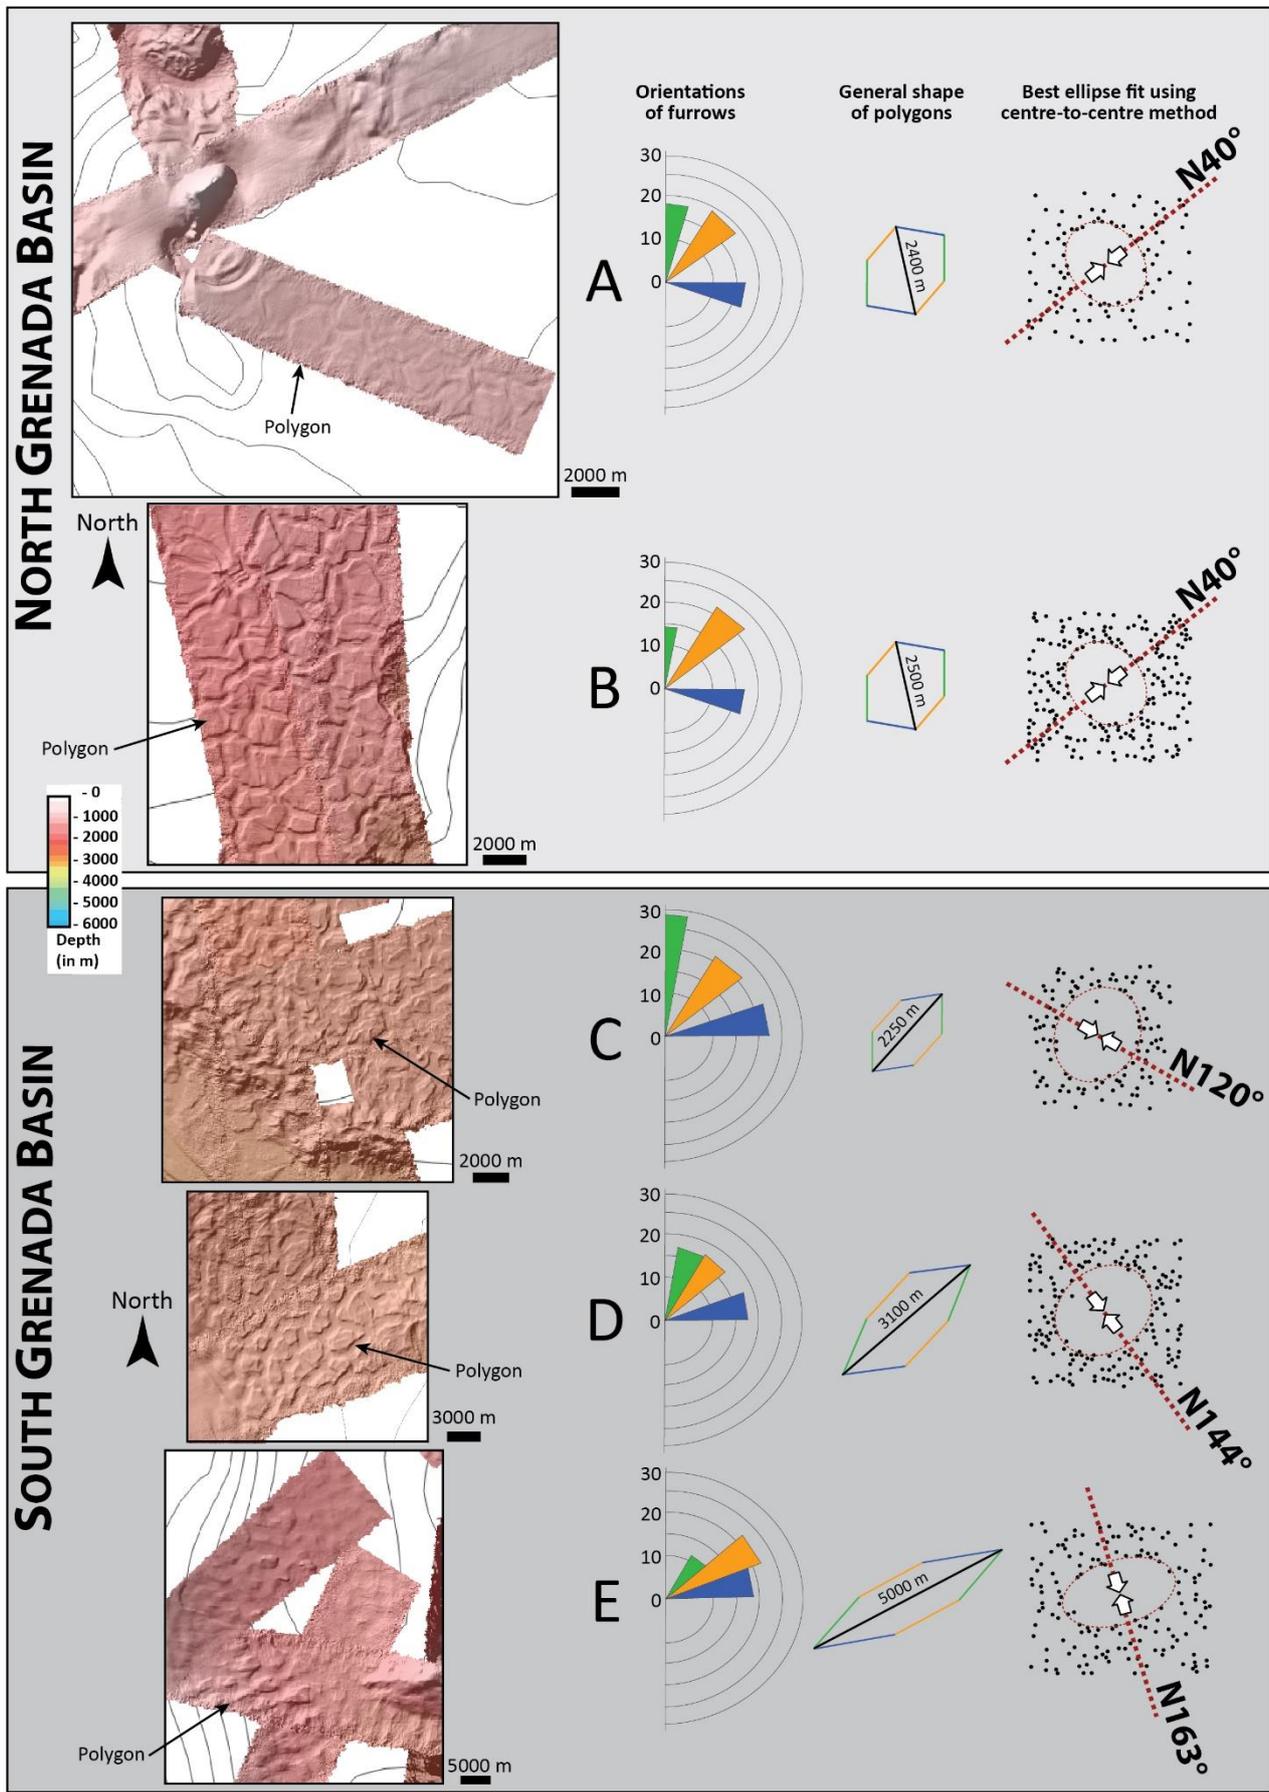

256 The sub-zone E displays polygon edges oriented N30-50°, N50-70° and N70-90° with lengths of 1653,
 257 1935 and 1677 ±15 m respectively. They define very elongated polygons with a major axis of ~5000 m in
 258 length, clearly visible on the bathymetric map. The seafloor furrows are 20-30 m deep.

259 In the NGB the polygons are very similar in shape and orientation. The ellipses obtained from the centre-
 260 to-centre method show a minor axis oriented N40° indicating the main direction of anisotropic contraction of
 261 polygons. In the SGB the polygons are more elongated and their orientation progressively rotates southward.
 262 Seafloor furrows are deeper in the north than in the south by a factor of two. The minor axes are oriented
 263 N120°, N144° and N163° respectively, indicating that they are progressively changing towards the SGB.
 264 Consequently, two main areas are defined in the Grenada Basin in the north and the south by both the general
 265 shape of polygons and the direction of the minor axis obtained from the centre-to-centre method.

266

267 **Figure 7:** Statistical analysis conducted on seafloor polygons bounded by furrows in sub-zones A to E.
 268 Polygons are very similar in size and shape in sub-zones A and B in the NGB, although they are getting longer
 269 from sub-zone C to E towards the SGB. This is confirmed by best fit ellipses obtained from the centre-to-
 270 centre method, giving a minor axis oriented N40° in sub-zones A and B whereas it is turning from N120° in
 271 sub-zone C to N144° in sub-zone D and N163° in sub-zone E.

272

274 **Discussion**

275 *Origin of sediments and sequences*

276 The volcanic arc is volumetrically the most important source for sediments, with abundant volcanoclastics
 277 being produced by explosive subaerial and/or subaqueous eruptions and secondary erosion of the arc complex
 278 (Carey & Sigurdsson, 1984). Except for direct ash-fall deposits, the recent sediments in the flanks of the
 279 Grenada Basin are composed of volcanogenic debris emplaced by turbidity currents and debris-flows coming
 280 from both the LAA (Carey & Sigurdsson, 1978; 1980; Sigurdsson et al., 1980; Deplus et al., 2001; Brunet et
 281 al., 2016; Le Friant et al., 2020; Seibert et al., 2020) and from the Aves Ridge (Bader et al., 1970; Holcombe
 282 et al., 1990). The hemipelagic sedimentation mixing dispersed ash and clastic clays coming from South
 283 America is the dominant process in the deeper part of the Grenada Basin (Sen Gupta et al., 1982), entering the
 284 Grenada basin by northward flowing Caribbean ocean currents (Corredor et al., 2004).

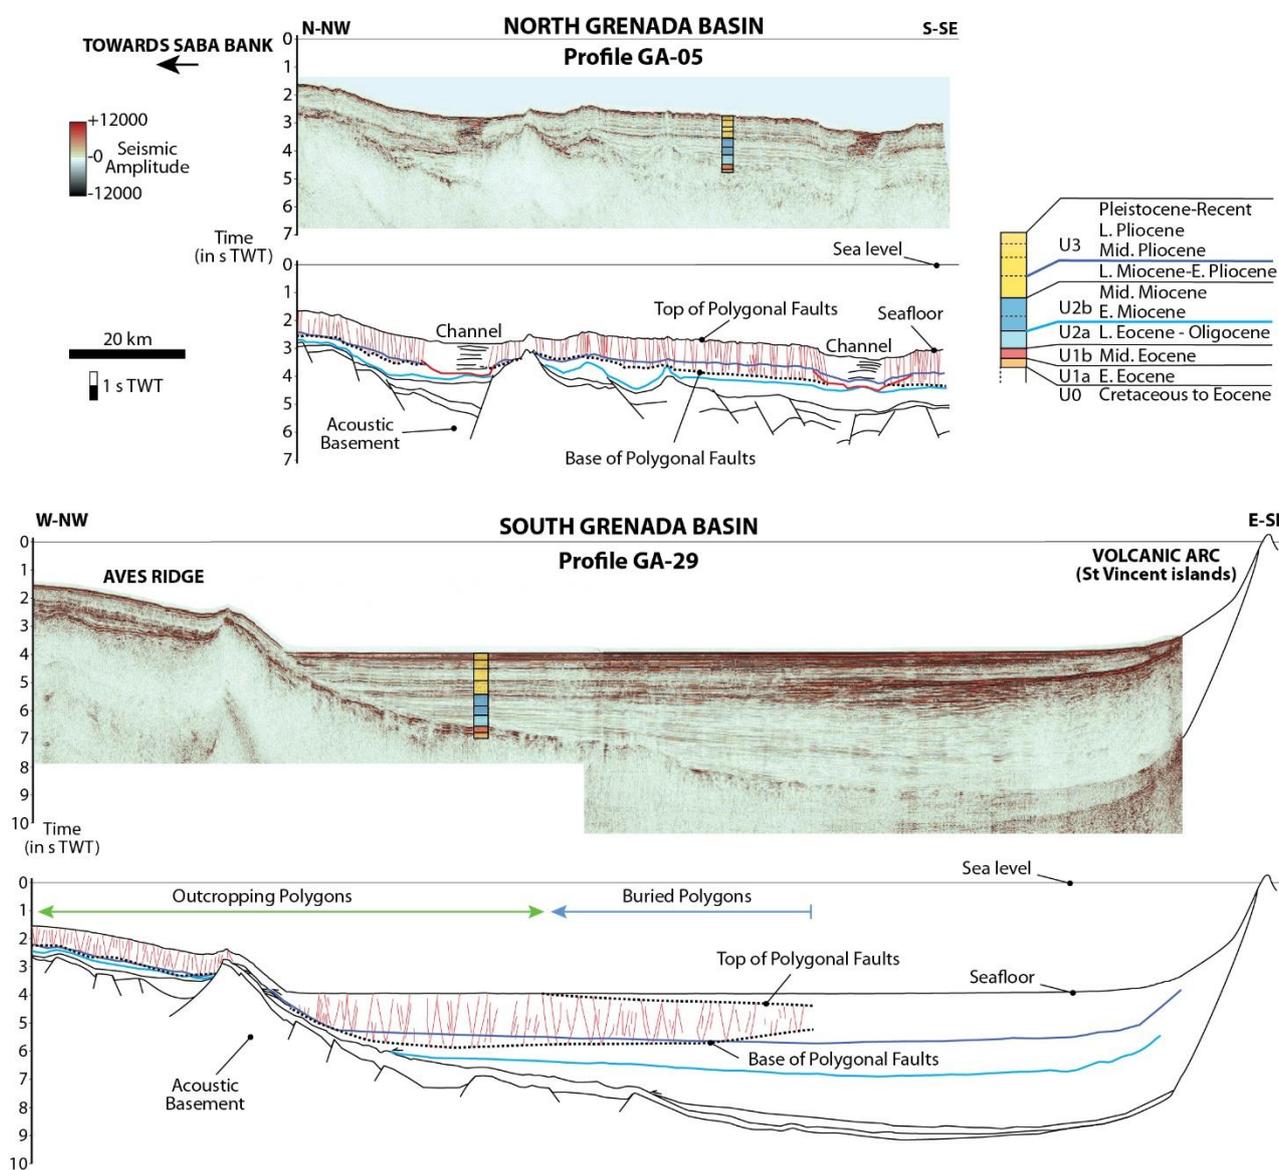

285 This mixed sedimentation is active since middle Miocene (Aitken et al., 2011) defining unit U3 (**Fig. 8**)
 286 identified on seismic sections as chaotic and semi-continuous tabular high amplitude reflectors (Garroq et al.,
 287 2021). The LAA is composed of mostly andesitic igneous rocks (MacDonald et al., 2000) whose weathering
 288 products carry a distinctive signature. Smectites and kaolinite are the dominant clay minerals produced by the
 289 weathering of Lesser Antillean igneous rocks, with over twice as much smectite produced as kaolinite. Another
 290 typical weathering characteristic of an igneous island arc terrane is the absence of illite or illite-smectite mixed
 291 layers. Hydrothermal illite and illite-smectite mixed-layers may form in the geothermal fields related to the
 292 volcanic activity, as documented on the islands of Guadeloupe to Grenada (Parra et al., 1986; Mas et al, 2003;
 293 Mas et al. 2006; Murray et al., 2018). However, the spatial extension of the geothermal areas is too limited to
 294 exert a significant contribution to the clay material accumulated in marine sediments. Hence, high smectite
 295 and low illite contents are typical of sediments with a volcanogenic (Lesser Antillean) source (Pautrizel &
 296 Pons, 1981; Parra et al., 1986). Crustal terranes of the South American continent made of granites and gneisses
 297 act as the source area for non-volcanic abiogenic sediments deposited in the Caribbean. Tropical weathering
 298 of these continental rocks produces four dominant clay minerals: illite, kaolinite, smectites, and chlorite. This
 299 fine-grained terrigenous material is carried in suspension to the southeast Caribbean by major rivers,
 300 particularly the Amazon and the Orinoco (Bowles & Fleischer, 1985). Thus, a clay mineral assemblage
 301 characterized by high abundances of illite, kaolinite, chlorite and minor pyrophyllite is typical of a South
 302 American terrigenous source, as is the presence of detrital quartz (Pautrizel & Pons, 1981). Some deep channels
 303 across the Aves Ridge permitted the transport of the Venezuela Basin bottom water (commonly labeled
 304 Caribbean Bottom Water or CBW) into the Grenada Basin (Kinder et al., 1985).

305 Unit U2 (Early to Middle Miocene) was fed by the Orinoco whereas its delta front was oriented North-
 306 South towards the Grenada basin. During Tertiary times the Orinoco drainage basin and its associated delta
 307 has migrated eastward over more than 500 km because of the eastward deformation in north Venezuela due to
 308 the Caribbean plate/South America relative movements (Beck et al., 1990; Pindell, 2006, Audemard et al.,
 309 2009). Presently, the turbidite system issued from the present-day Orinoco delta develops at the eastern edge
 310 of the East Caribbean active margin partly above the large southern part of the Barbados accretionary prism

311 and downslope at the front of this prism, within the Demerara abyssal plain (Deville et al., 2015). Unit U2 is
 312 marked by a shallowing of the facies corresponding to a progressive infilling of the Grenada Basin (Garrocq
 313 et al., 2021). Sediments in Unit U1 are deep-water, pelagic and volcanogenic shale and siltstone, with some
 314 biogenic limestone in the deeper parts (Ysaccis, 1997), whereas seismic reflections in Unit U0 are very chaotic
 315 but they are well organized in some places, possibly related to cretaceous sediments.

316

317 **Figure 8:** Top: Seismic profile GA-05 and its line-drawing displaying the PFI in the NGB. The polygonal
 318 faults do not develop where deep turbiditic channels are present. The PFI is getting thicker southward affecting
 319 almost all unit U2. Units U0 to U3 were correlated on GARANTI seismic data from previous studies and
 320 ODP/DSDP wells (Garrocq et al., 2021); Bottom: Seismic profile GA-29 and its line-drawing displaying the
 321 PFI in the SGB. In both the western part of the SGB and the Aves Ridge, the polygonal faults are reaching the
 322 seafloor. The base of the PFI varies from west to east generally affecting the top of U2. In the eastern part of
 323 the SGB the PFI is thinning eastward (both the top and the base of the PFI are crosscutting stratigraphic
 324 horizons) and abruptly ends 40-70 km off the volcanic arc.

325

326

327 In the NGB, the polygonal faults reach the seafloor, except in the vicinity of deep turbiditic channels where
 328 they do not develop at all (Fig. 8). The PFI is getting progressively thicker southward as its base is getting
 329 deeper. However, the PFI abruptly ends at the toe of the Saba Bank (not shown in this study but visible on
 330 profile GA-15C in Cornée et al., 2021).

331 In the western part of the SGB, the PFS are affecting unit U3 (Fig. 8) and giant polygons are cropping out
 332 at the seabed. The base of PFI is not concordant with the base of unit U3 and, as shown on Fig. 4, it is
 333 undulating over the Grenada Basin within the top of unit U2, depending on the depth at which the faults have
 334 propagated downward. In the centre of the SGB the PFS do not reach the seafloor nor unit U2 where the PFI
 335 appears buried (500 ms TWT below seafloor) and thinner (700 ms TWT) defining a lenticular shape. The PFS
 336 abruptly end eastward at a distance of ~40-70 km from the LAA. On the Aves ridge, the PFI appears thinner
 337 by a factor of 2, which is correlated with thinner sedimentary sequences.

338 The total area covered by both outcropping and buried polygonal faults is about 75000 km² (55000 + 20000
 339 km² respectively), defining a crescent shape more or less concordant with the shape of the Grenada Basin (Fig
 340 1).

341 *Polygonal faults orientations as a marker of basin extension*

342 The main hypothesis for polygonal faults formation considers a finite bed length extension and the
 343 development of conjugate fault planes with extensional offsets (apparent normal faults) due to a bulk volume
 344 loss of pore fluids. This process leads to a thinned sequence, which is partly compacted (Cartwright &
 345 Lonergan, 1996; Gay et al., 2004). The consequences are that the complex polygonal fault systems in mudstone
 346 dominated sequences formed due to volumetric contraction and concomitant fluid expulsion (Shin et al., 2008;
 347 Gay et al., 2004; Gay et al., 2007) that leads to shrinkage in mud-dominated sequences (Cartwright & Lonergan
 348 1996; Dewhurst et al. 1999). Normal faulting related to burial and sediment loading is not a common process
 349 that has been already proposed for rocks deformation, probably because soft sediments like clays have a
 350 specific rheological behaviour. The dominant orientation of minor axis of fabric ellipses obtained from the
 351 centre-to-centre method as well as their bending in the slope direction suggests the interaction of gravity-driven
 352 shearing of the compacting interval. For example, sedimentary structures, such as dewatering pipes and sand
 353 volcanoes (Waldron, 1988), may display diffuse outlines but nonetheless show anticlustered distributions. A
 354 radial stress tension related to the volumetric contraction of clay could allow to reduce the lithostatic mean
 355 stress, also increasing the differential stress, and then to reach shear failure along a Coulomb-type conventional
 356 envelope. However, this process assumes that 1) the faulted material has a common frictional envelope, 2) the
 357 lithostatic stress state prior to faulting due to compaction was sub-critical (i.e. close to shear failure), and/or 3)
 358 the stress tension related to the volumetric change is large enough. In such unlithified and uncompacted clay
 359 sediments, the coefficient of Earth pressure at rest (K₀) is generally large (0.45–0.8) implying a little
 360 differential stress due to the vertical loading (Earl, 1997; James, 2006). This suggests that a high horizontal
 361 tension due to internal contraction is needed to get the failure envelope (Cartwright & Lonergan, 1996),
 362 coupled to an external regional extension (Laurent et al., 2012; Bureau et al., 2013). This model suggests that

363 progressive sediment loading acts as a centrepiece in the initiation and propagation of polygonal faults (Gay
 364 et al., 2004; Gay et al., 2007; Reiche et al., 2011). It also implies that, at great burial depths, the compaction
 365 through the process of volumetric contraction ends and the dissolution–precipitation mechanisms become
 366 dominant (Gay et al., 2004). Clausen et al. (1999) have suggested that PF developed within a broadly polygonal
 367 array due to gravitational sliding influenced by far-field tectonic stresses, even if Wrona et al. (2017) have
 368 recently suggested that such processes played no or an imperceptible role in the growth of this specific North
 369 Sea system. However, the hypothesis that layer-parallel displacements of these faults are accommodated by
 370 regional extension of the host strata has been confirmed in various basins, such as in the Lower Congo Basin
 371 (Gay et al., 2004) or in the Angola basin (Ho et al., 2018), and more recently by field studies showing that a
 372 radial extension may account for PFS development (Antonellini & Mollema, 2015; Petracchini et al., 2015).
 373 Syn-thrusting non-diagenetic polygonal normal faults were reported in the Cingoli anticline. The PF nucleated
 374 into multi-directional stretching processes that are consistent with the fault slip indicators (Petracchini et al.,
 375 2015). This study also reported that faults are not systematically parallel to the general trending anticline axis
 376 suggesting an evolving pattern of PFS influenced by structural paleo-stresses conditions. So, the development
 377 of PFS at the seabed could thus be indicative of the present-day strain state within the sedimentary column
 378 (Tuckwell et al., 2003; Ho et al., 2018; Jitmahantakul et al., 2020).

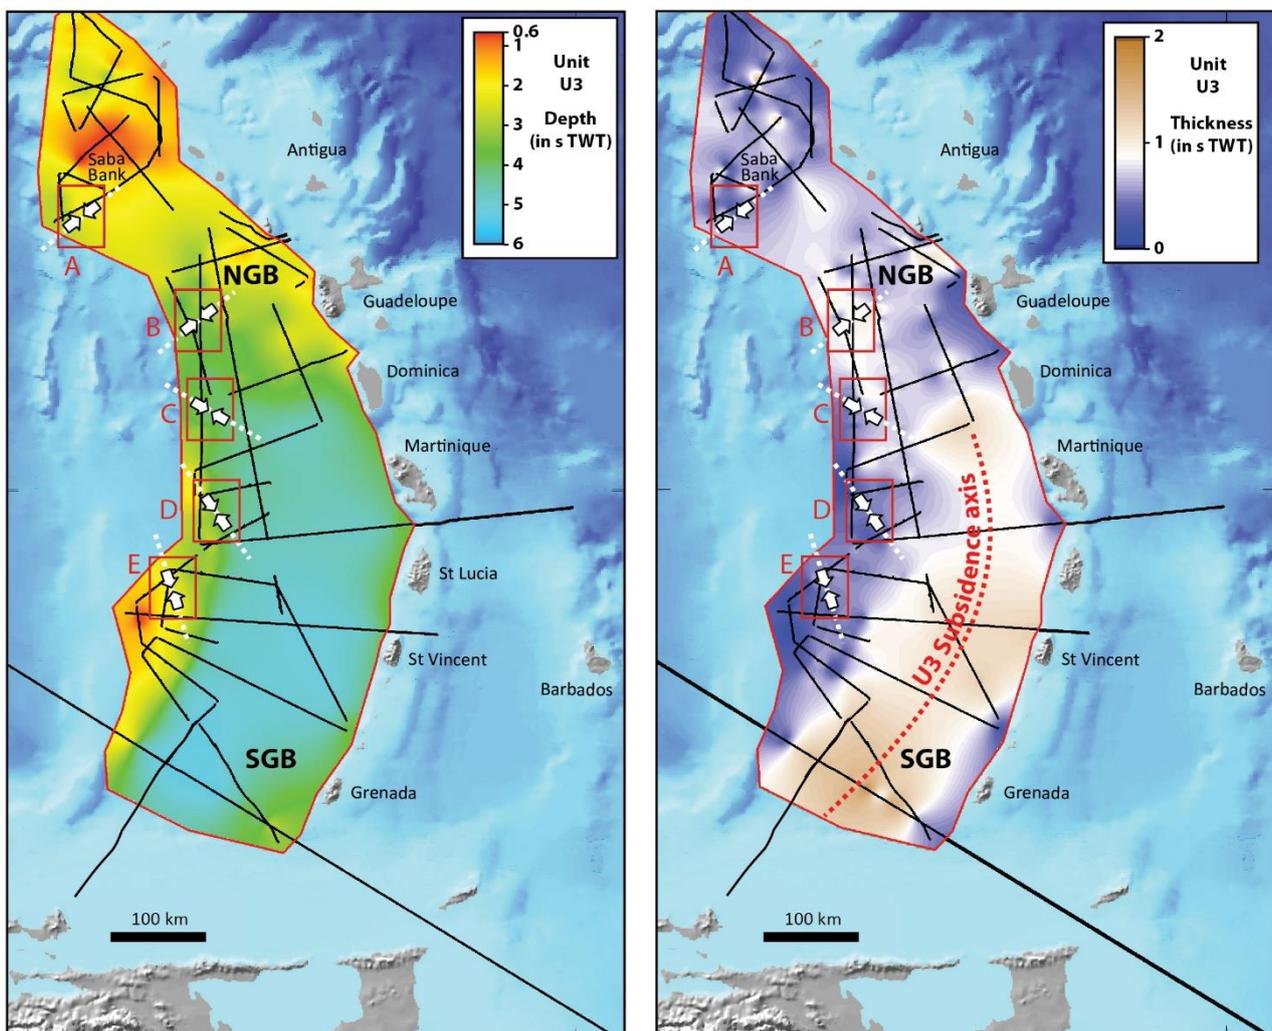

379 In the NGB, the strain ellipses show a similar minor axis orientation of N40° in both areas A and B, meaning
 380 that all polygons are contracting following the same major direction. It is now commonly admitted that such
 381 direction of contraction is parallel to the minimum principal stress σ_3 (Petracchini et al., 2015; Ho et al., 2018),
 382 which represent a direction of extension within the sedimentary column. So, we assume here that the PFI is
 383 currently in extension following one major direction of N40°. The forearc-backarc domain has undergone a
 384 regional subsidence and a NE-SW extension since Late Miocene, evidenced in the Northern Lesser Antilles
 385 forearc (Boucard et al., 2021) and in the intra-arc Kalinago Basin (Cornée et al., 2021). The N40° extension
 386 evidenced from PF orientations thus may indicate that the upper sedimentary cover (unit U3 at least) is
 387 submitted to similar processes in the backarc. During this period, uplifts phases were moderate compared to
 388 this subsidence, which has submerged islands and previously uplifted areas (Bouysse, 1988; Mann et al., 1995;
 389 Feuillet et al., 2010; Philippon et al., 2020a; Legendre et al., 2018; Cornée et al., 2020; Cornée et al., 2021).
 390 The extensive deformation has triggered deeply-rooting NW-SE faults in the forearc (Boucard et al., 2021)
 391 and in the Kalinago Basin (Cornée et al., 2021). This is possibly explained by thermal relaxation related to the
 392 cessation of arc activity in the northeastern LAA (MacPhee et al., 1989; Jany et al., 1990; Philippon et al.,
 393 2020b) and/or by distal tectonics influence of subduction dynamics (Boucard et al., 2021). The more recent
 394 and continuous subsidence since Late Miocene - Early Pliocene may explain shallower depths of both the
 395 present-day seafloor and the base of unit U3, with an average depth of 2 s TWT (Fig. 9). The isopach map of
 396 unit U3 shows a constant thickness of about 0.7-0.8 s TWT, even in the area of Saba Bank, indicating a
 397 homogeneous subsidence in the entire area (Fig. 9).

398 In the SGB, the ellipses show a change in direction of the minor axis, indicating varying orientations of the
 399 extension of the PFI pointing towards the centre of the SGB where the curved depocenter of unit U3 follows

400 the curvature of the modern volcanic arc (**Fig. 9**). The major faults identified in the SGB (Speed & Westbrook,
 401 1984; Pindell & Barrett, 1990; Pindell & Kennan, 2009; Aitken et al., 2011; Garrocq et al., 2021) do not seem
 402 to control the orientation of PF, indicating that the upper part of the sedimentary column, particularly unit U3,
 403 is actually in extension following a general subsidence in the south. In this area, the subsidence has
 404 significantly increased from Late Miocene to present, possibly explained by a southeastward regional tilting
 405 and/or a greater sediment compaction in response to sediment loading in the basin (Garrocq et al., 2021). The
 406 base of unit U3 is characterized by a sharp change in average depth from 2 to 5 s TWT west off Dominica
 407 island and a slight deepening to the South where it reaches about 6 s TWT west off Grenada island (**Fig. 9**).
 408 However, the isopach map of unit U3 shows a curved NE-SW depocenter with a maximum thickness of 2,3
 409 km in the southwest indicating a higher subsidence rate in the south.

410

411 **Figure 9:** Left: isochron map of the base of U3 displaying a crescent shape following the LAA. There is a
 412 sharp change west off Dominica where U3 is strongly deepening of ~3 s TWT. From Dominica to the south
 413 of Grenada Island the base of U3 is slightly deepening to reach ~5,5 s TWT. U3 is very shallow on Saba Bank
 414 and on top of the Aves Ridge. Right: Isopach map of U3 showing a homogeneous thickness in the NGB. In
 415 the SGB, U3 progressively thickens southward, indicating a differential subsidence between north and south.

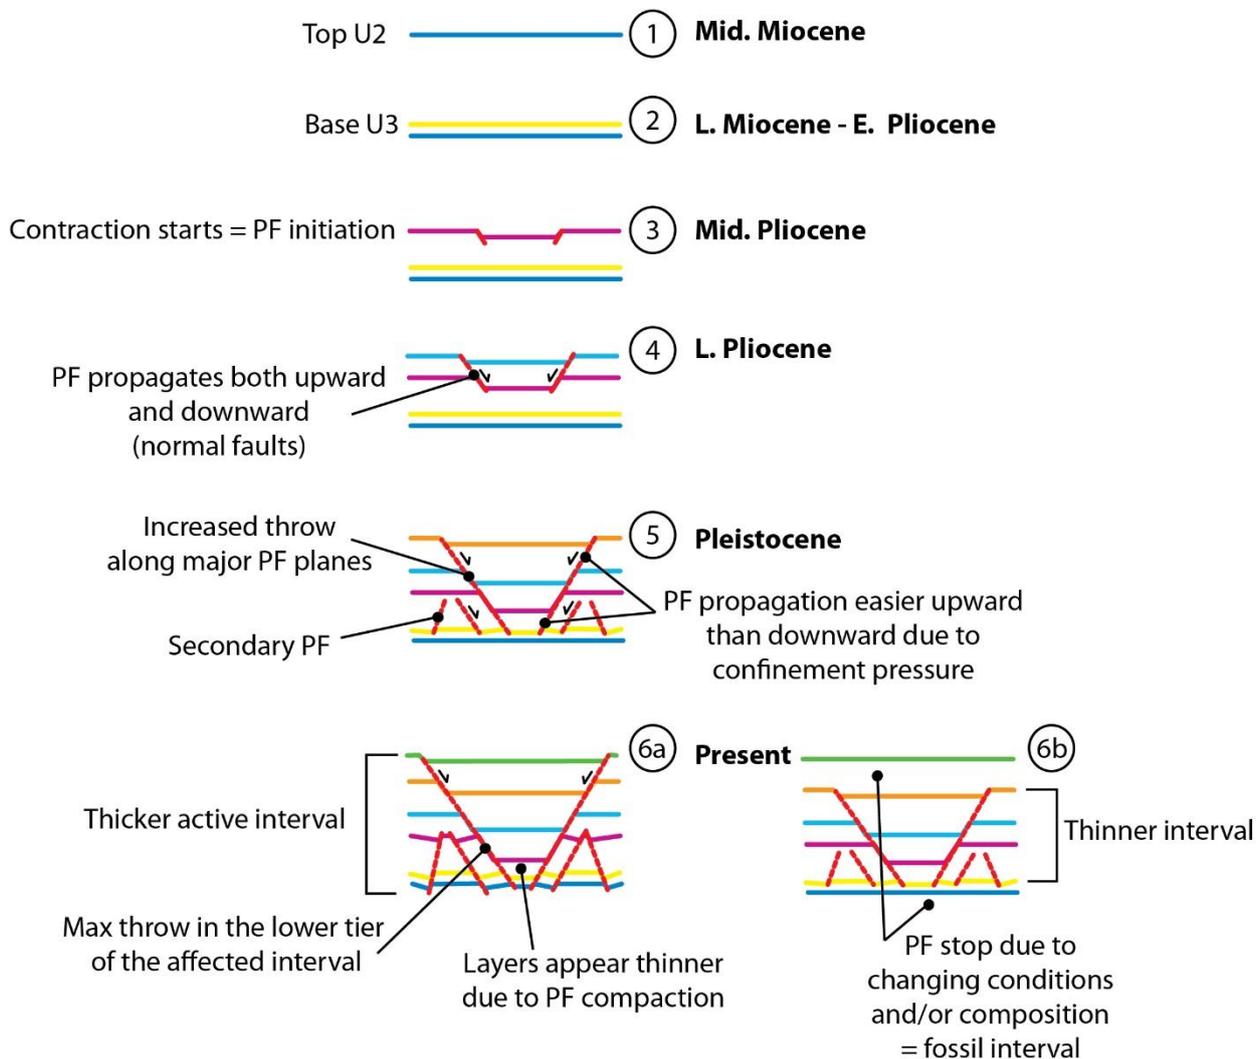

416

417 *Factors controlling the initiation and propagation of polygonal faults*

418 Lithological analyses conducted on wells penetrating polygonal fault intervals show that the amount of
 419 shrinkage in layers appears to increase as the grain size decreases and smectite content increases (Dewhurst et
 420 al., 1999; Gay et al., 2007). This composition forms a fine texture of flocculated particles, 2 µm in size,
 421 submitted to shrinkage upon drying leaving voids that are about 5 µm in width (Forsberg & Locat, 2005). This
 422 process occurs at a microscale, and could explain 1) the spontaneous contraction of mud-dominated sediments,
 423 leading to the formation of normal faults at a wider scale and 2) the development of polygonal faults
 424 outcropping at the seabed, meaning that the volumetric contraction can form during early compaction, leading
 425 to a rapid bulk volume loss.

427 **Figure 10:** Schematic sketch illustrating the initiation and propagation of PF starting at the seabed. The PFS
 428 started at the transition between Early and Middle Pliocene. They are then propagating both upward and
 429 downward during sedimentation and as long as the sediment composition remains clay- and smectite-rich and
 430 the extension is large enough to allow proper contraction of sediments.

432 The PF initiation and propagation in the Grenada Basin can be summarized in an evolutionary model taking
 433 into account their morphology both at the seabed and on seismic profiles (**Fig. 10**). Unit U2 was fed by clastic
 434 metamorphic material coming from the Orinoco delta while it was oriented NS, which is not compatible with
 435 spontaneous volumetric sediment contraction at seabed (stage 1). During Late Miocene the lateral shift of the
 436 Orinoco river on the eastern flank of the LAA has limited the coarser metamorphic material input into the
 437 Grenada basin (**Diaz de Gamero, 1996; Escalona & Mann, 2010**). The base of unit U3 was more and more fed
 438 by smectite-rich sediments derived from the volcanic arc and/or coming from the South American continent
 439 through the CBW current (stage 2) and the contraction started during the Middle Pliocene (stage 3). The
 440 process of contraction has gone on as long as sediments deposited at the seabed had the composition required
 441 for PF development (**Gay et al., 2007; Jackson et al., 2014**). Increased dewatering during burial implied more
 442 displacement along faults (**Jitmahantakul et al., 2020**), which would continue to grow as long as the dewatering
 443 cell contracted volumetrically (stage 4). The PF propagated both upward and downward although the
 444 progressive reduction in bed length through contraction was balanced by an incremental increase in the amount
 445 of displacement distributed along the faults (stage 5). Fault propagation is much easier towards the seabed than
 446 at depth due to the confinement pressure, and the throw maximum along major PF planes is always found in
 447 the lower tier of the affected interval. At depth, secondary faults are initiated due to sediment loading in order
 448 to better drain the centre of polygons (stage 5). They display lower amount of displacement than the major
 449 polygonal faults at the same stratigraphic level, confirming that the nucleation of PF occurred where/when the
 450 throw is maximum (i.e. Middle Pliocene) (stage 6a). The kinematic model of polygonal fault growth in which
 451 the propagation of faults is discontinuous during basin infilling leads to a 4D interpretation of the whole
 452 polygonal fault system. In the eastern part of the SGB, the polygonal fault interval appears buried and the PFI
 453 is thinning towards the east, cross-cutting stratigraphic horizons. The eastern part of the Grenada Basin can be
 454 considered as a fossil interval of PF (stage 6b), whereas polygonal faulting remains active to the west and
 455 although the initiation point is at the same stratigraphic level both in east and west. This could reflect 1) a
 456 progressive westward migration of the extension domain affecting the upper part of the sedimentary column
 457 or 2) the western area remains dominated by clay- and smectite-rich sedimentation, whereas the eastern area
 458 has received different lithologies. Flank collapse events have occurred all along the LAA, resulting in debris
 459 avalanches, some of them involving large volumes of material (**Deplus et al., 2001, Brunet et al., 2016**). A
 460 striking characteristic of the deposits in the Grenada Basin is the presence of a thick chaotic unit in seismic
 461 data, about 250 ms TWT in thickness, west off emerged islands in the deep basin. Some of the debris
 462 avalanches have evolved into debris flows and turbidity currents, feeding the eastern deep basin with coarser
 463 material (**Deplus et al., 2001**). At this point, the change in sediment input (and composition) seems the most
 464 probable cause for stopping PF propagation in the east Grenada Basin.

465 *Model of polygonal faults in the asymmetric basin of Grenada*

466 Major differences in depths, morphologies and PF between the NGB and the SGB are evidenced along a
 467 NS profile (GH) (**Fig. 11**):

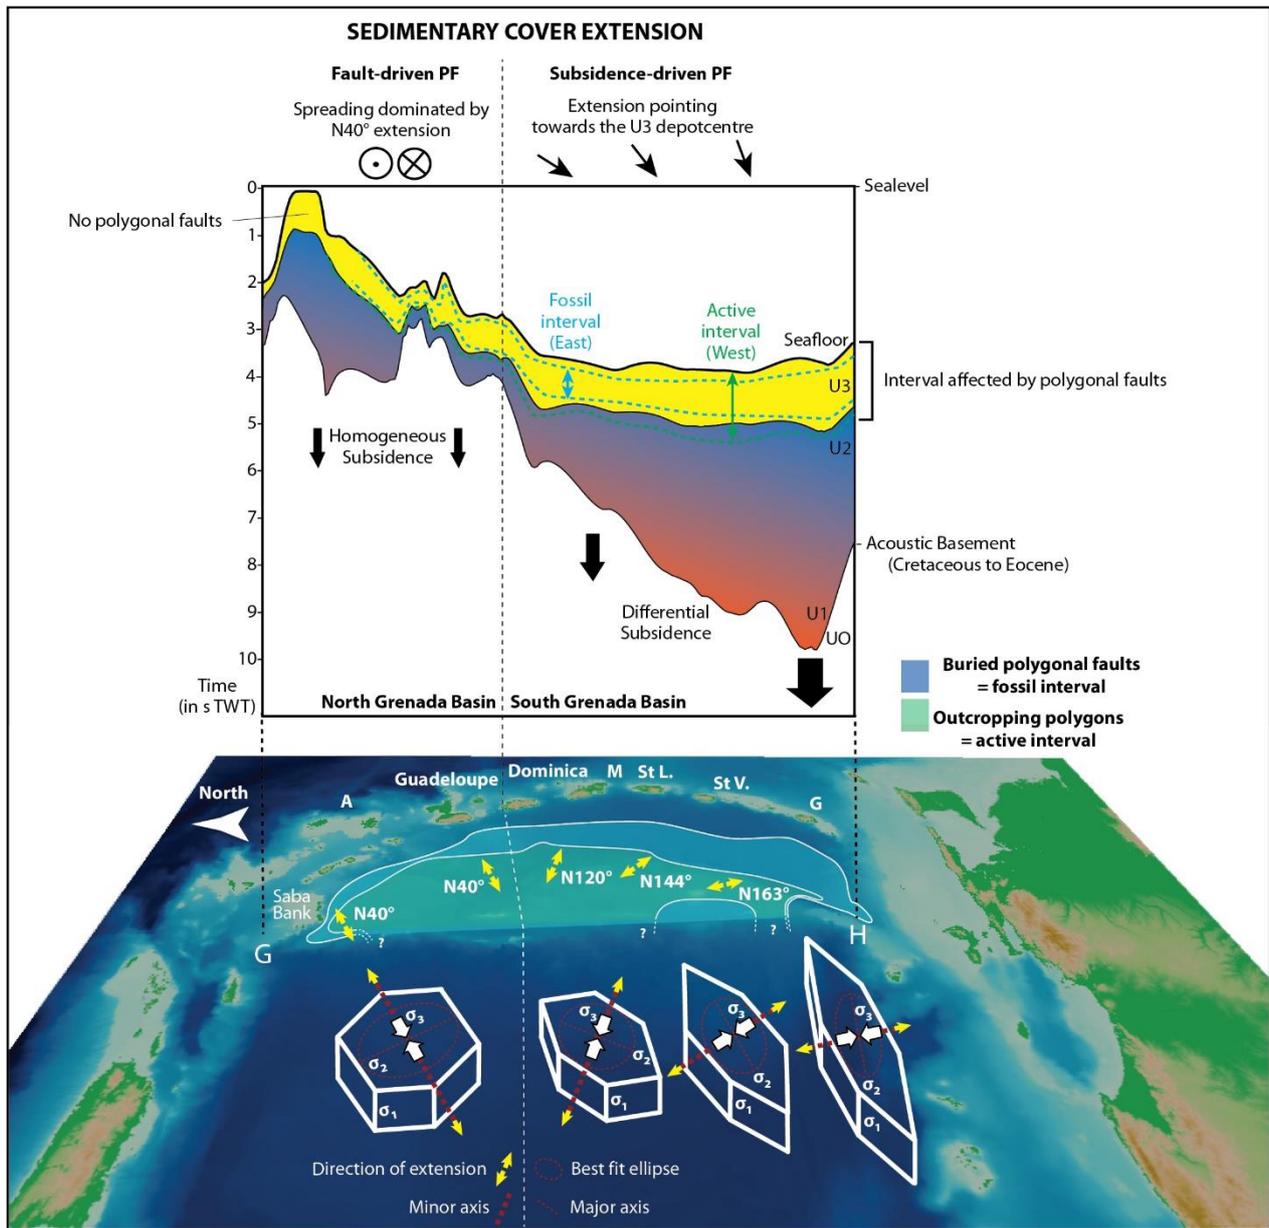

468 > The basin infilling is controlled by the available space for sedimentation. Due to repeated episodes of
 469 uplift and emersion in the north, the thickness of the sedimentary cover is relatively thin with a maximum of
 470 about 3 s TWT south of Saba Bank and west of Antigua. Unit U3 appears isopachous with a seabed slightly
 471 deepening to the south, indicating that the present-day subsidence is homogeneous in the area. The continuous
 472 subsidence in the south since Eocene has led to a very thick sedimentary cover of about 6 s TWT between the
 473 Aves Ridge and the Grenada Island. Unit U3 is thickening southward with a relative flat seabed, indicating an
 474 actual differential subsidence which is stronger in the south.

475 > Classical normal faults usually propagate parallel to the principal stress σ_1 , while hydraulic fractures
 476 open in parallel to the intermediate horizontal stress σ_2 and against the minimum principal stress σ_3 (Cosgrove,
 477 1995). However, PFS do not follow such behavior due to the anisotropy of unlithified cohesive fine-grained
 478 sediments and the anisotropic stress attributed to perturbations of the regional stress field can control the PF
 479 orientations (Ho et al., 2018). Volumetric contraction is a spontaneous process forming polygons by joints
 480 growing from an initiation point in all directions at the same time, such as in cooling lava flows (Aydin &
 481 DeGraff, 1988). In sedimentary basins, σ_1 is generally vertical and corresponds to the lithostatic vertical stress
 482 (σ_v) and we assume here that σ_2 and σ_3 are respectively perpendicular and parallel to the minor axis of fabric
 483 ellipses obtained from the centre-to-centre method. In the north, the PFI abruptly ends at the toe of Saba Bank,
 484 a lithified reefal and red algal platform (Cornée et al., 2021) in which PF cannot develop. PF are controlled by
 485 a general N40° extension of the present-day backarc basin. In the south, PF are following the deepest point of
 486 subsidence actually towards the south. The active interval of PF has continued growing until the present day
 487 in the centre and in the west of the Grenada Basin whereas it has stopped or never developed in the east due to
 488 coarser and/or less smectite-rich input coming from the active LAA.

489 > Between the NGB and the SGB, the change in depths, morphologies and polygonal faults orientations is
 490 sharp, suggesting that both basins are presently submitted to very different tectonic regimes. The boundary
 491 between both PF domains is estimated to be west off Dominica island, which is consistent with a NGB
 492 underlain by about 90 Ma subducted lithosphere, whereas the subducted lithosphere is up to 120 Ma old
 493 beneath the SGB (Müller et al., 2019). This is confirmed by a basement that remains high in the north, reaching
 494 a maximum of about 4 s TWT in depth, although it is strongly deepening in the south, reaching a maximum of
 495 10 s TWT. This limit between two underlying geodynamic domains may actually be recorded by shallow PFI
 496 in the backarc domain.

497
 498 **Figure 11:** Model of PF occurrence in the Grenada Basin. Between north and south the change in depths,
 499 morphologies and polygonal faults orientations is sharp, suggesting that both basins are actually submitted to
 500 very different tectonic regimes. The best fit ellipses extracted from the centre-to-centre method allowed the
 501 identification of preferential contraction orientations in unit U3. It is assumed that the minor axis of the ellipse
 502 represents the main orientation of volumetric contraction of sediments and it can be related to the minimum
 503 principal stress σ_3 . σ_1 and σ_2 orientations are deduced from the orientation of σ_3 . The extension is N40° and
 504 remains constant in the NGB, although it is changing (N120° to N144° to N163°) in the SGB, following the

505 U3 depocenter. Giant seabed polygons in the Grenada Basin and the underlying PFS are markers of the present-
 506 day (or recent) strain state within the upper sedimentary column.

507

508 Conclusion

509 A regional acquisition of seismic data and multibeam imagery at a basin scale provided new insights on the
 510 recent Grenada Basin history and improved the understanding of post-depositional processes occurring in PFI.
 511 We have identified giant seabed polygons covering the widest area ever found on Earth, with a surface of
 512 approximately 55000 km², and even up to 75000 km² taking into account those which do not reach the seafloor
 513 in the centre and the eastern Grenada Basin. Moreover, the western extent of the PFS area is limited by our
 514 investigation area but we suspect that most of the Aves Ridge and even its western flank is concerned.

515 The horizon depths, seabed and thickness morphologies are very different in the NGB and the SGB, which
 516 is consistent with their respective and very different geodynamic histories. The NGB underwent repeated

517 episodes of uplift (including aerial exposures at some places) and subsidence although the SGB is on a
 518 continuous state of subsidence since Eocene. They are both subsiding since middle Pliocene but at different
 519 rates.

520 Surprisingly, different orientations of polygons have been evidenced in both domains. The polygons are
 521 very regular in the north, whereas they are more elongated in the south. The centre-to-centre method applied
 522 to seabed polygons provided major orientations of extension needed for polygons to initiate. In the NGB minor
 523 axes are oriented N40°, indicating a general NE-SW extension of the upper part of the sedimentary cover. This
 524 could indicate that the backarc basin is currently submitted to similar processes than the forearc. In the SGB,
 525 minor axes are progressively turning towards the south, pointing out the actual maximum subsidence point.

526 In both cases, these observations imply that the development of PFS at the seabed could thus be indicative
 527 of the present-day strain state within the upper sedimentary column. Further investigations, including extensive
 528 seismic acquisitions and sampling, must be considered in order to completely map the extent of both active
 529 and fossil/buried intervals in the entire Aves Ridge area as PFI could be a marker of both actual or passed
 530 strain states within affected intervals, which is of high interest for the characterization of tectonic contexts.

531 **Aknowledments:**

532 This work was supported by the INSU TelluS-SYSTER grant call 2017, the GAARAnti project (ANR-17-
 533 CE31-0009), the GARANTI Cruise (2017). We are indebted to Saba Bank Resources N.V. and managing
 534 director Clark Gomes-Casseres for the provision of seismic lines of the Saba Bank. We gratefully thank the
 535 captain and crew of *R/V L'Atalante*, as well as the technical staff of Genavir for having successfully completed
 536 the acquisition of seismic data and dredge samples during the GARANTI cruise
 537 (<https://doi.org/10.17600/17001200>). Multichannel seismic processing was performed with Geovation
 538 software of CGG and Seismic Unix. All geophysical data and GARANTI cruise data are available on demand
 539 at SISMER (www.ifremer.fr/sismer/).
