121	Abstract: Total daily energy expenditure ("total expenditure", MJ/d) reflects daily energy needs
122	and is a critical variable in human health and physiology, yet it is unclear how daily expenditure
123	changes over the life course. Here, we analyze a large, globally diverse database of total
124	expenditure measured by the doubly labeled water method for males and females aged 8 days to
125	95 yr. We show that total expenditure is strongly related to fat free mass in a power-law manner
126	and identify four distinct metabolic life stages. Fat free mass-adjusted daily expenditure
127	accelerates rapidly in neonates (0-1yr) to ~46% above adult values at ~1 yr, declines slowly
128	throughout childhood and adolescence (1-20 yr) to adult levels at ~20 yr, remains stable in
129	adulthood (20-60 yr) even during pregnancy, and declines in older adults (60+ yr). These
130	changes in total expenditure shed new light on human development and aging and should help
131	shape nutrition and health strategies across the lifespan.
132	
133	One Sentence Summary: Expenditure varies as we age, with four distinct metabolic life stages
134	reflecting changes in behavior, anatomy, and tissue metabolism.
135	
136	Main Text: All of life's essential tasks, from development and reproduction to maintenance and
137	movement, require energy. Total expenditure is thus fundamental to understanding both daily
138	nutritional requirements and the body's investment among activities. Yet we know surprisingly
139	little about the determinants of total expenditure in humans or how it changes over the lifespan.
140	Most large (n>1,000) analyses of human energy expenditure have been limited to basal

141 expenditure, the metabolic rate at rest (1), which accounts for only a portion (usually ~50-70%)

142 of total expenditure, or have estimated total expenditure from basal expenditure and daily

143 physical activity (2-5). Measurements of total expenditure in humans during daily life, outside of

the laboratory, became possible in the 1980's with the advancement of the doubly labeled water method, but doubly labeled water studies to date have been limited in sample size (n < 600), geographic and socioeconomic representation, and/or age (*6-9*).

147 Body composition, size, and physical activity change over the life course, often in 148 concert, making it difficult to parse the determinants of energy expenditure. Total expenditure 149 increases with age as children grow (10), but the relative effects of increasing physical activity 150 (11-13) and age-related changes in tissue-specific metabolic rates, as have been reported for the 151 brain (14), are unclear. Total and basal expenditure increase from childhood through puberty, but 152 much of this increase is attributable to increased fat free mass, and the role of endocrine or other 153 effects is uncertain (15). The decline in total expenditure beginning in the sixth decade of life 154 corresponds with a decline in fat free mass (9) and "physical activity level", PAL (the ratio of 155 total/basal expenditure), but may also reflect age-related reductions in organ metabolism.

156 We investigated the effects of age, body composition, and sex on total expenditure and its 157 components, using a large (n = 6.421; 64% female), geographically and economical diverse (n =158 29 countries) database of doubly labeled water measurements for subjects aged eight days to 95 159 years (16), calculating total expenditure from isotopic measurements using a single, validated 160 equation for all subjects (17). Basal expenditure, measured via indirect calorimetry, was 161 available for a n = 2,008 subjects, and we augmented the dataset with additional published 162 meaures of basal expenditure in neonates and doubly labeled water-mesaured total expenditure in 163 pregnant and post-partum women (Methods; Table S1).

We found that both total and basal expenditure increased with fat free mass in a powerlaw manner (TEE= 0.677FFM<sup>0.708</sup>, r<sup>2</sup>=0.83 Figures 1, S1, S2, Table S1). Thus, body size, particularly fat free mass, accounted for most (83%) of the variation in daily expenditure,

167 requiring us to adjust for body size in subsequent analyses of expenditure across subjects and 168 cohorts to isolate potential effects of age, sex, and other factors. Notably, analyses indicated an 169 exponent <1, meaning that the ratio of energy expenditure/mass does not adequately control for 170 body size because the ratio inherently trends lower for larger individuals (Figure S1 (18)). 171 Instead, we used regression analysis to control for body size (18). A general linear model with 172 *In*-transformed values of energy expenditure (total or basal), fat free mass, and fat mass in adults 173 20-60 y (Table S2) was used to calculate residual energy expenditures for each subject. We 174 converted these residuals to "adjusted" expenditures for clarity in discussing age-related 175 changes: 100% indicates an expenditure that matches the expected value given the subject's fat 176 free mass and fat mass, 120% indicates an expenditure 20% above expected, etc. (Methods). 177 Using this approach, we also calculated the portion of adjusted total expenditure attributed to 178 basal expenditure (Figure 2D; Methods). Segmented regression analysis of (Methods) revealed 179 four distinct phases of adjusted (or residual) total and basal expenditure over the lifespan. 180 <u>Neonates (0 to 1 y)</u>: Neonates in the first month of life had size-adjusted energy expenditures 181 similar to adults, with adjusted total expenditure of  $99.0 \pm 17.2\%$  (n = 35) and adjusted basal 182 expenditure of  $78.1 \pm 15.0\%$  (n = 34; Figure 2). Both measures increased rapidly in the first year. 183 In segmented regression analysis, adjusted total expenditure rose  $84.7 \pm 7.2\%$  per year from birth 184 to a break point at 0.7 years (95% CI: 0.6, 0.8); a similar rise (75.5  $\pm$  5.6%) and break point (1.0 185 y, 95% CI: 0.9, 1.1) were evident in adjusted basal expenditure (Table S4). For subjects between 186 9 and 15 months, adjusted total and basal expenditures were nearly ~50% elevated compared to 187 adults (Figure 2).

*Juveniles (1 to 20 y)*: Total and basal expenditure, along with fat free mass, continued to increase
 with age throughout childhood and adolescence (Figure 1), but body size-adjusted expenditures

190 steadily declined. Adjusted total expenditure declined at a rate of  $-2.8 \pm 0.1\%$  per year from 191  $147.8 \pm 22.6\%$  for subjects 1 - 2 y (n = 102) to  $102.7 \pm 18.1\%$  for subjects 20 - 25 y (n = 314; 192 Tables S2, S4). Segmented regression analysis identified a breakpoint in adjusted total 193 expenditure at 20.5 y (95% CI: 19.8, 21.2), after which it plateaued at adult levels (Figure 2). A 194 similar decline (-3.8  $\pm$  0.2% per year) and break point (18.0 y, 95% CI: 16.8, 19.2) were evident 195 in adjusted basal expenditure (Figure 2, Text S1, Table S4). No pubertal increases in adjusted 196 total or basal expenditure were evident among subjects 10 - 15 y. In multivariate regression for 197 subjects 1 to 20 y, males had a higher total expenditure and adjusted total expenditure (Tables 198 S2, S3), but sex had no detectable effect on the rate of decline in adjusted total expenditure with 199 age (sex:age interaction p=0.30).

200 Adults (20 to 60 y): Total and basal expenditure and fat free mass were all stable from age 20 to 201 60 (Figure 1, 2; Tables S1, S2; Text S1). Sex had no effect on total expenditure in multivariate 202 models with fat free mass and fat mass, nor in analyses of adjusted total expenditure (Tables S2, 203 S4). Adjusted total and basal expenditures were stable even during pregnancy, the elevation in 204 unadjusted expenditures matching those expected from the gain in mothers' fat free mass and fat 205 mass (Figure 2C). Segmented regression analysis identified a break point at 63.0 y (95% CI: 206 60.1, 65.9), after which adjusted TEE begins to decline. This break point was somewhat earlier 207 for adjusted basal expenditure (46.5, 95% CI: 40.6, 52.4), but the relatively small number of 208 basal measures for 45 - 65 y (Figure 2D) reduces our precision in determining this break point. 209 <u>Older adults (>60 y)</u>: At ~60 y, total and basal expenditure begin to decline, along with fat free 210 mass and fat mass (Figures 1, S3, Table S1). Declines in expenditure are not only a function of 211 reduced fat free mass and fat mass, however. Adjusted total expenditure declined by -0.7  $\pm 0.1\%$  per year, and adjusted basal expendiure fell at a similar rates (Figure 2, Figure S3, Text S1, Table
S4). For subjects in their nineties, adjusted TEE was ~26% below that of middle-aged adults.

214 In addition to providing empirical measures and predictive equations for total expenditure 215 from infancy to old age (Tables S1, S2), our analyses bring to light major changes in metabolic 216 rate across the life course. To begin, we can infer fetal metabolic rates from maternal measures 217 during pregnancy: if body size-adjusted expenditures were elevated in the fetus, then adjusted 218 expenditures for pregnant mothers, particularly late in pregnancy when the fetus accounts for a 219 substantial portion of a mother's weight, would be likewise elevated. Instead, the stability of 220 adjusted total and basal expenditures at  $\sim 100\%$  during pregnancy (Figure 2B) indicates that the 221 growing fetus maintains a fat free mass- and fat mass-adjusted metabolic rate similar to adults, 222 which is consistent with adjusted expenditures of neonates (both  $\sim 100\%$ ; Figure 2) in the first 223 weeks after birth. Total and basal expenditures, both absolute and size-adjusted values, then 224 accelerate rapidly over the first year. This early period of metabolic acceleration corresponds to a 225 critical period in early development in which growth often falters in nutritionally-stressed 226 populations (19). Increasing energy demands could be a contributing factor.

After rapid acceleration in total and basal expenditure during the first year, adjusted expenditures progressively decline thereafter, reaching adult levels at ~20 yr. Elevated adjusted expenditures in this life stage may reflect the metabolic demands of growth and development. Adult expenditures, adjusted for body size and composition, are remarkably stable, even during pregnancy and post-partum. Declining metabolic rates in older adults could increase the risk of weight gain. However, neither fat mass nor percentage increased in this period (Figure S3), consistent with the hypothesis that energy intake is coupled to expenditure (*20*).

Following previous studies (21-25), we calculated the effect of organ size on basal 234 235 expenditure over the lifespan (Methods). At rest, the tissue-specific metabolic rates (Watts/gram) 236 of the heart, liver, brain, and kidneys are much greater than those of the muscles and other lean 237 tissue or fat (21-25). Organs with a high tissue-specific metabolic rate, particularly the brain and 238 liver, account for a greater proportion of fat free mass in young individuals, and thus organ-based 239 basal expenditure, estimated from organ size and tissue-specific metabolic rate, follows a power-240 law relationship with fat free mass, roughly consistent with observed basal expenditures 241 (Methods, Figure S6). Still, observed basal expenditure exceeded organ-based estimates by 242  $\sim$ 30% in early life (1 – 20 y) and was  $\sim$ 20% lower than organ-based estimates in subjects over 60 243 y (Figure S6), consistent with previous work indicating that tissue-specific metabolic rates are 244 elevated in children and adolescents (22, 24) and reduced in older adults (21, 23, 25). 245 We investigated the contributions of daily physical activity and changes in tissue-specific 246 metabolic rate to total and basal expenditure using a simple model with two components: activity 247 and basal expenditure (Figure 3; Meethods). Activity expenditure was modeled as a function of 248 physical activity and body mass, assuming activity costs are proportional to weight, and could 249 either remain constant at adult levels over the lifespan or follow the trajectory of daily physical 250 activity measured via accelerometry, peaking at 5 - 10 y and declining thereafter (11, 26, 27) 251 (Figure 3). Similarly, basal expenditure was modeled as a power function of fat free mass (consistent with organ-based BEE estimates; Methods) multiplied by a "tissue specific 252 253 metabolism" term, which could either remain constant at adult levels across the lifespan or 254 follow the trajectory observed in adjusted basal expenditure (Figure 2). For each scenario, total

255 expenditure was modeled as the sum of activity and basal expenditure (Methods).

256 Models that hold physical activity or tissue-specific metabolic rates constant over the 257 lifespan do not reproduce the observed patterns of age-related change in absolute or adjusted 258 measures of total or basal expenditure (Figure 3). Only when age-related changes in physical 259 activity and tissue-specific metabolism are included does model output match observed 260 expenditures, indicating that variation in both physical activity and tissue-specific metabolism 261 contribute to total expenditure and its components across the lifespan. Elevated tissue-specific 262 metabolism in early life may be related to growth or development (22, 24). Conversely, reduced 263 expenditures in later life may reflect a decline in organ level metabolism (23, 25, 28). 264 Metabolic models of life history commonly assume continuity in tissue-specific 265 metabolism over the life course, with cellular metabolic rates increasing in a power-law manner (Energy = aMass<sup>b</sup>) and the energy available for growth during the juvenile period made available 266 267 for reproduction in adults (29, 30). Measures of humans here challenge this view, with size 268 adjusted metabolism elevated ~50% in childhood compared to adults (including pregnant 269 females), and  $\sim 25\%$  lower in the oldest subjects. It remains to be determined whether these 270 fluctuations occur in other species. In addition to affecting energy balance, nutritional needs, and 271 body weight, these metabolic changes present a potential target for clinical investigation into the 272 kinetics of disease, pharmaceutical activity, and healing, processes intimately related to 273 metabolic rate. Further, there is considerable metabolic variation among individuals, with TEE 274 and its components varying more than  $\pm 20\%$  even when controlling for fat free mass, fat mass, 275 sex, and age (Figure 1, 2, Table S2). Elucidating the processes underlying metabolic changes 276 across the life course and variation among individuals may help reveal the roles of metabolic 277 variation in health and disease.

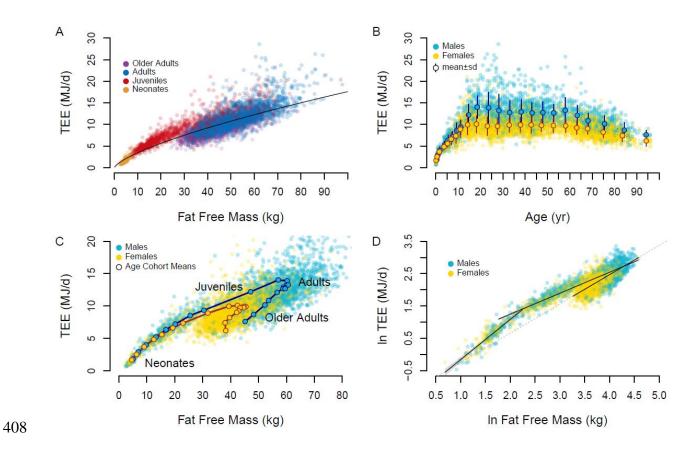

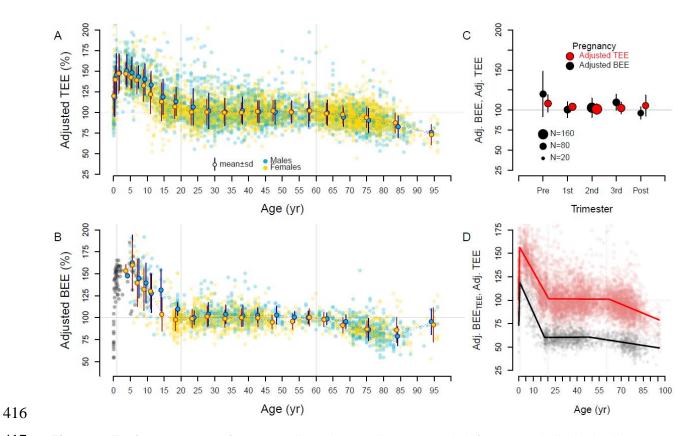

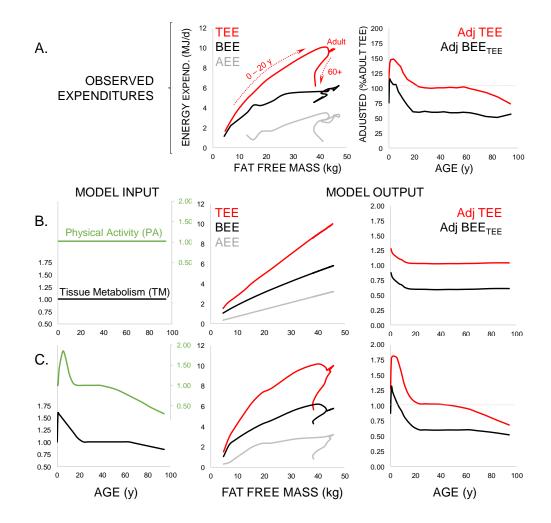

Figure 1. A. Total expenditure (TEE) increases with fat free mass in a power-law manner, but age groups cluster about the trend line differently. B. Total expenditure rises in childhood, is stable through adulthood, and declines in older adults. Means±sd for age-sex cohorts are shown. C. Age-sex cohort means show a distinct progression of total expenditure and fat free mass over the life course. D. Neonate, juveniles, and adults exhibit distinct relationships between fat free mass and expenditure. The dashed line, extrapolated from the regression for adults, approximates the regression used to calculate adjusted total expenditure.

417 Figure 2. Fat free mass- and fat mass-adjusted expenditures over the life course. Individual subjects and 418 age-sex cohort mean ± SD are shown. For both total (Adj. TEE) (A) and basal (Adj. BEE) expenditure (B), 419 adjusted expenditures begin near adult levels (~100%) but guickly climb to ~150% in the first year. 420 Adjusted expenditures decline to adult levels ~20y, then decline again in older adults. Basal expenditures 421 for infants and children not in the doubly labeled water database are shown in gray. C. Pregnant mothers 422 exhibit adjusted total and basal expenditures similar to non-reproducing adults (Pre: prior to pregnancy; 423 Post: 27 weeks post-partum). D. Segmented regression analysis of adjusted total (red) and adjusted 424 basal expenditure (calculated as a portion of total; Adj. BEE<sub>TEE</sub>; black) indicates a peak at  $\sim 1$  y, adult 425 levels at ~20 y, and decline at ~60 y (see text).

426

427 Figure 3. Modeling the contribution of physical activity and tissue-specific metabolism to daily 428 expenditures. A. Observed total (TEE, red), basal (BEE, black), and activity (AEE, gray) expenditures 429 (Table S1) show age-related variation with respect to fat free mass (see Figure 1C) that is also evident in 430 adjusted values (Table S3; see Figure 2D). B. These age effects do not emerge in models assuming 431 constant physical activity (PA, green) and tissue-specific metabolic rate (TM, black) across the life course. 432 C. When physical activity and tissue-specific metabolism follow the life course trajectories evident from 433 accelerometry and adjusted basal expenditure, respectively, model output is similar to observed 434 expenditures.

### 450 Material and Methods

451 1. <u>Doubly Labeled Water Database</u>

452 Data were taken from IAEA Doubly Labelled Water (DLW) Database, version 3.1,

453 completed April, 2020 (16). This version of the database comprises 6,743 measurements of total

- 454 expenditure using the doubly labeled water method. Of these, a total of 6,421 had valid data for
- total expenditure, fat free mass, fat mass, sex, and age. These 6,421 measurements were used in
- this analysis. This dataset was augmented with published basal expenditure measurements for
- 457 n=136 neonates and infants (*31-36*) that included fat free mass and fat mass. Malnourished or

preterm infants were excluded. For sources that provided cohort means rather than individual
subject measurements (*33*, *36*) means were entered as single values into the dataset without
reweighting to reflect sample size. This approach resulted in 77 measures of basal expenditure,
fat free mass, and fat mass for n=136 subjects. We also added to the dataset published basal and
total expenditure measurements of n=141 women before, during, and after pregnancy (*37-39*)
that included fat free mass and fat mass. These measurements were grouped as pre-pregnancy, 1<sup>st</sup>
trimester, 2<sup>nd</sup> trimester, 3<sup>rd</sup> trimester, and post-partum for analysis.

465 In the doubly labeled water method (5), subjects were administered a precisely measured dose of water enriched in  ${}^{2}\text{H}_{2}\text{O}$  and  $\text{H}_{2}{}^{18}\text{O}$ . The subject's body water pool is thus enriched in 466 deuterium (<sup>2</sup>H) and <sup>18</sup>O. The initial increase in body water enrichment from pre-dose values is 467 468 used to calculate the size of the body water pool, measured as the dilution space for deuterium  $(N_d)$  and <sup>18</sup>O  $(N_o)$ . These isotopes are then depleted from the body water pool over time: both 469 isotopes are depleted *via* water loss, whereas  $^{18}$ O is also lost *via* carbon dioxide production. 470 Subtracting the rate (%/d) of deuterium depletion ( $k_d$ ) from the rate of <sup>18</sup>O depletion ( $k_o$ ), and 471 multiplying the size of the body water pool (derived from N<sub>d</sub> and N<sub>o</sub>) provided the rate of carbon 472 473 doxide production, rCO<sub>2</sub>. Entries in the DLW database include the original k and N values for 474 each subject, which were then used to calculate CO<sub>2</sub> using a common equation that has been 475 validated in subjects across the lifespan (17). The rate of CO<sub>2</sub> production, along with each 476 subject's reported food quotient, was then used to calculate energy expenditure (MJ/d) using the 477 Weir equation (40). We used the food quotients reported in the original studies to calculate total 478 energy expenditure from  $rCO_2$  for each subject.

The size of the body water pool, determined from N<sub>d</sub> and N<sub>o</sub>, was used to establish FFM,
using hydration constants for fat free mass taken from empirical studies. Other anthropometric

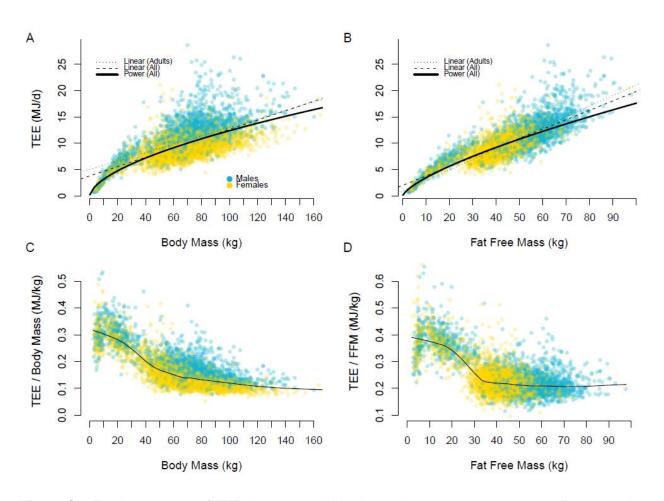

481 variables (age, height, body mass, sex) were measured using standard protocols. Fat mass was
482 calculated as (body mass) – (fat free mass).

#### 483 2. <u>Basal Expenditure, Activity Expenditure, and Physical Activityl Level (PAL)</u>

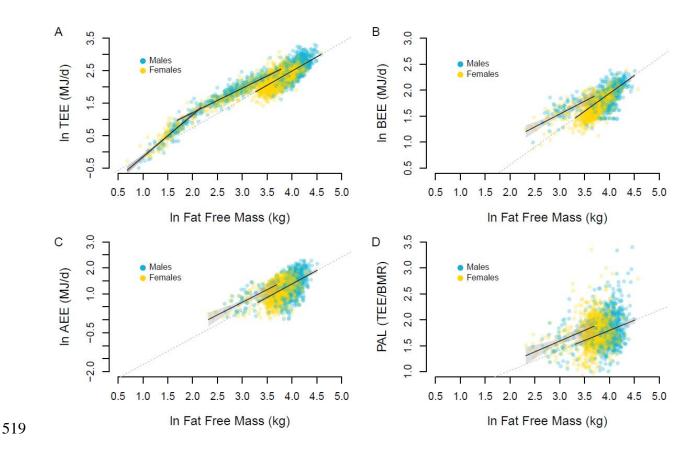

484 A total of 2,008 subjects in the database had associated basal expenditure, measured *via* 485 respirometry. For these subjects, we analyzed basal expenditure, activity expenditure, and 486 "physical activity level" (PAL). Activity expenditure was calculated as [0.9(total expenditure) – 487 (basal expenditure)] which subtracts basal expenditure and the assumed thermic effect of food 488 [estimated at 0.1(total expenditure)] from total expenditure. The PAL ratio was calculated as 489 (total expenditure)/(basal expenditure). As noted above, the basal expenditure dataset was 490 augmented with measurements from neonates and infants, but these additional measures do not 491 have associated total expenditure and could not be used to calculate activity expenditure or PAL.

#### 492 3. Predictive Models for Total, Basal, and Activity Expenditures and PAL

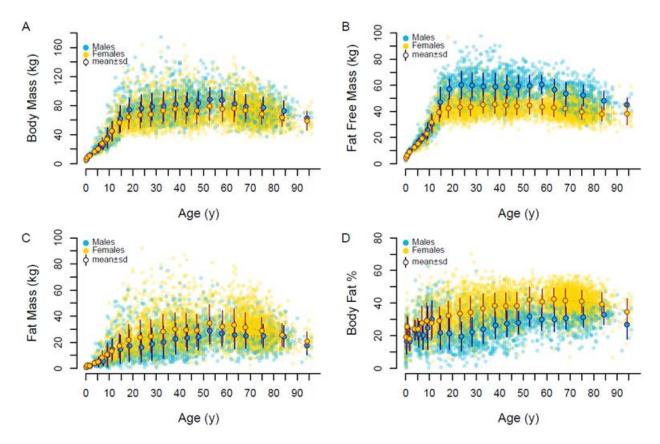

493 We used general linear models to regress measures of energy expenditure against 494 anthropometric variables. We used the base package in R version 4.0.3 (41) for all analyses. 495 General linear models were implemented using the lm function. These models were used to 496 develop predictive equations for total expenditure for clinical and research applications, and to 497 determine the relative contribution of different variables to total expenditure and its components. 498 Given the marked changes in metabolic rate over the lifespan (Figure 1, Figure 2) we calculated 499 these models separately for each life history stage: infants (0 - 1 y), juveniles (1 - 20 y), adults 500 (20 - 60 y), and older adults (60 + y). These age ranges were identified using segmented 501 regression analysis. Results of these models are shown in Table S2.

503 Figure S1. Total expenditure (TEE) increases with body size in a power-law manner. For the entire 504 dataset (n = 6,407): A. the power-law regression for total body mass ( $InTEE = 0.593 \pm 0.004$  InMass – 505  $0.214 \pm 0.018$ , p < 0.001, adj. r<sup>2</sup> = 0.73, model std. err. = 0.223, df = 6419) is less predictive than the 506 regression for **B.** fat free mass (*In*TEE =  $0.708 \pm 0.004$  *In*FFM -  $0.391 \pm 0.015$ , p < 0.001, adj. r<sup>2</sup> = 0.83, 507 model std. err. = 0.176, df = 6419). For both body mass and fat free mass regressions, power-law 508 regressions outperform linear models, particularly at the smallest body sizes. For all models, for both 509 body mass and fat free mass, children have elevated total expenditure, clustering above the trend line. 510 Children also exhibit elevated basal and activity expenditures (Figure S2). Power-law regressions have 511 an exponent < 1.0, and linear regressions (dashed: linear regression through all data; dotted: linear 512 regression through adults only) have a positive intercept, indicating that simple ratios of C. (total 513 expenditure)/(body mass) or D. (total expenditure)/(fat free mass) do not adequately control for 514 differences in body size (18) as smaller individuals will tend to have higher ratios. Lines in C and D are 515 lowess with span 1/6. In body mass regressions (panel A, power and linear models) and the ratio of (total 516 expenditure)/(body mass) (C), adult males cluster above the trend line while females cluster below due to 517 sex differences in body composition. In contrast, males and females fit the fat free mass regressions (B) 518 and ratio (D) equally well.

520 Figure S2. Infants and children exhibit different relationships between fat free mass and expenditure and 521 the PAL ratio. A: For total expenditure (TEE), regressions for infants (age <1 y, left regression line) and 522 adults (right regression line) intersect for neonates, at the smallest body size. However, the slopes differ, 523 with the infants' regression and 95% CI (gray region) falling outside of that for adults (age 20 - 60 y, 524 extrapolated dashed line). Juvelines (age 1 - 20 y, middle regression line) are elevated, with a regression 525 outside the 95% CI of adults. Juvenile (1 - 20 y) regressions (with 95%CI) are also elevated for basal 526 expenditure (BEE) (B), activity expenditure (AEE) (C), and PAL (D) compared to adults (20 - 60 y). Sex 527 differences in expenditure (A-D) are attributable to differences in fat free mass. Note that total and basal 528 expenditures are measured directly. Activity expenditure is calculated as (0.9TEE - BEE), and PAL is 529 calculated as (TEE/BEE); see Methods.

**Figure S3.** Changes in body composition over the lifespan: **A.** Body mass; **B.** Fat free mass; **C.** Fat Mass;

<sup>532</sup> and **D.** Body fat percentage.

533 4. Adjusted Expenditures

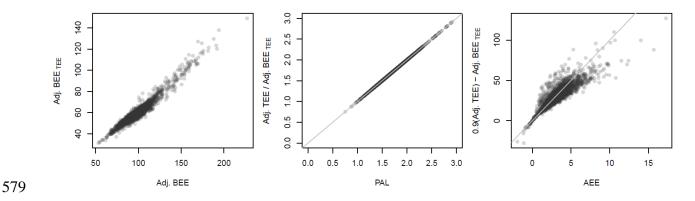

534 We used general linear models with fat free mass and fat mass in adults (20 - 60 y) to 535 calculate adjusted total expenditure and adjusted basal expenditure. The 20 - 60 y age range was 536 used as the basis for analyses because segmented regression analysis consistently identified this 537 period as stable with respect to size-adjusted total expenditure (see below). 538 We used models 2 and 5 in Table S2, which have the form  $ln(Expenditure) \sim ln(FFM) +$ 539 ln(Fat Mass) and were implemented using the lm function in base R version 4.0.3 (41). We 540 used *ln*-transformed variables due to the inherent power-law relationship between body size and 541 both total and basal expenditure (ref. 2; see Figure 1, Figure S1). Predicted values for each 542 subject, given their fat free mass and fat mass, were calculated from the model using the 543 pred () function; these *ln*-transformed values were converted back into MJ as exp(Predicted). 544 Residuals for each subject were calculated as (Observed – Predicted) expenditure, and were then 545 used to calculate adjusted expenditures as: 546 Adjusted Expenditure = 1 + Residual / Predicted[1] 547 The advantage of expressing residuals as a percentage of the predicted value is that it allows us 548 to compare residuals across the range of age and body size in the dataset. Raw residuals (MJ) do 549 not permit direct comparison because the relationship between size and expenditure is 550 heteroscedastic; the magnitude of residuals increases with size (see Figure S1). Ln-transformed 551 residuals (lnMJ) avoid this problem but are more difficult to interpret. Adjusted expenditures, 552 used here, provide an easily interpretable measure of deviation from expected values. An 553 adjusted expenditure value of 100% indicates that a subject's observed total or basal expenditure 554 matches the value predicted for their fat free mass and fat mass, based on the general linear

555 model derived for adults. An adjusted expenditure of 120% indicates an observed total or basal

expenditure value that exceeds the predicted value for their fat free mass and fat mass by 20%.
Similarly, an adjusted expenditure of 80% means the subject's measured expenditure was 20%
lower than predicted for their fat free mass and fat mass using the adult model. Adjusted total
expenditure and adjusted basal expenditure values for each age-sex cohort are given in Table S3.
Within each metabolic life history stage we used general linear models (1m function in R) to
investigate the effects of sex and age on adjusted total and basal expenditure.

This same approach was used to calculate adjusted basal expenditure as a proportion of total expenditure (Figure 2D), hereafter termed adjusted  $BEE_{TEE}$ . Residual<sub>BEE-TEE</sub>, the deviation of observed basal expenditure from the adult total expenditure regression (eq. 2 in Table S2), was calculated as (Observed Basal Expenditure – Predicted Total Expenditure) and then used to calculate adjusted  $BEE_{TEE}$  as

567 Adjusted  $BEE_{TEE} = 1 + Residual_{BEE-TEE} / Predicted Total Expenditure$ [2] 568 When adjusted  $BEE_{TEE} = 80\%$ , observed basal expenditure is equal to 80% of predicted total 569 expenditure given the subject's fat free mass and fat mass. Adjusted  $BEE_{TEE}$  is equivalent to adjusted basal expenditure (Figure S4) but provides some analytical advantages. The derivation 570 571 of adjusted BEE<sub>TEE</sub> approach applies identical manipulations to observed total expenditure and 572 observed basal expenditure and therefore maintains them in directly comparable units. The ratio 573 of (adjusted total expenditure)/(adjusted basal expenditure) is identical to the PAL ratio of (total 574 expenditure)/(basal expenditure), and the difference (0.9adjusted total expenditure- adjusted 575 basal expenditure) is proportional to activity expenditure (Figure S4). Plotting adjusted total 576 expenditure and adjusted BEE<sub>TEE</sub> over the lifespan (Figure 2D) therefore shows both the relative 577 magnitudes of total and basal expenditure and their relationship to one another in comparable 578 units.

**Figure S4.** Left: Adjusted  $BEE_{TEE}$  corresponds strongly to adjusted basal expenditure (Adj. BEE). <u>Center:</u> The ratio of adjusted total expenditure (adj. TEE) to adjusted  $BEE_{TEE}$  is identical to the PAL ratio. <u>Right:</u> The difference (0.9adjusted total expenditure – adjusted  $BEE_{TEE}$ ) is proportional to activity energy expenditure (AEE). Gray lines: center panel: y = x, right panel: y = 10x.

#### 584 5. <u>Segmented Regression Analysis</u>

585 We used segmented regression analysis to determine the change points in the relationship 586 between adjusted expenditure and age. We used the Segmented (version 1.1-0) package in R 587 (42). For adjusted total expenditure, we examined a range of models with 0 to 5 change points, 588 using the npsi= term in the segmented () function. This approach does not specify the 589 location or value of change points, only the number of them. Each increase in the number of 590 change points from 0 to 3 improved the model adj.  $R^2$  and standard error considerably. 591 Increasing the number of change points further to 4 or 5 did not improve the model, and the 592 additional change points identifed by the segmented () function fell near the change points for 593 the 3-change point model. We therefore selected the 3-change point model as the best fit for 594 adjusted total expenditure in this dataset. Segmented regression results are shown in Table S4. A 595 similar 3-change point segmented regression approach was conducted for adjusted basal 596 expenditure (Figure S4) and adjusted BEE<sub>TEE</sub> (Figure 2D). We note that the decline in adjusted 597 basal expenditure and adjusted BEE<sub>TEE</sub> in older adults begins earlier (as identified by segmented

regression analysis) than does the decline in adjusted total expenditure among older adults. However, this difference may reflect the relative paucity of basal expenditure measurements for subjects 40 - 60 y. Additional measurements are needed to determine whether the decline in basal expenditure does in fact begin earlier than the decline in total expedinture. Here, we view the timing as essentially coincident and interpret the change point in adjusted total expenditure (~60 y), which is determined with a greater number of measurements, as more accurate and reliable.

605 Having established that 3 break points provided the best fit for this dataset, we examined 606 whether changes in the age range used to calculate adjusted total energy expenditure affected the 607 age break-points identified by segmented regression. When the age range used to calculate 608 adjusted expenditure was set at 20 - 60 y, the set of break point (95% CI) was: 0.69 (0.61-0.76), 609 20.46 (19.77-21.15), 62.99 (60.14-65.85). When the age range was expanded to 15 - 70 y, break 610 points determined through segmented regression were effectively unchanged: 0.69 (0.62 - 0.76), 611 21.40 (20.60-22.19), 61.32 (58.60-64.03). Break points were also unchanged when the initial age 612 range for adjusted expenditure was limited to 30 - 50 y: 0.69 (0.62-0.77), 20.56 (19.84-21.27), 613 62.85 (59.97-65.74).

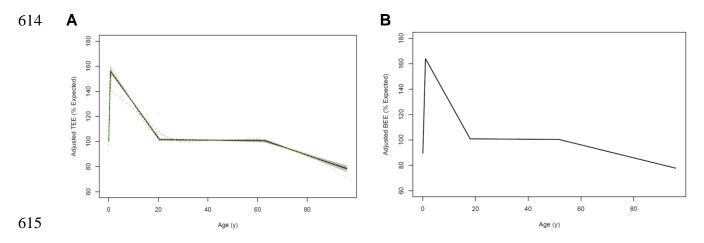

Figure S5. Segmented regression analysis of adjusted TEE (A) and adjusted BEE (B). In both panels, the black line and gray shaded confidence region depicts the 3 change-point regression. For adjusted TEE, segmented regressions are also shown for 2 change points (red), 4 change points (yellow), and 5 change points (green). Segmented regression statistics are given in Table S4.

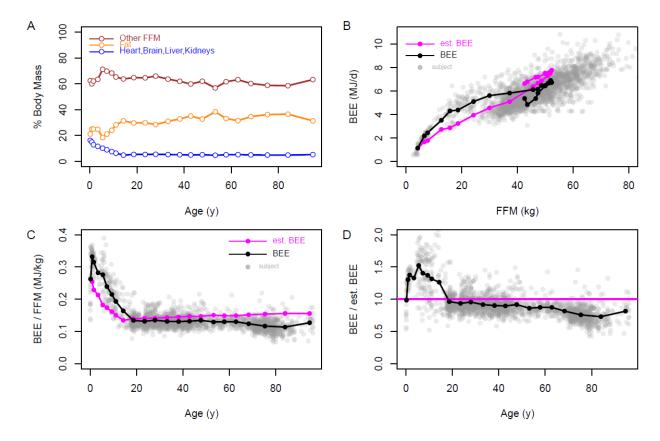

### 620 6. Organ Size and Basal Expenditure

621 Measuring the metabolic rate of individual organs is notoriously challenging, and the 622 available data come from only a small number of studies. The available data indicate that organs differ markedly in their mass-specific metabolic rates at rest (43). The heart (1848 kJ kg<sup>-1</sup> d<sup>-1</sup>), 623 liver (840 kJ kg<sup>-1</sup> d<sup>-1</sup>), brain (1008 kJ kg<sup>-1</sup> d<sup>-1</sup>), and kidneys (1848 kJ kg<sup>-1</sup> d<sup>-1</sup>) have much greater 624 mass-specific metabolic rates at rest than do muscle (55 kJ kg<sup>-1</sup> d<sup>-1</sup>), other lean tissue (50 kJ kg<sup>-1</sup> 625  $d^{-1}$ ), and fat (19 kJ kg<sup>-1</sup>  $d^{-1}$ ). Consequently, the heart, liver, brain, and kidneys combined account 626 627 for  $\sim 60\%$  of basal expenditure in adults (21, 22, 44, 45). In infants and children, these 628 metabolically active organs constitute a larger proportion of body mass. The whole body mass-629 specific basal expenditure [i.e., (basal expenditure)/(body mass), or (basal expenditure)/(fat free 630 mass)] for infants and children is therefore expected to be greater than adults' due to the greater 631 proportion of metabolically active organs early in life adults (21, 22, 44, 45). Similarly, reduced 632 organ sizes in elderly subjects may result in declining basal expenditure (21). 633 To examine this effect of organ size on basal expenditure in our dataset, we used 634 published references for organ size to determine the mass of the metabolically active organs 635 (heart, liver, brain, and kidneys) as a percentage of body mass or fat free mass for subjects 0 - 12y (22, 44-46), 15 to 60 y (21, 22), and 60 to 100 y (21, 47). We used these relationships to 636 637 estimate the combined mass of the metabolically active organs (heart, liver, brain, kidneys) for 638 each subject in our dataset. We then subtracted the mass of the metabolically active organs from 639 measured fat free mass to calculate the mass of "other fat free mass". These two measures, along 640 with measured fat mass, provided a three-compartment model for each subject: metabolically 641 active organs, other fat free mass, and fat (Figure S6A).

642 Following previous studies (21-25), we assigned mass-specific metabolic rates to each 643 compartment and estimated basal expenditure for each subject. We used reported mass-specific 644 metabolic rates for the heart, liver, brain, and kidneys (see above; (43)) and age-related changes 645 in the proportions of these organs for subjects 0 - 12 y(22, 46), 15 to 60 y (21-25), and 60 to 100 646 y (21, 23, 25, 47) to calculate an age-based weighted mass-specific metabolic rate for the 647 metabolically active organ compartment. We averaged the mass-specific metabolic rates of resting muscle and other lean tissue (see above; (21, 22)) and assigned a value of 52.5 kJ kg<sup>-1</sup> d<sup>-1</sup> 648 to "other fat free mass", and we used a mass-specific metabolic rate of 19 kJ kg<sup>-1</sup> d<sup>-1</sup> for fat. 649 650 Results are shown in Figure S6. Due to the greater proportion of metabolically active 651 organs in early life, the estimated basal expenditure from the three-compartment model follows a power-law relationship with FFM (using age cohort means,  $BEE = 0.38 \text{ FFM}^{0.75}$ ; Figure S6B) 652 653 that is similar to that calculated from observed basal expenditure in our dataset (see Table S2 and 654 7. Modeling the Effects of Physical Activity and Tissue Specific Metabolism, below). Estimated 655 BEE from the three-compartment model produced mass-specific metabolic rates that are 656 considerably higher for infants and children than for adults and roughly consistent with observed 657 age-related changes in (basal expenditure)/(fat free mass) (Figure S6C). Thus, changes in organ 658 size can account for much of the variation in basal expenditure across the lifespan observed in 659 our dataset.

Nonetheless, observed basal expenditure was ~30% greater early in life, and ~20% lower
in older adults, than estimated basal expenditure from the three-compartment model (Figure
S6D). The departures from estimated basal expenditure suggest that the mass-specific metabolic
rates of one or more organ compartments are considerably higher early in life, and lower late in
life, than they are in middle-aged adults, consistent with previous assessments (21-25). It is

notable, in this context, that observed basal expenditure for neonates is nearly identical to basal
expenditure estimated from the three-compartment model, which assumes adult-like tissue
metabolic rates (Figure S6B,C,D). Observed basal expenditure for neonates is thus consistent
with the hypothesis that the mass-specific metabolic rates of their organs are similar to those of
other adults, specifically the mother.

670

671 Figure S6. Organ sizes and BEE. A. The relative proportions of metabolically active organs (heart, 672 brain, liver, kidneys), other fat free mass (FFM), and fat changes over the life course. Age cohort means 673 are shown. B. Consequently, estimated basal expenditure (BEE) from the three-compartment model 674 increases with fat free mass (FFM) in a manner similar to observed basal expenditure, with C. greater 675 whole body mass-specific basal expenditure (BEE/FFM) early in life. D. Observed basal expenditure is 676 ~30% greater early in life, and ~20% lower after age 60 y, than estimated basal expenditure from the 677 three-compartment model (shown as the ratio of BEE/est.BEE). In panels B, C, and D, age-cohort means 678 for observed (black) and estimated (magenta) basal expenditure are shown.

679 7. Modeling the Effects of Physical Activity and Tissue Specific Metabolism

680 We constructed two simple models to examine the contributions of physical activity and 681 variation in tissue metabolic rate to total and basal expenditure. In the simplest version, we used 682 the observed relationship between basal expenditure and tat free mass for all adults 20 - 60 y 683 determined from linear regression of ln(basal expenditure) and ln(fat free mass) (untransformed regression equation: basal expenditure = 0.32 (fat free mass)<sup>0.75</sup>, adj.  $r^2 = 0.60$ , df = 1684, p < 684 685 0.0001) to model basal expenditure as Basal expenditure =  $0.32 \text{ TM}_{age}$  (fat free mass)<sup>0.75</sup> 686 [3] 687 The TM<sub>age</sub> term is tissue metabolic rate, a multiplier between 0 and 2 reflecting a relative 688 increase ( $TM_{age} > 1.0$ ) or decrease ( $TM_{age} < 1.0$ ) in organ metabolic rate relative that expected 689 from the power-law regression for adults. Note that, even when  $TM_{age} = 1.0$ , smaller individuals 690 are expected to exhibit greater mass-specific basal expenditure (that is, a greater basal 691 expenditure per kg body weight) due to the power-law relationship between basal expenditure 692 and fat free mass. Further, we note that the power-law relationship between basal expenditure 693 and fat free mass for adults is similar to that produced when estimating basal expenditure from 694 organ sizes (see Organ Size and Basal Expenditure, above). Thus, variation in TMage reflects 695 modeled changes in tissue metabolic rate *in addition* to power-law scaling effects, and also, in 696 effect, in addition to changes in basal expenditure due to age-related changes in organ size and 697 proportion. To model variation in organ activity over the lifespan, we either 1) maintained TM<sub>age</sub> 698 at adult levels ( $TM_{age} = 1.0$ ) over the entire lifespan, or 2) had  $TM_{age}$  follow the trajectory of 699 adjusted basal expenditure with age (Figure S8).

700 To incorporate effects of fat mass into the model, we constructed a second version of the 701 model in which basal expenditure was modeled following the observed relationship with FFM

[4]

Basal expenditure =  $0.32 \text{ TM}_{age}$  (fat free mass)<sup>0.7544</sup> (fat mass)<sup>0.0003</sup> 703 704 As with the fat free mass model (eq. 3), we either maintained  $TM_{age}$  at 1.0 over the life span or 705 modeled it using the trajectory of adjusted basal expenditure.

and fat mass for adults 20 - 60 y,

702

706 Activity expenditure was modeled as a function of physical activity and body mass 707 assuming larger indivduals expend more energy during activity. We began with activity 708 expenditure, calculated as [0.9(total expenditure) – (basal expenditure)] as described above. The observed ratio of (activity expenditure)/(fat free mass) for adults 20 - 60 y was 0.07 MJ d<sup>-1</sup> kg<sup>-1</sup>. 709 710 We therefore modeled activity expenditure as

711 Activity expenditure = 
$$0.07 \text{ PA}_{age}$$
 (fat free mass) [5]

712 To incorporate effects of fat mass, we constructed a second version using the ratio of (activity 713 expenditure)/(body weight) for adults 20 - 60y,

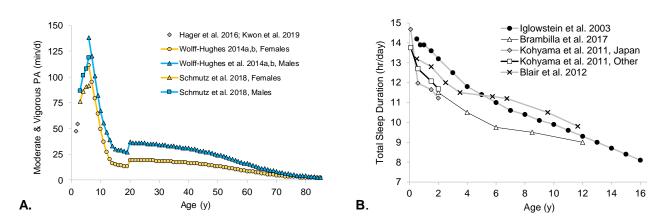

714 Activity expenditure = 
$$0.04 \text{ PA}_{age}$$
 (body weight) [6]

715 In both equations, PA<sub>age</sub> represents the level of physical activity relative to the mean value for 20 716 -60 y adults. PA<sub>age</sub> could either remain constant at adult levels (PA<sub>age</sub>=1.0) over the lifespan or 717 follow the trajectory of physical activity measured via accelerometry, which peaks between 5 -718 10 y, declines rapidly through adolescence, and then declines more slowly beginning at  $\sim$ 40 y 719 (11-13, 26, 27, 48-51). Different measures of physical activity (e.g., moderate and vigorous PA, 720 mean counts per min., total accelerometry counts) exhibit somewhat different trajectories over 721 the lifespan, but the patterns are strongly correlated; all measures show the greatest activity at 5-722 10 y and declining activity in older adults (Figure S7). We chose total accelerometry counts (11,

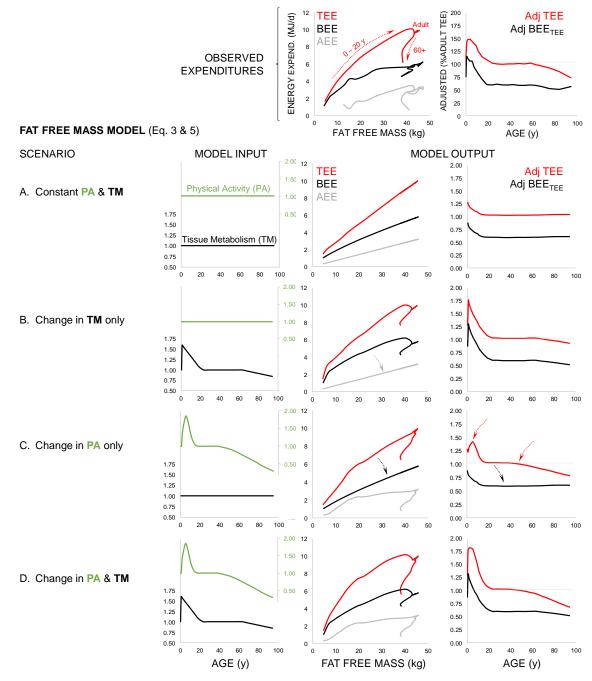

723 26), which sum all movement per 24-hour period, to model age-related changes in PA<sub>age</sub>. We
724 chose total counts because activity energy expenditure should reflect the summed cost of all
725 activity, not only activity at moderate and vigorous intensities. Further, the amplitude of change
726 in moderate and vigorous activity over the lifespan is considerably larger than the observed
727 changes in adjusted total expenditure or adjusted activity expenditure (Figure S10). Determining
728 the relative contributions of different measures of physical activity to total expenditure is beyond
729 the scope of the simple modeling approach here and remains an important task for future

research.

731

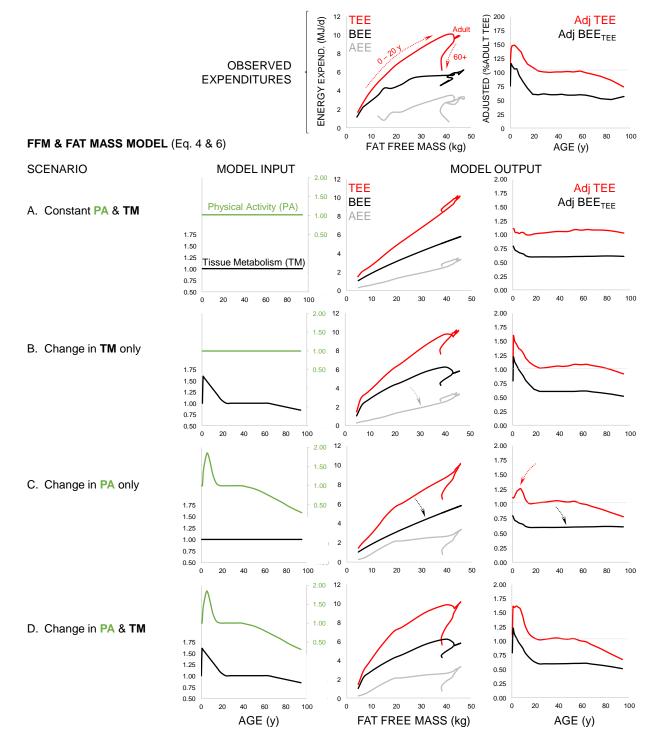

733 Figure S7. Modeling physical activity across the lifespan. A. Across studies and countries, 734 accelerometer-measured physical activity rises through infancy and early childhood, peaking between 5 735 and 10y before declining to adult levels in the teenage years (11-13, 26, 27, 48-51). Physical activity 736 declines again, more slowly, in older adults. The onset of decline in older adults varies somewhat across 737 studies, beginning between ~40 y and ~60 y. Here, physical activity is shown as minutes/day of moderate 738 and vigorous physical activity. Other measures (e.g., total accelerometer counts; mean counts/min, vector 739 magnitude) follow a similar pattern of physical activity over the life span (11, 26). B. The increase in 740 physical activity from 0 to ~10 y is mirrored by the steady decline in total daily sleep duration during this 741 period (52-55).

742

743 Figure S8. Results of the fat free mass model. Observed expenditures exhibit a marked age effect on the 744 relationship between expenditure and fat free mass that is evident in both absolute (Figure 1C) and 745 adjusted (Figure 2D) measures. A. If physical activity (PA) and cellular metabolism (TM) remain constant 746 at adult levels, age effects do not emerge from the model. B. When only TM varies, age effects emerge 747 for total expenditure (TEE) and basal expenditure (BEE), but not activity expenditure (AEE; gray arrow). 748 C. Conversely, if only physical activity varies age effects emerge for AEE and TEE but not BEE (black 749 arrows). Adjusted TEE also peaks later in childhood and declines earlier in adulthood (red arrows) than 750 observed. D. Varying both PA and TM gives model outputs similar to observed expenditures.

751

**Figure S9.** Results of the fat free mass and fat mass model. Model outputs are similar to those of the fat free mass model (Figure S8). The scenario that best matches the observed relationships between fat free mass, age, and expenditure is D, in which AEE is influenced by age-related variation in both physical activity and cellular metabolism. Abbreviations as in Fig S8.

#### 756 <u>8. Physical Activity, Activity Expenditure and PAL</u>

778

757 To further interrogate our simple model of expenditure and the contribution of physical 758 activity, we examined the agreement between accelerometery-measured physical activity, 759 adjusted activity expenditure, and modeled PAL over the lifespan. First, as noted in our 760 discussion of the simple expenditure model (see above; Figures 3, S8, S9), moderate and 761 vigorous physical activity and total accelerometry counts show a similar shape profile when 762 plotted against age, but moderate and vigorous physical activity shows a greater amplitude of 763 change over the lifespan (Figure S10). Moderate and vigorous physical activity reach a peak ~4-764 times greater than the mean values observed for 20 - 30 y men and women, far greater than the 765 amplitude of change in adjusted total expenditure.

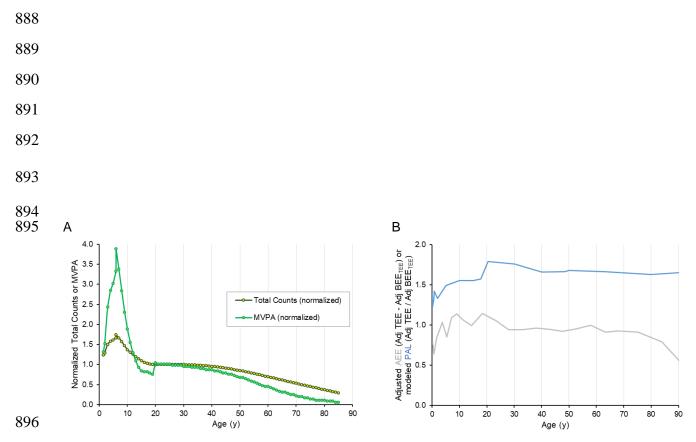

766 We used adjusted total and basal expenditures to model activity expenditure and PAL 767 over the lifespan for comparison with published accelerometry measures of physical activity. 768 Modeling activity expenditure and PAL was preferable because our dataset has no subjects less 769 than 3 y with measures of both total and basal expenditure, and only 4 subjects under the age of 6 770 y with both measures (Table S1). Using values of adjusted total expenditure and adjusted 771  $BEE_{TEE}$  (basal expenditure expressed as a percentage of total expenditure) for age cohorts from 772 Table S3 enabled us to model activity expenditure and PAL for this critical early period of 773 development, in which both physical activity and expenditure change substantially. We modeled 774 adjusted activity expenditure as [(adjusted total expenditure) – (adjusted  $BEE_{TEE}$ )] and PAL as 775 [(adjusted total expenditure) / (adjusted  $BEE_{TEE}$ )], which as we show in Figure S4 corelate 776 strongly with unadjusted measures of activity expenditure and PAL, respectively. 777 Modeled adjusted activity expenditure and PAL showed a somewhat different pattern of

change over the lifecoure than either total counts or moderate and vigorous activity measured via

779	accelerometry (Figure S10). Modeled activity expenditure was most similar to total counts, rising
780	through childhood, peaking between 10 and 20 y before falling to a stable adult level; the adult
781	level was stable from $\sim 30 - 75$ y before declining (Figure S10). Modeled PAL rose unevenly
782	from birth through age 20, then remained largely stable thereafter.
783	The agreement, and lack thereof, between the pattern of accelerometry-measured physical
784	activity and modeled activity expenditure and PAL must be assessed with caution. These
785	measures are from different samples; we do not have paired accelerometry and energy
786	expenditure measures in the present dataset. The life course pattern of accelerometry-measured
787	physical activity, particularly total counts, is broadly consistent with that of modeled activity
788	expenditure. However, more work is clearly needed to determine the effects of physical activity
789	and other factors to variation in activity expenditure and PAL over the lifecourse.
