5 **SUMMARY**

6
7 Seismic and magnetic observations have suggested the presence of a stably stratified layer atop
8 Earth's core. Such a layer could affect the morphology of the geomagnetic field and the evolu-
9 tion of the core, but the precise impact of this layer depends largely on its internal dynamics.
10 Among other physical phenomena, stratified layers host *internal gravity waves*, which can be
11 excited by adjacent convective motions. Internal waves are known to play an important role
12 on the large scale dynamics of the Earth's climate and on the long-term evolution of stars.
13 Yet, they have received relatively little attention in the Earth's outer core so far and deserve
14 detailed investigations in this context. Here, we make a first step in that direction by running
15 numerical simulations of internal gravity waves in a non-rotating spherical shell in which a
16 stratified layer lies on top of a convective region. We use a non-linear equation of state to
17 produce self-consistently such a two-layer system. Both propagating waves and global modes
18 coexist in the stratified layer. We characterise the spectral properties of these waves and find
19 that energy is distributed across a wide range of frequencies and length scales, that depends
20 on the Prandtl number. For the control parameters considered and in the absence of rotational
21 and magnetic effects, the mean kinetic energy in the layer is about 0.1% that of the convec-

22 tive region. Gravity waves produce perturbations in the gravity field that may fall within the
23 sensitivity limit of present-day instruments and could potentially be detected in available data.
24 We finally provide a road map for future, more geophysically realistic, studies towards a more
25 thorough understanding of the dynamics and impact of internal waves in a stratified layer atop
26 Earth's core.

27 **Key words:** core dynamics– stratified layer – internal waves – numerical simulations.

28 1 INTRODUCTION

29 Numerous studies support the existence of a stably stratified layer atop Earth's core. Observation-
30 based evidence for a stratification comes mostly from anomalous travel times of SmKS body
31 waves sampling the top of the core (Helfrich & Kaneshima, 2010; Kaneshima & Helfrich, 2013;
32 Kaneshima & Matsuzawa, 2015; Tang et al., 2015; Kaneshima, 2018) and from interpretations of
33 temporal fluctuations in the geomagnetic field (Buffett, 2014; Buffett et al., 2016). Several sce-
34 narios have been proposed for the formation of this layer. The outermost core may be thermally
35 stratified if the core mantle boundary (CMB) heat flow is subisentropic (Labrosse, 2015). Alterna-
36 tively, barodiffusion (Gubbins & Davies, 2013), accumulation of light materials emitted by inner
37 core crystallization (Moffatt & Loper, 1994; Bouffard et al., 2019), chemical interactions with the
38 mantle (Buffett & Seagle, 2010) or immiscibility between liquid Fe-Si and Fe-Si-O in core con-
39 ditions (Arveson et al., 2019) may form a stratified pool of light elements under the CMB over
40 long time scales. On the other hand, geochemical models of core formation (Rubie et al., 2011;
41 Jacobson et al., 2017), laboratory experiments of giant impacts (Landeau et al., 2016) and numer-
42 ical simulations of convective erosion of a chemically stratified layer (Bouffard et al., 2020) all
43 suggest that the layer may be an ancient chemical feature, formed at the same time as the core and
44 preserved up to the present day. The properties of the layer (thickness and stratification) inferred
45 from these various observations and models are sometimes contradictory and range from a thick
46 (up to 450 km) and strongly-stratified layer to a rather thin (100 km or less) and weakly-stratified
47 layer. A stratified layer atop Earth's core may affect the evolution of the core (Labrosse, 2015) and
48 the structure of the magnetic field generated by the geodynamo underneath (Christensen & Wicht,

2008; Nakagawa, 2011; Olson, Landeau & Reynolds, 2017; Gastine et al., 2020). However, the precise geophysical impacts of such a layer strongly depend on its exact structure, properties and internal dynamics, which remain largely unknown.

Even though stratification inhibits radial motions, stratified layers can have rich and complex dynamics. Several instabilities can develop in stratified environments under certain conditions, such as double diffusive convection when buoyancy is controlled by two physical fields with different molecular diffusivities (e.g. temperature and salt concentration, see for instance Schmitt, 1994 and Monville et al., 2019). Stratified layers can also host internal *gravity waves* (GW), which are the focus of the present study. GW are a type of waves that develops in stratified environments and for which gravity acts as a restoring force. They can be excited by an adjacent convective region (Couston et al., 2018a) or by large-scale tidal flows (Ogilvie & Lin, 2004), and propagate in the stratified layer, transporting energy and momentum. In oceanic, atmospheric and astrophysical sciences, it is well known that GW can profoundly affect the large-scale dynamics in various ways. In the Earth’s tropical stratosphere, GW drive a mean eastward/westward flow that reverses approximately every 28 months. This phenomenon, called the “quasi-biennial oscillation” (QBO), affects the entire climate system by modulating atmospheric circulation, gas distributions and seasonal weather patterns up to the poles (Baldwin et al., 2001). Similar internal wave-driven mean flows may contribute to the long-term angular momentum evolution of stars (Rogers et al., 2013; Fuller et al., 2014). Angular momentum transport by GW also enhances mixing of chemicals, which is often thought to be responsible for anomalous abundances of lithium and other elements at the surface of stars (Charbonnel & Talon, 2005). GW are also used in asteroseismology to probe the otherwise inaccessible cores of stars (Aerts, Christensen-Dalsgaard & Kurtz, 2010).

GW have received a marked attention in stars. Several authors performed numerical simulations of GW in the anelastic approximation or with fully compressible equations, either in a 2D equatorial plane (Rogers, Lin & Lau, 2012; Rogers et al., 2013; Horst et al., 2020) or in a full 3D rotating sphere (Alvan, Brun & Mathis, 2014; Edelmann et al., 2019). In the Earth’s core, the properties of GW have been calculated theoretically for a fully stratified outer core (Crossley & Rochester, 1978; Dintrans et al., 1999; Olson, 1977; Friedlander, 1987). The same authors dis-

77 cussed the potential existence of GW signatures in the Earth’s gravity field records, but attempts
78 to detect such signals have remained unsuccessful so far. This may be because the important role
79 played by the Lorentz and Coriolis forces in the Earth’s core brings further complexity by mod-
80 ulating GW and allowing for other types of waves to coexist (Braginsky, 1999). For instance,
81 Buffett (2014), Buffett et al. (2016) and Jaupart & Buffett (2017) show that MAC waves—that
82 arise from the interplay between Magnetic, Archimedean and Coriolis forces—could in theory ex-
83 plain both a 60 year fluctuation in the geomagnetic dipole and a time-dependent zonal flow at the
84 top of the core inferred from geomagnetic secular variation. Vidal & Schaeffer (2015) evaluated
85 the geomagnetic signatures of a stratified layer by looking at its effect on quasi-geostrophic inertial
86 modes in the core. However, these theoretical predictions for the properties and signatures of GW,
87 MAC waves and inertial modes have not yet been confirmed by 3D numerical simulations. As for
88 the dynamical effects of GW in the Earth’s core, several questions remain unexplored. Notably,
89 whether large-scale mean flows analogous to the Earth’s QBO are taking place in the Earth’s core
90 is unknown. The angular momentum transport by GW in stars (Rogers et al., 2013) also suggests
91 that GW in the core could deposit angular momentum on the CMB, which would affect the length
92 of day. Detecting unequivocal signatures of GW in the geomagnetic field, gravity data, length of
93 day or other observables would strengthen confidence in the existence of a stratified layer below
94 the CMB and offer another window on the dynamics of the Earth’s outer core by remotely probing
95 the local, physical properties.

96 Previous numerical simulations of GW excited in a self-consistent, two-layer system in non-
97 rotating and non-magnetic Cartesian geometries by Couston et al. (2017, 2018a, 2019) showed
98 that the waves dynamics are already very rich in simple geometries. There is thus a long way
99 ahead from these Cartesian physical studies towards geophysical applications to planetary cores
100 in which rotation and magnetic fields play a dominant role. This paper constitutes a first step in
101 that direction by extending the Couston studies to a non-rotating, non-magnetic, spherical shell,
102 the top half of which is stably stratified and lies on top of a turbulent convective region (figure 1).
103 While a layer that occupies half of the shell is certainly much larger than expected for the core,
104 a thick stratified layer is expected for Mercury (Christensen, 2006). In addition, a larger stratified

layer allows us to have well-developed GW in the layer for the control parameters accessible in the numerical simulations. We perform a first study of the non-rotating, non-magnetic case and provide tools and concepts for characterizing the properties of GW. These will be applicable to the rotating and magnetic cases in future studies. Therefore, this study should be considered as a proof of concept providing first interesting physical insights rather than a realistic study including all geophysically relevant ingredients. In this first step, neglecting rotation and magnetic effects allows us to reach turbulent regimes at a more moderate numerical expense and to conduct a systematic study by varying parameters. We also note that while rotational effects are dominant in most planetary cores, they may be of moderate or even negligible importance in some cases, including the Earth's primitive magma ocean (Maas & Hansen, 2019) and the outer cores of Mercury and Venus (Evonuk & Samuel, 2012). In all these contexts, stratified layers may be present (Ohtani, 1985; Christensen et al., 2006; Jacobson et al., 2017; Laneuville et al., 2018) and would thus be in contact with a convective region only marginally influenced by rotation. The results for a non-rotating sphere derived in the present paper may apply to such cases.

The paper is divided as follows. Section 2 presents the mathematical modeling and its numerical implementation. Section 3 provides a qualitative description of the excitation and morphology of waves in the stratified layer. The spectral properties of the waves are then analysed more quantitatively in section 4. In section 5, we quantify the energy transfer from the convective region to the waves, which allows us to evaluate potential geophysical signatures of the waves in section 6. The final section 7 summarizes our findings and provides a road map for future studies.

2 MATHEMATICAL AND NUMERICAL MODELING

2.1 Main equations

We consider the dynamics of an incompressible fluid in a 3D spherical shell with inner and outer radii r_i and r_o . In addition to the equation for mass conservation,

$$\nabla \cdot \mathbf{u} = 0, \quad (1)$$

130 we solve the Navier-Stokes equation for a Newtonian non-rotating fluid in the Boussinesq approx-
131 imation,

$$132 \quad \frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla) \mathbf{u} = -\frac{1}{\rho_0} \nabla \Pi + \nu \Delta \mathbf{u} - g(r) \frac{\delta \rho}{\rho_0} \mathbf{e}_r - \frac{1}{\tau(r)} \mathbf{u}, \quad (2)$$

133 where t , \mathbf{u} and Π are the time, velocity and dynamic pressure, respectively, ρ_0 a reference density
134 and $\delta \rho$ the density perturbation which depends only on the temperature. ν is the constant kinematic
135 viscosity, g the gravity is a linear function of the radius r ,

$$136 \quad g(r) = g_o \frac{r}{r_o} \quad (3)$$

137 and $-\mathbf{u}/\tau(r)$ is a damping term significant only close to the top boundary, used to prevent waves
138 reflections in one case, with τ a fixed characteristic time. The energy conservation equation is

$$139 \quad \frac{\partial T}{\partial t} + \mathbf{u} \cdot \nabla T = \kappa \nabla^2 T, \quad (4)$$

140 where T denotes the temperature and κ the constant thermal diffusivity.

141 To model a stratified layer at the top of the shell in contact with a convecting region under-
142 neath, two strategies are possible. Most studies so far have imposed the stratified layer through
143 a background temperature gradient that is positive (convectively unstable) in the bottom part and
144 negative (stable to convection) in the top part (Christensen, 2006; Stanley and Mohammadi, 2008;
145 Manglik, Wicht & Christensen, 2010; Nakagawa, 2015; Christensen, 2018; Olson, Landeau &
146 Reynolds, 2018; Mound et al., 2019). Instead, we assume a non-linear equation of state for the
147 density anomaly $\delta \rho$,

$$148 \quad \delta \rho / \rho_0 = -\alpha(T)(T - T_{\text{inv}}), \quad (5)$$

149 in which α , the thermal expansivity, is a piecewise function of temperature,

$$150 \quad \alpha(T) = \begin{cases} \alpha_0 & \text{if } T \geq T_{\text{inv}} \\ -S\alpha_0 & \text{if } T < T_{\text{inv}}, \end{cases} \quad (6)$$

151 with α_0 the reference thermal expansivity and $S > 0$ the stiffness. T_{inv} is an inversion temperature
152 around which α changes sign. This formulation is inspired by the behavior of water around 4°C
153 (Townsend, 1964; Le Bars et al., 2015; Léard et al., 2020). Although such behaviour is unlikely
154 in the Earth's outer core, this formulation allows for the formation of a self-consistent two-layer

convective/stratified system. When a negative temperature gradient ($\partial T/\partial r < 0$) is imposed in the shell by prescribing $T = T_i > T_{\text{inv}}$ at the inner boundary and $T = T_o < T_{\text{inv}}$ at the outer boundary, the change of sign around T_{inv} in (6) divides the shell into two distinct regions (figure 1). For $T_i \geq T \geq T_{\text{inv}}$, the negative temperature gradient is convectively unstable: the bottom part of the shell convects. For $T_{\text{inv}} > T \geq T_o$, the temperature gradient becomes stable to convection: the top of the core is stably stratified. The interface region between the convective and stratified regions is located at the radius r_{int} where $T \approx T_{\text{inv}}$. The respective sizes of the convective and stratified regions adjust so that the system reaches thermal equilibrium: at the radial position corresponding to $T = T_{\text{inv}}$, the heat flux transported by convection matches the conductive heat flux in the stratified layer providing the heat flux transported by waves is negligible compared to this conductive flux (this is indeed always the case here). Another advantage of this formulation is that it is relatively straightforward to implement in pre-existing codes as only the buoyancy term is modified. We have checked that the discontinuity in $\alpha(T)$ around $T = 0$ does not generate any spurious behavior in the simulation, and that the flow computed using a smooth alpha profile (using e.g. a tanh function) rapidly converges towards the flow computed using the discontinuous $\alpha(T)$ profile (6), which is hence used here. For more details on this approach, see Couston et al. (2017) and Le Bars et al. (2020). Note that our model departs from the classical Boussinesq approximation since the thermal expansion coefficient varies with temperature.

We scale distances and times using the shell thickness $D = r_o - r_i$ and the thermal diffusion time D^2/κ , respectively. The velocity is scaled by κ/D and the pressure by $(\rho_0\kappa^2/D^2)$. The temperature scale is the temperature difference $\Delta T = T_i - T_{\text{inv}}$ between the bottom of the shell and the interface with the stratified region. Therefore, in non-dimensional units we set $T_i = 1$ and $T_{\text{inv}} = 0$. The dimensionless expression of equation (2) is

$$\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla) \mathbf{u} = -\nabla \Pi + Pr \Delta \mathbf{u} + Pr Ra T \frac{\mathbf{r}}{r_o} - \frac{1}{\tau(r)} \mathbf{u}, \quad (7)$$

where

$$Pr = \frac{\nu}{\kappa} \quad (8)$$

Table 1. Parameters for the simulations. N_r is the number of radial grid points. ℓ_{\max} is the maximum spherical harmonic degree. The maximal azimuthal wavenumber is $m_{\max} = \ell_{\max}$. Pr is the Prandtl number, Ra_0 the Rayleigh number as defined in (10), S the stiffness and T_o the imposed top temperature. $f_N = \bar{N}/2\pi$ is the mean buoyancy frequency in the stratified layer and $f_c = U_{\text{conv}}/(2\pi H)$ the convective frequency. $Re_{\text{conv}} = U_{\text{conv}}H/\nu$ is the Reynolds number in the convective region that has a height $H \approx D/2$. U_{conv} is the rms velocity in the convective region.

Simulation	(N_r, ℓ_{\max})	Pr	Ra_0	S	T_o	f_N/f_c	damping	Re_{conv}
P03	(400,160)	0.3	4.7×10^8	30	-6.7	20.1	no	2.518×10^3
P1	(400,160)	1	6×10^8	30	-6.7	99.67	no	2.218×10^3
P1.S100	(400,160)	1	6×10^8	100	-6.7	187.81	no	2.149×10^3
P1d	(400,160)	1	6×10^8	30	-6.7	102.94	yes	2.147×10^3
P3	(400,160)	3	1.2×10^9	30	-6.7	457.19	no	2.055×10^3

181 is the Prandtl number and

$$182 \quad Ra = \begin{cases} Ra_0 & \text{if } T \geq 0 \\ -SRa_0 & \text{if } T < 0 \end{cases} \quad (9)$$

183 is the Rayleigh number, with

$$184 \quad Ra_0 = \frac{\alpha_0 g_0 \Delta T D^3}{\kappa \nu}. \quad (10)$$

185 Since the convective region extends only to a spherical shell of (dimensionless) thickness H , the
186 effective Rayleigh number for the convective region is:

$$187 \quad Ra_{\text{eff}} = Ra_0 H^3. \quad (11)$$

188 Equation (4) becomes, in non-dimensional form,

$$189 \quad \frac{\partial T}{\partial t} + \mathbf{u} \cdot \nabla T = \nabla^2 T. \quad (12)$$

190 The stratification strength in the stable region is measured by the Brunt-Väisälä frequency,

$$191 \quad N(r) = \sqrt{-\frac{g(r)}{\rho} \frac{\partial \langle \bar{\rho} \rangle}{\partial r}}, \quad (13)$$

192 where $\langle \bar{\rho} \rangle$ is the density averaged in time and azimuth. In non-dimensional form, N is

$$193 \quad N(r) = \sqrt{-Ra_0 S Pr \frac{\partial \langle \bar{T} \rangle}{\partial r} \frac{r}{r_o}}, \quad (14)$$

194 where $\langle \bar{T} \rangle$ is the time and horizontally averaged temperature and S is the stiffness parameter
 195 that appears in equation (6). S is therefore a measure of how “stiff” *i.e.* strongly stratified the
 196 stable layer is. Because both the temperature gradient and the gravity vary across the layer, N
 197 varies between the interface and the top of the layer. N is larger immediately above the interface
 198 and gradually decreases by about 20% towards the top of the layer. Note that this does not sig-
 199 nificantly affect the following results: for physical interpretation of the results, it is most of the
 200 time sufficient to assume the stratified layer to be linearly stratified in first approximation, with a
 201 constant Brunt-Väisälä frequency \bar{N} . In one simulation we introduced a damping term $-\mathbf{u}/\tau$ to
 202 prevent wave reflection at the top boundary. Note that this is not geophysically relevant to cores
 203 where rigid boundaries promote wave reflection; but as will be seen below, this will help us dis-
 204 entangling contributions from propagating waves and standing modes. We pick a similar form as in
 205 Couston et al. (2018a),

$$206 \quad \tau^{-1} = \pi \sqrt{Ra_0 S T_o / 0.5} [1 + 20 \tanh(r - r_o + 0.15)], \quad (15)$$

207 where $T_o/0.5$ approximates the temperature gradient in the stratified layer of thickness $H \approx D/2$.

208 We impose no-slip ($\mathbf{u} = 0$) and fixed temperature boundary conditions. The bottom boundary
 209 is set to $T = T_i = 1$ (in non-dimensional units) while at the top boundary $T = T_o$. We pick the
 210 value of T_o such that in statistically steady state, the convection zone has $H \approx D/2$, as explained
 211 in subsection 2.2.

212 **2.2 Numerical method**

213 To solve equations (1), (7) and (12) with the non-linear equation of state (5) we use a modified ver-
 214 sion of the code PARODY (E. Dormy, J. Aubert; Dormy, 1997; Aubert et al., 2008). The equations
 215 are discretized on N_r points in the radial direction using a classical second-order finite difference
 216 scheme on a nonuniform grid. In the two-layer system studied here, both the boundary layers and
 217 the interface region require enhanced resolution. To achieve that, we distribute 400 points along
 218 the radius so that about 240 points span the convective region, 100 points cover the interface region
 219 ($r_{\text{int}} \pm 0.05$) and the ratio of the maximum to minimal radial spacing is 10.

At each radius, the physical quantities are decomposed into spherical harmonics up to degree ℓ_{\max} and order $m_{\max} = \ell_{\max}$. To prevent aliasing errors, the numbers of grid points in the latitudinal and longitudinal directions are respectively $N_\theta = 1.5\ell_{\max}$ and $N_\phi = 3\ell_{\max}$. The non-linear terms (now including the buoyancy term) are computed in physical space on Gauss collocation points involving N_θ points in latitude and N_ϕ in longitude before being transformed back to spectral space. The time-integration is performed using a semi-implicit scheme, Crank-Nicolson, for diffusion and second-order Adams-Bashforth for the other terms. The waves dynamics imposes a supplementary criterion on the time step to ensure that all waves are properly resolved. As the frequency of GW is bounded by the Brunt-Väisälä frequency, we impose

$$\Delta t = \min(\Delta t_{\text{conv}}, 0.1/\bar{N}), \quad (16)$$

where Δt_{conv} is derived from the classic CFL criterion on the velocity. Adaptive time stepping is used to reach the statistically stationary state. Then, the time step is fixed to the minimal time step reached to avoid temporal interpolations during the computation of time spectra. Frequency spectra shown in the paper are calculated using a Hamming window method.

The top temperature T_o for which the thickness of the convective region H equals our assigned value $H = D/2$ in thermal equilibrium is not known *a priori*. To obtain a first guess for T_o , we run a purely convective simulation in a “half” spherical shell comprised between radii r_i and $r_i + H$ with Ra_{eff} as the input Rayleigh number and we measure the heat flux

$$Q_0 = -\frac{dT}{dr}(r = r_i + H) \quad (17)$$

at the top of this convective region. Then, when the stratified layer is added, T_o must be such that the convective heat flux Q_0 matches the diffusive heat flux in the stratified layer above, neglecting heat flux from GW. This condition is

$$T_o = \frac{(r_i + H)(r_i + H - r_o)}{r_o} Q_0. \quad (18)$$

Following Couston et al. (2018a), we then perform iterative adjustment of T_o to reach $H_{\text{eff}} \approx H = D/2$ at the equilibrated state. At each step of the iterative process, we run the simulation for a few

245 advection times. T_o is then adjusted such that:

$$246 \quad Q_i \left(\frac{r_i}{r_i + H} \right)^2 = T_o \frac{r_o}{(r_i + H - r_o)(r_i + H)}, \quad (19)$$

247 where

$$248 \quad Q_i = -\frac{\partial T}{\partial r}(r_i) \quad (20)$$

249 is the heat flux measured at the bottom of the convective region. The process repeats until T_o varies
 250 by less than 10% between two consecutive iterations. This procedure was applied to our reference
 251 simulation at $Pr = 1$. Then, when changing the Prandtl number, T_o was kept the same and only
 252 the Ra_0 number was adjusted so that $H_{\text{eff}} \approx H = D/2$ at the equilibrated state.

253 We explore the parameter space between $Pr = 0.3$ to $Pr = 3$. We consider large values
 254 of the stiffness ($S = 30$ and $S = 100$), which produces a strongly stratified layer and a sharp
 255 interface with the convective region (Couston et al., 2017). The Rayleigh numbers are chosen
 256 so that the convection is turbulent, characterized by Reynolds number $Re_{\text{conv}} = U_{\text{conv}}H/\nu \sim$
 257 $2 - 3 \times 10^3$, where U_{conv} and $H \approx D/2$ are the rms velocity and the thickness of the convective
 258 region, respectively. Table 1 summarizes the parameters for all simulations. In this table we also
 259 define the buoyancy frequency $f_N = \bar{N}/2\pi$, where \bar{N} is the mean Brunt-Väisälä frequency in
 260 the layer, and the convective frequency $f_c = U_{\text{conv}}/(2\pi H)$, with U_{conv} the rms velocity in the
 261 convective region. Note that, for the Earth's core with $\Omega = 7.292 \times 10^{-5} \text{ s}^{-1}$, $N \sim 0.7\Omega - 25\Omega$
 262 (for this estimation of N , see references given in section 6), $U_{\text{conv}} \approx 5 \times 10^{-4} \text{ m s}^{-2}$ (Finlay &
 263 Amit, 2011), we have $f_N/f_c \sim 10^6 - 10^7 \gg 1$, i.e. the frequency of GW is large compared to
 264 the convective frequency. This is also the case in our simulations, as we have large f_N/f_c ratios
 265 ($f_N/f_c \in [20.1 - 457.19]$).

266 3 EXCITATION OF WAVES

267 3.1 Propagating waves

268 At statistically steady state, the spherical shell is divided into a convective region in the bottom
 269 and a stably stratified layer above (figure 2a). These two layers occupy one half of the shell each
 270 and are separated by a sharp interface located at $r \approx 1$ (see figure 1 for a schematic illustration

and figure 2b for a snapshot from simulation P1). Convection takes the form of a turbulent flow involving multiple length scales (figure 2b, inner half of the shell; see also movie attached). The turbulent motions that occur close to the stable layer deform slightly the interface or penetrate shortly into the layer. These interface processes couple the convective region with the stratified layer by generating internal gravity waves (GW) immediately above the interface, which then propagate in the entire stratified layer (figure 2b, outer half of the shell; see also movie attached).

Convective plumes hit the interface and overshoot in the stratified layer (figure 3). Reynolds stresses near the conductive-convective interface transfer power from convective motions to linear waves (e.g. Lecoanet et al., 2015). GW satisfy the dispersion relation

$$\omega = \frac{\bar{N}k_{\perp}}{\sqrt{k_r^2 + k_{\perp}^2}}, \quad (21)$$

where ω is the frequency of the wave, $\mathbf{k} = k_r \mathbf{e}_r + \mathbf{k}_{\perp}$ the wavevector decomposed in its radial and horizontal parts and \bar{N} is the averaged Brunt-Väisälä frequency which we assume to be constant for simplicity. Convective plumes generate waves over a large range of possible frequencies, and especially with frequency similar to the inverse convective time scale, U_{rms}/H , which propagate at a characteristic angle α ,

$$\alpha = \arccos \frac{\omega}{\bar{N}}. \quad (22)$$

Therefore, GW transport energy away along a cone originating from the impact point. The intersection of this cone with a spherical surface ($r = \text{cst}$) is a circle. At a given radius in the stratified layer, several circular patterns can be seen in the velocity field, each one being the trace of the waves produced by a plume impact underneath (figure 4). In a plane perpendicular to the interface and containing the impact point, the waves form a characteristic shape sometimes referred to as a “half St Andrew’s cross” (figure 3 middle). The group velocity \mathbf{v}_g , at which the envelope of the waves and hence the energy are transported, is perpendicular to the phase velocity \mathbf{v}_p and inclined at the angle α from the local vertical (figure 3). Along their course, GW are attenuated owing to viscous and thermal dissipation, and due to a geometrical effect in a sphere, so that the intensity of propagative waves is maximal immediately above the impact point and decreases as the

297 waves spread out (figure 5). Attenuation is larger for high wavenumbers and/or lower frequencies
 298 (Lecoanet et al., 2015).

299 In addition, there are also waves that are secularly generated by convective Reynolds stresses
 300 not associated with plumes. These predominantly excite lower frequency waves, and are harder to
 301 see by eye, as they are being continuously generated throughout the convection zone (Lecoanet et
 302 al., 2015).

303 3.2 Standing modes

304 GW produced at the interface by Reynolds stresses may travel across the entire stratified layer
 305 and reflect on the top boundary. The constructive interactions of propagating waves and their
 306 reflections excite and maintain *standing modes* (SM), which are global resonances of the cavity
 307 formed by the stratified layer. As will be shown in section 4, numerous SM are excited, each
 308 one corresponding to a given wavelength and frequency. We mostly find SM with relatively small
 309 wavenumbers and/or relatively large frequencies, because they saturate at higher amplitude (see
 310 section 4).

311 As multiple SM coexist, it is difficult to isolate them visually. Sometimes, one mode dominates
 312 locally, appearing as a checkerboard-like pattern associated with well-defined wavelengths in the
 313 radial and horizontal directions, as visible on the bottom right part of figure 5. Yet, most of the
 314 background is usually a mix of propagating waves and various SM (for example, see the back-
 315 grounds of the stratified layers in figures 3 left and 5). To distinguish between all contributions
 316 and analyze the properties of each wave separately, a spectral analysis, both in space and time, is
 317 necessary. This is the purpose of the next section.

318 4 SPECTRAL PROPERTIES OF INTERNAL GRAVITY WAVES

319 4.1 (ℓ, ω) spectra

320 The properties of GW can be characterized by their kinetic energy spectrum in both space and time,
 321 which indicates how much energy is contained in each spherical harmonics degree ℓ and frequency
 322 ω . To obtain these spectra, we record the velocity components $V_r(r_j, \ell, m, t)$, $V_\theta(r_j, \ell, m, t)$ and

323 $V_\phi(r_j, \ell, m, t)$ at each time step and at 10 different radii r_j ($j = 1$ to 10) across the shell. Then, at
 324 each radius r_j , we compute the kinetic energy spectrum for each component,

$$325 \quad E_{r/\theta/\phi}(r_j, \ell, \omega) = \sum_m \text{psd} [V_{r/\theta/\phi}(r_j, \ell, m, t)], \quad (23)$$

326 where psd denotes the power spectrum density, calculated using the `pwelch` function of Matlab.

327 The total kinetic energy spectrum is then

$$328 \quad E(r_j, \ell, \omega) = E_r(r_j, \ell, \omega) + E_\theta(r_j, \ell, \omega) + E_\phi(r_j, \ell, \omega). \quad (24)$$

329 Kinetic energy spectra $E(r_j, \ell, \omega)$ in (ℓ, ω) space are plotted on figure 6 at four different radii, one
 330 in the convective region and the three others in the stratified layer, for simulation P1. Figure 6a
 331 shows that the convective flows that excite GW contain energy at a range of length scales and
 332 frequencies with, as expected for a turbulent flow in 3D, a decreasing amplitude when wavenumber
 333 and/or frequency increases. Yet, the spectral energy distribution in the stratified layer contains
 334 more complex structures, indicating that a large set of waves is excited (figure 6b, 6c and 6d). This
 335 shows that, even though the energy for the excitation of GW is injected by the convection, GW
 336 create their own dynamics inside the layer.

337 Whether or not the signal displayed on figures 6b-d represents GW can be confirmed by taking
 338 advantage of the geometric properties of internal waves. Campagne et al. (2015) then Savaro et al.
 339 (2020) showed that, when the kinetic energy is dominated by linear GW, we have

$$340 \quad \frac{E^r(\ell, \omega)}{E^\perp(\ell, \omega)} = \frac{(\omega^*)^2}{1 - (\omega^*)^2}, \quad (25)$$

341 where the spectra $E^r(\ell, \omega)$ and $E^\perp(\ell, \omega)$ contain respectively the radial and horizontal components
 342 of the kinetic energy and $\omega^* = \omega/N$ is the frequency normalized by the Brunt-Väisälä frequency.
 343 Figure 7 shows the ratio $E^r(\ell, \omega)/E^\perp(\ell, \omega)$ averaged between $\ell = 1$ and $\ell = 140$ at $r = 1.318$. The
 344 relation (25) is satisfied for frequencies between $0.4N$ and N , which indicates that this portion of
 345 the spectra contains GW only. On the contrary, at frequencies $\omega < 0.4N$, there is a clear mismatch
 346 with relation (25) which indicates that the low-frequency part on figure 6 does not contain only
 347 linear GW and that most of its energy is non-linear GW patterns.

348 At each radius displayed, the GW lobe is bounded by the Brunt-Väisälä frequency (indicated

349 by horizontal dashed lines in figures 6b-d), since higher frequencies waves are evanescent. This
 350 GW lobe is composed of a continuous background and a series of discrete ridges. Each of the
 351 discrete patches forming these ridges corresponds to a standing mode with specific ℓ and ω . The
 352 ridges formed by these patches are visible at all radii across the stratified layer and each ridge
 353 corresponds to a given radial wavelength. At a given radius, a vertical cut at fixed degree ℓ of the
 354 (ℓ, ω) spectrum gives the frequency profiles shown on figure 8b. These profiles show an overall
 355 decrease of the kinetic energy with ω , superimposed by modes in the form of sharp peaks of kinetic
 356 energy, which are sometimes two orders of magnitude larger than the local background. Increasing
 357 the stiffness, *i.e.* the stratification strength, to $S = 100$ leads to more numerous modes, especially
 358 in the low- ℓ high- ω part of the spectrum. In fact, increasing the stiffness creates a sharper, less
 359 deformable interface: the cavity formed by the stratified layer keeps a constant geometry over
 360 time, which facilitates resonances and modes formation. On the contrary, for lower values of the
 361 stiffness, the interface is more deformable. In that case, the cavity is less clearly defined which
 362 makes it harder for modes to form. However for the $S = 100$ case, we observe that modes and
 363 propagating waves saturate at a comparatively much lower amplitude (figure 9).

364 These well-identifiable modes are present over a more diffuse background, which contains
 365 propagating waves. Figures 6b to 6d show that, as the radius increases, the area covered by this
 366 background shrinks, particularly in the low- ω , high- ℓ part of the lobe, as a result of the gradual
 367 attenuation of propagating waves when they progress upwards. Linear wave damping causes the
 368 wave energy flux F to decrease exponentially with the distance to the interface ($r = r_{\text{int}}$) as

$$369 \quad F(r) = F(r_{\text{int}})e^{-2\gamma(r-r_{\text{int}})}, \quad (26)$$

370 where

$$371 \quad \gamma = \frac{(1 + Pr)}{2} k_{\perp}^3 N^3 / \omega^4 \quad (27)$$

372 is the waves decay rate with k_{\perp} the horizontal wavenumber. In that case, for fixed N , $\lambda = (2\gamma)^{-1}$ is
 373 the typical attenuation length for propagating waves, that depends only on ω and k_{\perp} . In spherical
 374 geometry, $k_{\perp} = r^{-1}[\ell(\ell + 1)]^{1/2}$, which has a dependence on the radius. In addition, N varies
 375 slightly with r in our model. Therefore, here γ is a function of ω , ℓ and r . A GW with degree ℓ and

376 frequency ω sees an effective decay rate

$$377 \quad \gamma_{\text{eff}}(\ell, \omega) = \frac{1}{r_o - r_{\text{int}}} \int_{r_{\text{int}}}^{r_o} \gamma(r) dr = [\ell(\ell + 1)]^{3/2} \omega^{-4} \phi, \quad (28)$$

378 where

$$379 \quad \phi = \frac{1}{r_o - r_{\text{int}}} \int_{r_{\text{int}}}^{r_o} r^{-3} N^3(r) dr. \quad (29)$$

380 Therefore, the effective attenuation length is

$$381 \quad \lambda_{\text{eff}}(\ell, \omega) = \frac{1}{2\gamma_{\text{eff}}} = \frac{1}{2} \phi^{-1} [\ell(\ell + 1)]^{-3/2} \omega^4. \quad (30)$$

382 Hence, in the (ℓ, ω) spectral space, iso- λ_{eff} lines are defined by

$$383 \quad \omega = (2\lambda_{\text{eff}}\phi)^{1/4} [\ell(\ell + 1)]^{3/8}. \quad (31)$$

384 Three iso- λ_{eff} lines defined by equation (31) are represented in the (ℓ, ω) spectra in figures 6b-d.

385 Immediately above the interface (figure 6b), numerous propagating waves are present, with various
 386 length scales, frequencies and intensities, depending on how they were excited. When r increases,
 387 the waves associated to the smallest attenuation depth disappear, while the less attenuated waves
 388 remain. This is well visible on figures 6b-d in which the waves signal located below a line of
 389 constant λ_{eff} progressively disappear when r increases. When the attenuation length λ_{eff} reaches a
 390 critical value compared to the thickness of the layer, propagating waves above the iso- λ_{eff} line can
 391 reach the top of the layer, reflect on the outer boundary and eventually form modes by constructing
 392 interferences at selected resonance values in radial structure. In that case, the iso- λ_{eff} line (the
 393 dashed-dotted line on figures 6b-d) separates approximately propagating waves (below the line)
 394 from modes (above the line). Equation (27) indicates that high ω , low ℓ waves are comparatively
 395 less attenuated. This is the reason why modes are found in the top left part of the waves lobe in the
 396 (ℓ, ω) spectra. The saturation amplitude of modes depends both on the attenuation of propagating
 397 waves and on their excitation by the convection. Propagating waves with a higher excitation energy
 398 and/or a smaller decay rate tend to form more energetic modes.

399 To separate the contributions of propagating waves and standing modes in the spectra, we apply
 400 a damping term in the top part of the stratified layer as described in equation (2) (simulation P1d).
 401 This damping term replaces the top rigid boundary by a region across which waves rapidly vanish.

402 By preventing wave reflection off the top boundary this term eliminates most standing modes. The
 403 introduction of a damping term at the top of the stable layer is not motivated by physical arguments
 404 for application to cores bounded by a rigid mantle, it is simply a numerical trick that allows us to
 405 remove standing modes and isolate the contribution of propagating waves in the spectra. Figure 10
 406 shows (ℓ, ω) spectra of the kinetic energy for simulations P1 (without damping, figure 10a) and
 407 P1d (with damping, figure 10b). The damped spectrum confirms that the diffuse background is
 408 produced by propagating waves and that the discrete ridges are the traces of standing modes.

409 To compare the energy contained in standing modes versus propagating waves, we integrate
 410 the (ℓ, ω) spectra with and without the damping term in the top part of the layer. The total energy
 411 of waves (propagating waves and standing modes) is

$$412 \quad E_{\text{tot}}(r_j) = \sum_{\ell} \int_{\omega} E(r_j, \ell, \omega) d\omega. \quad (32)$$

413 The energy of propagating waves can be estimated by integrating the spectra obtained with the
 414 damping term at the top of the layer:

$$415 \quad E_{\text{PW}}(r_j) \approx \sum_{\ell} \int_{\omega} E_{\text{damped}}(r_j, \ell, \omega) d\omega. \quad (33)$$

416 Note that this assumes that all modes have been effectively removed by the damping term, which
 417 in practice is difficult to fully ensure. The energy contained in standing modes is the total energy
 418 minus the energy of propagating waves:

$$419 \quad E_{\text{SM}}(r_j) = E_{\text{tot}}(r_j) - E_{\text{PW}}(r_j). \quad (34)$$

420 We then compute the ratio

$$421 \quad R_{\text{SM}}(r_j) = E_{\text{SM}}(r_j) / E_{\text{tot}}(r_j), \quad (35)$$

422 which estimates the fraction of the total energy contained in standing modes. Marginally above
 423 the interface, at $r = 1.046$, we find that $R_{\text{SM}}(r_j)$ is close to 21%, which indicates that propagating
 424 waves account for most of the energy above the interface. Further up, at $r = 1.136$ and $r = 1.227$,
 425 the ratio rises to respectively $R_{\text{SM}}(r_j) \approx 59\%$ and $R_{\text{SM}}(r_j) \approx 83\%$. This is because propagating
 426 waves are gradually attenuated whereas the magnitude of modes is mostly the same throughout

the layer. This shows that, while propagating waves dominate the signal immediately above the interface, modes account for most of the total waves energy higher in the stratified layer.

The spectra from figure 6 can be confronted to the theoretical predictions of Lecoanet & Quataert (2013). That work used the same assumptions as Goldreich & Kumar (1990): i) waves are excited by Reynolds stresses associated with turbulent convective eddies; ii) the flow can be decomposed into eddies, the excitation can be calculated for each eddy individually and the total wave generation is given by summing over all eddies; iii) the eddies of size h have velocities which scale like $h^{1/3}$ and stay coherent for their turnover time. Put together, these predict the kinetic energy spectrum

$$KE \sim \rho_0 (\omega_c H)^2 \left(\ell \frac{H}{r} \right)^5 \left(\frac{\omega}{\omega_c} \right)^{-17/2}. \quad (36)$$

This theory is only applicable for moderately low ℓ and high ω : at high ℓ and low ω , damping will dominate and cause the kinetic energy to drop rapidly. Figure 8a shows ℓ -spectra for two different frequencies and at two different radii for simulation P1. We include a ℓ^5 power law as predicted by the theory for the energy increase at low values of ℓ which is in good agreement with the curves from the simulation. Similarly, figure 8b displays ω -spectra for $\ell = 2$ and $\ell = 6$ at two different radii for simulation P1, showing a very rapid drop in the kinetic energy when increasing the frequency up to $\omega \sim 10^5$. We include a $\omega^{-8.5}$ power law scaling as predicted by the theory. Here as well, the agreement with the theory is rather satisfactory. This suggests that the Reynolds stress mechanism is indeed at play in our simulations. Note that the peaks that superimpose to the average curves are caused by standing modes, which are not included in the theory. Furthermore, since this theory is based on (i) the assumption that Reynolds stresses are the main source of GW and (ii) a simple model of turbulence based on a Kolmogorov type turbulence, this agreement opens new perspectives for developing predictive tools of GW in more relevant (e.g. rotating) configurations.

4.2 Effect of the Prandtl number

Figure 11 shows (ℓ, ω) spectra for simulations P03, P1 and P3, which have a comparable convective forcing but differ by their Prandtl numbers (respectively $Pr = 0.3$, $Pr = 1$ and $Pr = 3$).

454 Although the variation in the Prandtl number is modest, we observe dramatic changes in the spec-
 455 tra. For simulation $Pr = 0.3$, all the energy is confined to $\ell \lesssim 70$, while higher Prandtl number
 456 simulations have energy up to higher spherical harmonics degrees (up to $\ell \sim 120 - 130$ for
 457 $Pr = 3$). The $Pr = 0.3$ simulation also appears to have more energetic modes compared to
 458 the larger Prandtl number simulations and contains more energy in the low- ω , low- ℓ part of the
 459 spectrum.

460 Interpreting these observations is not straightforward since both the excitation and the attenu-
 461 ation of waves may vary when changing the Prandtl number. The attenuation of waves increases
 462 with the Prandtl number (see equation (27)) because the viscous damping is stronger. As a conse-
 463 quence of this stronger attenuation, modes saturate at a lower amplitude for higher Prandtl num-
 464 bers. This explains the lower amplitudes of modes in the $Pr = 3$ simulation compared to the
 465 $Pr = 0.3$ simulation. Note that the study of Couston et al. (2018b) showed that, in a Cartesian
 466 box, the QBO is obtained for low Prandtl numbers and strengthens when the Prandtl number de-
 467 creases.

468 Such differences observed for relatively modest variations of the Prandtl number suggest that
 469 the wave dynamics of a thermally stratified layer ($Pr \sim 0.1$) could be very different from that of
 470 a chemically stratified layer ($Sc > 10$, where $Sc = \nu/\kappa^\xi$ is the Schmidt number, the equivalent
 471 of the Prandtl number for composition, with κ^ξ the compositional molecular diffusivity). In a
 472 thermally stratified layer, we expect the energy to be concentrated in fewer but more energetic
 473 modes, whereas a chemically stratified layer could host more numerous but weaker modes up to
 474 high spherical harmonics degrees. We also expect a thermally stratified layer to be more prone to
 475 the development of a QBO-like mean flow than a chemically stratified layer. More generally, our
 476 results show that important aspects of the dynamics of the core may be missed when considering
 477 only the $Pr = 1$ simulation, as is classically done in numerical studies of the outer core. These
 478 conjectures need to be confirmed by running simulations including rotational and magnetic effects.

5 ENERGY TRANSFER

How much energy is transferred from the convective region to GW in a stratified layer is an important question for the evolution of the Earth's core and to assess the effect of the layer on the gravity field. The global energy transfer can be measured by the ratio of the mean kinetic energy in the stratified and convective regions,

$$R = \frac{\langle E_{\text{strat}} \rangle}{\langle E_{\text{conv}} \rangle} = \frac{\frac{1}{V_{\text{sup}}} \int_{r=r_{\text{int}}+\delta}^{r_o} \langle E(r) \rangle r^2 dr}{\frac{1}{V_{\text{inf}}} \int_{r=r_i}^{r_{\text{int}}-\delta} \langle E(r) \rangle r^2 dr}, \quad (37)$$

where $E(r)$ is the horizontally averaged kinetic energy at radius r and r_{int} is the interface radius. Brackets $\langle \rangle$ denote time averages. The interface region has been excluded by setting $\delta = 0.025$, so that the region of rapidly dropping kinetic energy between the convective and stratified regions is not considered. For simulation P1 ($Pr = 1$) we find $R \sim 1.6 \times 10^{-3}$, *i.e.* the rms velocity has decreased by a factor ~ 25 . We find a similar ratio $R \sim 1.2 \times 10^{-3}$ for simulation P03 ($Pr = 0.3$), and $R \sim 1.4 \times 10^{-3}$ for simulation P3 ($Pr = 3$). Note that these ratios are obtained with the Rayleigh number and stiffness adopted in our simulations. They may change significantly when moving towards more realistic parameters (*i.e.* higher Rayleigh number with rotational effects). They may also depend on the choice of the parameter δ in equation (37), on the stratification strength and on whether the stratification is thermal (low Prandtl number) or chemical (high Schmidt number).

These global ratios mask the fact that the kinetic energy in the stratified layer is a strong function of radius, wavelength and frequency. Figure 12a shows the time average radial profiles of the angle-integrated kinetic energy for simulation P1 ($Pr = 1$). In the convective region, the kinetic energy is fairly stable around $\langle E_{\text{conv}} \rangle \sim 2 - 3 \times 10^6$. Within the first 15% of the layer above the interface, the kinetic energy drops by almost 3 orders of magnitude, so that the rms velocity is about 30 times less than the rms velocity in the convective region. Then, the kinetic energy further drops by about 2 orders of magnitude when moving upwards in the stratified layer, until the rms velocity in the outermost portion of the layer has dropped by a factor ~ 250 compared with the convective region. These factors are consistent with the rescaling factor of 43 – 100 that we had to apply on velocities in the stratified layers on figures 3 to 5 to visualize velocities both in the convective region and in the stratified layer using the same colorbar. For a given horizontal

506 wavenumber k_{\perp} , the theory of Lecoanet & Quataert (2013) finds that the kinetic energy decrease
 507 follows a power law,

$$508 \quad E(r, k_{\perp}) \sim [(1 + Pr)Nk_{\perp}^3(z - z_{\text{int}})]^{-17/8}, \quad (38)$$

509 where z_{int} is the radius of the interface. In spherical geometry, $k_{\perp} = \sqrt{\ell(\ell + 1)}/r$. Furthermore,
 510 in our case N depends slightly on the radius. Therefore we have

$$511 \quad \langle E(r) \rangle \sim \left[N(r) \frac{r - r_{\text{int}}}{r^3} \right]^{-17/8}. \quad (39)$$

512 This theoretical law is reported as a dashed line on figure 12a. We observe that the kinetic energy
 513 decays more slowly in our simulations compared to the theoretical prediction. We suggest that
 514 this lower decrease is due to the presence of numerous modes in our simulations, as these are
 515 attenuated less rapidly with the radius and are not considered in the theory of Lecoanet & Quataert
 516 (2013).

517 As already shown on the spectra of figure 6, the energy distribution at each radius depends on
 518 the spherical harmonic degree ℓ and frequency ω . Figure 12b shows the time averaged ℓ -spectra of
 519 the kinetic energy in each half space (excluding again the interface region $r_{\text{int}} \pm \delta$). The spectrum
 520 in the stratified layer has been normalized by the $\ell = 1$ value of the convective spectrum, to better
 521 visualize the relative drop as a function of ℓ . Like in figure 6, the spectrum in the stratified layer
 522 shows that the low ℓ components have a higher kinetic energy, with a peak at $\ell = 2$, and that these
 523 degrees are better transmitted from the convective region compared with higher ℓ s.

524 Figure 13 shows the kinetic energy ratio between the convective region and the stratified layer,
 525 at different radii. As was already visible on the spectra of figure 6, not all convective frequencies
 526 and wavelengths are transmitted to the stratified layer. Convection injects energy at all scales, but
 527 the energy distribution in the layer depends on the waves dynamics. We also note that the kinetic
 528 energy fraction of standing modes is nearly constant across all radii, which is expected since their
 529 amplitude is approximately constant throughout the stratified layer.

530 In the next section, we use the results above on the energy distribution and typical velocities
 531 in the stratified layer to evaluate orders of magnitude for the waves-induced perturbations of the
 532 gravity field.

6 GEOPHYSICAL SIGNATURES IN THE GRAVITY FIELD

GW produce small deviations from the mean density profile of the stratified layer, as well as pressure fluctuations at the CMB. These anomalies of density and pressure induce small perturbations in the gravity field of the Earth, which may be detected in gravity data. Previous attempts to detect the gravitational signatures of inertial waves – another type of waves that develop in the whole rotating outer core – remained unsuccessful (Melchior & Ducarme, 1988). This was due to the lower sensitivity of gravimeters at the time and to the fact that the main frequencies of inertial waves coincide with stronger signals from tides or other geophysical phenomena. By contrast, the spectra from figure 6 reveal that GW in a stratified layer atop Earth’s core may exist over a wide range of frequencies and wavelengths, some of which may be distinct from any other geophysical signal. In addition, modern superconducting gravimeters, which are sensitive to fluctuations of only a few nGal or less at the Earth’s surface (Rosat & Hinderer, 2018), now offer more hope for the detection of GW. In the following lines, we estimate an order of magnitude for the gravity perturbations induced by GW at the Earth’s surface, and compare it to the sensitivity of present-day gravimeters. Since we aim at obtaining orders of magnitude, we will focus on gravity changes induced by density perturbations and will neglect elastic deformations caused by pressure fluctuations at the CMB, as these are mostly corrections and are negligible for $\ell > 2$ (Dumberry, 2010). Note that we write the calculations for the non-rotating and non-magnetic case here, but the same procedure can be followed for GW in a rotating core with a magnetic field.

In geodesy, the variation of gravitational potential $\Delta V(r, \theta, \phi)$ at a radius r above the Earth’s surface is usually expanded on a spherical harmonics basis,

$$\Delta V(r, \theta, \phi) = \frac{GM}{r} \sum_{\ell=2}^{\infty} \sum_{m=0}^{\ell} \left(\frac{r_e}{r}\right)^{\ell} \mathcal{V}_{\ell m}, \quad (40)$$

where M is the mass of the Earth, r_e the Earth’s radius and

$$\mathcal{V}_{\ell m} = (C_{\ell m} \cos m\phi + S_{\ell m} \sin m\phi) R_{\ell m} P_{\ell m}(\cos \theta), \quad (41)$$

where $P_{\ell m}(\cos \theta)$ are the Legendre polynomials with the 4π normalization factor

$$R_{\ell m} = \sqrt{(2 - \delta_{m,0})(2\ell + 1) \frac{(\ell - m)!}{(\ell + m)!}}. \quad (42)$$

559 Note that we do not consider degrees $\ell = 0$ and $\ell = 1$ in the above summation because we assume
 560 that mass is conserved and that core motions do not change the location of the centre of mass.
 561 In (41), $C_{\ell m}$ and $S_{\ell m}$ are referred to as the Stokes coefficients. Perturbations of the gravity field
 562 are usually measured in terms of changes in these coefficients. Typical changes ΔC in the Stokes
 563 coefficients caused by density perturbations $\delta\rho$ in the core can be estimated by (Dumberry, 2010)

$$564 \quad \Delta C \sim \frac{4\pi}{(2\ell + 1)^{3/2}} \left(\frac{r_o}{r_e}\right)^\ell \frac{r_o^2 h \delta\rho}{M}, \quad (43)$$

565 where r_o is the radius of the outer core and h the thickness of the region across which the density
 566 perturbations extend. Here, h is the thickness of the stratified layer at the top of the core. The
 567 typical density perturbation $\delta\rho$ induced by a GW of frequency ω and vertical velocity W can be
 568 estimated using the GW polarisation relation (Sutherland, 2010)

$$569 \quad i \frac{\omega g \delta\rho}{\rho_0} + N^2 W = 0, \quad (44)$$

570 where g is the gravitational acceleration at the top of the core, which leads to

$$571 \quad \delta\rho \sim \frac{\rho_0 N^2 W}{\omega g}. \quad (45)$$

572 Injecting (45) into (43) gives typical variations ΔC of the Stokes coefficient of order

$$573 \quad \Delta C \sim \frac{4\pi}{(2\ell + 1)^{3/2}} \left(\frac{r_o}{r_e}\right)^\ell \frac{r_o^2 h \rho_0 N^2 W}{M \omega g}. \quad (46)$$

574 From equation (43), it is clear that changes in the Stokes coefficients decrease very rapidly with
 575 increasing ℓ , by typically an order of magnitude for an increase of two in ℓ . Therefore, only waves
 576 with sufficiently low ℓ have a chance to produce a detectable signature. Since propagating waves
 577 are essentially local processes and typically involve large ℓ s and various frequencies, they will be
 578 hard to detect. On the contrary, low- ℓ modes are better candidates, because they resonate glob-
 579 ally in the entire stratified layer with a well-defined frequency. Low- ℓ modes also are the most
 580 energetic, particularly at low Prandtl number (figures 6, 11 and 12).

581 The spectra in figure 6 show that low- ℓ modes are found at frequencies significantly lower than
 582 N , typically $\omega \sim 0.2N$. In the literature, the value of N is often expressed through its squared ratio
 583 $(N/\Omega)^2$ to the Earth's rotation frequency Ω . A range of values has been proposed for this ratio in
 584 the literature. Geomagnetic observations require a ratio of order 1 (Buffett, 2014; Buffett et al.,

2016) while seismic observations favor larger values (Helfrich & Kaneshima, 2010), giving the range

$$\left(\frac{N}{\Omega}\right)^2 \in [0.5 - 600]. \quad (47)$$

Assuming $\omega \sim 0.2N$ and $\Omega = 7.292 \times 10^{-5} \text{ s}^{-1}$, we obtain typical GW periods comprised between 5 h and 170 h.

Eventually, the evaluation of ΔC requires a value for the typical radial velocity W of the waves. This can be evaluated from the kinetic energy ratios calculated in equation (37) and discussed in section 5. These ratios give a mean drop of kinetic energy of $\sim 10^{-3}$ between the convective region and the waves, which leads to typical wave velocities that are about 30 times as small as the convective rms velocity. Alternatively, W can be roughly estimated for the low- ℓ modes (which we focus on here) by looking at the bottom left corner of figure 13. This figure predicts kinetic energy ratios comprised between 10^{-2} and 10^{-1} for these modes, that is a velocity drop of only a factor 3-10. We therefore adopt a conservative factor 20 for the drop in kinetic energy for the low- ℓ modes. We note that these ratios may not be representative of realistic conditions in the Earth's core but here we aim at deriving a general estimation method. The calculations hereafter can be performed using kinetic energy ratios obtained with more realistic simulations including rotation and magnetic field. Taking $5 \times 10^{-4} \text{ m s}^{-1}$ as the typical velocity in the convecting region (Christensen & Aubert, 2006; Finlay & Amit, 2011), we estimate $W \sim 2.5 \times 10^{-5} \text{ m s}^{-1}$. For the other numerical values, we adopt $g = 10 \text{ m s}^{-2}$, $M = 5.97 \times 10^{24} \text{ kg}$, $\rho_0 = 9.903 \times 10^3 \text{ kg m}^{-3}$, $\Omega = 7.292 \times 10^{-5} \text{ s}^{-1}$, $r_o = 2.891 \times 10^6 \text{ m}$, $h = 100 \text{ km}$ and $r_e = 6.371 \times 10^6 \text{ m}$. Figure 14 displays the estimates for the changes in the Stokes coefficients obtained from equation (46) with the numerical values given above, for $\ell = 2$ to 10 and for the two end-member values of the $(N/\Omega)^2$ ratio (0.5 and 600). These typical changes in the Stokes coefficients should be compared to the accuracy of superconducting gravimeters, which is around 1 nGal (Rosat & Hinderer, 2018). The gravity variation Δg at the Earth's surface is the radial derivative of ΔV at $r = r_e$, that is

$$\Delta g = \frac{GM}{r_e^2} \sum_{\ell=2}^{\infty} \ell \sum_{m=0}^{\ell} (\Delta C_{\ell m} \cos m\phi + \Delta S_{\ell m} \sin m\phi) R_{\ell m} P_{\ell m}(\cos \theta). \quad (48)$$

The above equation can then be used to estimate the detection limit on ΔC for $\Delta g \sim 1 \text{ nGal}$. For

612 example, for $\ell = m = 2$ and $\Delta g = 1$ nGal, the minimal detectable change in the Stokes coefficient
 613 is $\Delta C_{22} = \Delta g r_e^2 / (GM\ell R_{22} P_{22}(\cos \theta)) \sim 2.5 \times 10^{-13}$ at the equator ($\theta = \pi/2$). The minimal
 614 detectable perturbation of the Stokes coefficients at the equator, for $\Delta g = 1$ nGal and $m = \ell$ is
 615 represented by a black dashed line on figure 14. This line shows that, for strong stratifications,
 616 several modes (possibly up to $\ell = 8$) could potentially be observed. For weaker stratifications,
 617 only the $\ell = 2$ mode would have a chance to be detected. Besides, GW modes in a stratified layer
 618 have typical frequencies comprised between ~ 1 hour to a few hundreds of hours, depending on
 619 the stratification strength N . Such frequencies may be distinct from tides or other geophysical
 620 phenomena. However, note that the above orders of magnitude depend on the typical velocity
 621 of gravity waves, which we have estimated from our non-rotating, non-magnetic, simulations,
 622 with control parameters far from realistic values. The typical wave velocity and hence the typical
 623 density anomaly and induced gravity signal of GW may change significantly in core conditions,
 624 so that the perturbations in the Stokes coefficients derived in the previous calculations may vary
 625 significantly when more geophysical ingredients are included. To conclude more robustly on the
 626 detectability of GW in the gravity data, a (much more costly) systematic study would be necessary
 627 to obtain scaling laws.

628 **7 SUMMARY AND DISCUSSION**

629 In this study, we performed numerical simulations of a two-layer, non-rotating, non-magnetic,
 630 spherical shell, in which a stratified layer lies on top of a turbulent convective region. This config-
 631 uration leads to the development of internal gravity waves (GW) in the stratified layer, for which
 632 gravity is the restoring force. Reynolds stresses generate GW that transport energy away from
 633 the interface. While they progress upwards, propagating waves are linearly damped. Waves with
 634 smaller horizontal wavenumbers and/or relatively large frequencies are comparatively less atten-
 635 uated. These waves can make it to the top of the layer and reflect on the outer boundary. The
 636 constructive interactions of propagating waves and their reflections on the top boundary excite
 637 and maintain standing modes that resonate in the cavity formed by the stratified layer. Analysis
 638 of wavenumber-frequency spectra reveals that the wave energy is distributed among propagating

639 waves and standing modes across wavelengths and frequencies. While energy is injected in the
640 stratified layer by convective motions, the energy distribution in the layer differs from that of the
641 convective region and depends on the waves' own dynamics. In the non-rotating and non-magnetic
642 case, we observe significant differences in the spectral energy distribution of the waves when only
643 modestly changing the Prandtl numbers, even if total wave energy does not change much. This
644 result suggests that one may miss important aspects of the dynamics of the core when fixing
645 $Pr = 1$, as is done in most studies for numerical convenience. It also suggests that thermally and
646 compositionally stratified layers may host GW with very different energy distributions. Overall,
647 for the control parameters considered in this study, we find that the average kinetic energy in the
648 stratified layer is about 0.1% that of the convective region; that is, the typical waves velocity is
649 about 30 times smaller than the rms convective velocity. Based on this typical wave velocity, we
650 find that signatures of GW could potentially be detected in gravimetric data. However, the typical
651 waves velocity, upon which these results are based, may change when moving towards more re-
652 alistic control parameters and including rotational and magnetic effects. The wave dynamics may
653 also depend on the thickness of the stratified layer, which is unrealistically large in our simulations.
654 Therefore, the figures derived from the non-rotating simulations in this paper should be interpreted
655 very cautiously, as they may not be relevant values for the core. To draw robust conclusions, it is
656 necessary to perform a more systematic exploration of the parameter space including rotational
657 and magnetic effects.

658 Although this study neglects rotational and magnetic effects, it sets the conceptual bases and
659 tools necessary to analyse the properties of internal waves in a stratified layer and the perturbations
660 these waves might induce on the gravity field. Therefore, it is a first step towards more geophys-
661 ically realistic simulations. It also confirms the relevance of modelling the stratified layer using a
662 non-linear equation of state. Future works must include the effects of rotation and magnetic field
663 as these are key ingredients of core dynamics. In order to excite waves with a rich convective
664 spectrum, costly simulations at high Reynolds number and subsequently low Ekman number are
665 necessary. Since both rotation and magnetic fields break the isotropy of the system, several dif-
666 ferences may appear with respect to the non-rotating case. First, as rotationally-dominated flows

667 are strongly anisotropic, taking the form of columnar convection elongated along the rotation axis,
668 internal waves may be excited to very different amplitudes as a function of colatitude. Hence, the
669 total and latitudinal energy transfer from the convective region to the waves is likely to be affected.
670 Second, while propagating waves and modes may still coexist in the layer, they are likely to be
671 modulated by rotational effects and further damped by Ohmic dissipation. Furthermore, additional
672 types of waves such as MAC waves, magnetic Rossby waves and Alfvén waves may be present in
673 the layer (Braginsky, 1999). We anticipate that, to reach the Earth’s surface, magnetic waves will
674 need to have sufficiently long periods in order to pass the skin effect exerted by the not perfectly
675 insulating mantle. Eventually, symmetry breaking by rotation and magnetic field may lead to the
676 formation of large-scale mean zonal flows in the stratified layer, with various dynamical impacts
677 (Rogers et al., 2013). In all cases, the tools described in the present paper can also be used to study
678 the dynamics of internal waves in the presence of rotation and magnetic field, and to relate it to
679 observed geophysical quantities.

680 **DATA AVAILABILITY**

681 The data underlying this article will be shared on reasonable request to the corresponding author.

682 **ACKNOWLEDGMENTS**

683 We thank W. Dietrich and an anonymous reviewer for their valuable comments that were very
684 helpful to improve the quality of this manuscript. We also thank S. Rosat and F. Chambat for
685 useful help and discussions on determining the gravimetric signatures of GW. Calculations were
686 performed on the Cobra cluster of the MPCDF facility and on the Jean Zay CSL cluster (IDRIS,
687 Orsay, France) under project number i2015047370. The authors acknowledge funding by the Eu-
688 ropean Research Council under the European Union’s Horizon 2020 research and innovation pro-
689 gram through Grant No. 681835-FLUDYCO-ERC-2015-CoG.

Figure 1. Schematic of the problem studied. A stratified layer occupies the top half of the outer core and lies on top of a vigorously convective region. Reynolds stress in the convective zone excites waves that propagate in the stratified layer. As these waves propagate upwards, they are gradually attenuated. The constructive interactions of propagating waves and their reflections on the top boundary excite and maintain standing modes of various length scales and frequencies, that resonate in the entire cavity defined by the stratified layer. When the damping term in equation (2) is added, the reflection of propagating waves and hence the formation of standing modes is prevented. N denotes the Brunt-Väisälä frequency, as defined in equation (14). Temperatures and radii are indicated in non dimensional units. Although the cartoon is in 2D and shows only a fraction of the sphere, our simulations run in a full 3D spherical shell.

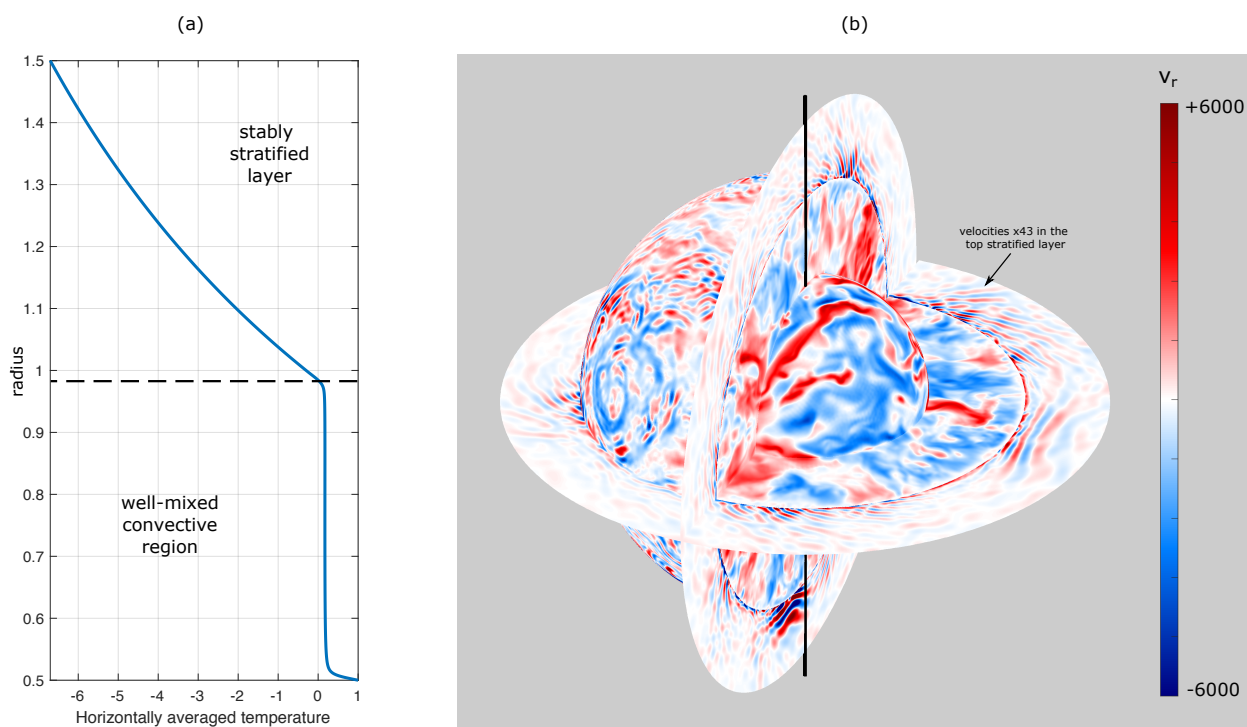

Figure 2. (a): Radial profile of the horizontally averaged temperature for simulation P1. In the well-mixed convective region, at $r \lesssim 1$, the temperature is almost constant while a conductive temperature profile exists in the stratified layer above. The horizontal dashed line corresponds to the radius where $\langle \bar{T} \rangle = 0$ and marks the approximate position of the interface. (b): Snapshot showing the radial velocity field for simulation P1. Velocities in the stratified region have been multiplied by a factor 43, so that they can be visualised together with the velocities in the convective region using the same colorbar. The apparent discontinuity is a result of this color scale adjustment but all numerical variables are continuous. The position of the interface is defined as the radius where the time and angle-averaged temperature $\langle \bar{T} \rangle$ equals the inversion temperature, *i.e.* $\langle \bar{T} \rangle = 0$ in non-dimensional units. See also the corresponding movie attached or at <https://youtu.be/qbPV81I8nkw>.

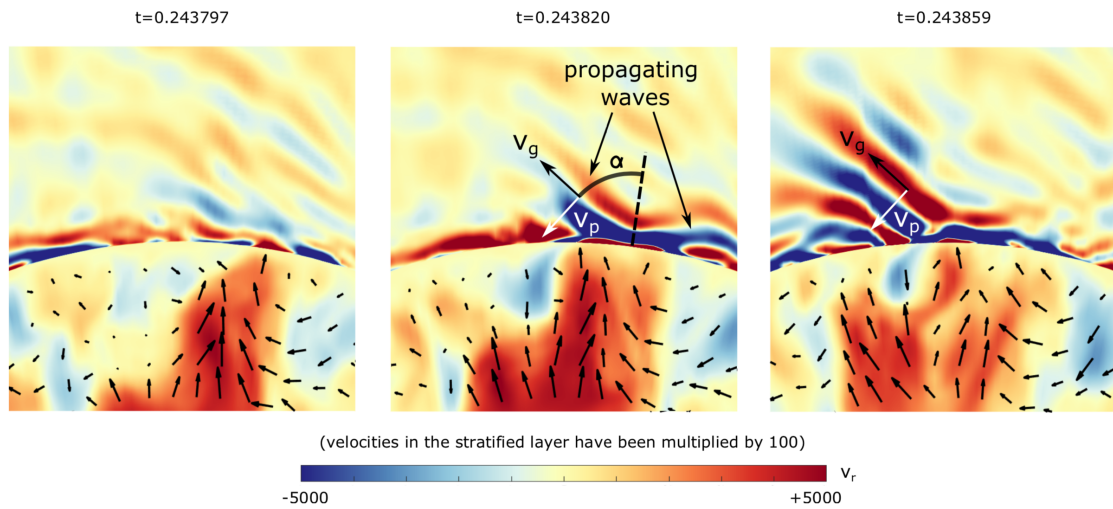

Figure 3. Snapshots of the radial velocity field for simulation P1 at three consecutive times showing a plume impact on the interface with the stratified layer. In a plane containing the impact point, the shape formed by the waves is sometimes referred to as a “half St Andrew’s cross” (Mowbray & Rarity, 1967). v_p and v_g denote the phase and group velocities, respectively. Their directions are indicated by arrows. The phase velocity is perpendicular to the group velocity. The energy transport rate and direction is given by the group velocity, at an angle α from the radial direction and oriented away from the convective region. Velocities in the stratified region have been multiplied by a factor 100 for a clearer visualisation. The position of the interface is defined as the radius where the angle-averaged temperature $\langle \bar{T} \rangle (r)$ equals the inversion temperature, *i.e.* $\langle \bar{T} \rangle = 0$ in non-dimensional units. In the convecting region, arrows show the direction and magnitude of the velocity in the plane of the figure.

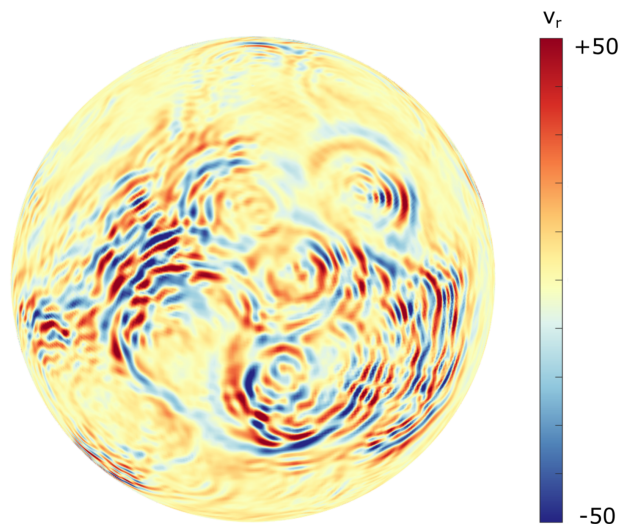

Figure 4. Snapshot of the radial velocity field in the stratified layer at $r = 1.066$ for simulation P1. Each concentric structure is the trace of a plume impact that occurred earlier on the interface underneath at $r \approx 1$.

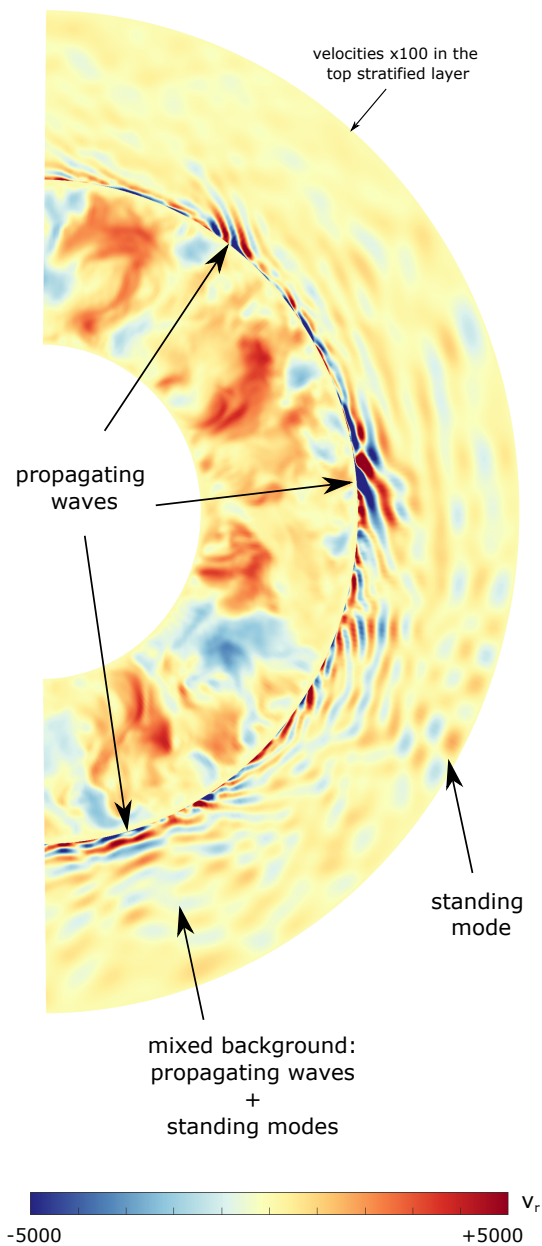

Figure 5. Snapshot of the radial velocity field for simulation P1. Velocities in the stratified region have been multiplied by a factor 100 for a clearer visualisation. The red and blue colors indicate positive and negative signs of the radial velocity, respectively. Propagating waves are excited at the interface with the convective region by Reynolds stresses. These waves propagate in the shell and can reflect on the outer boundary. The interaction of propagating waves with their reflections can lead to multiple standing modes that resonate in the entire cavity formed by the stratified layer. Even though numerous modes are superimposed and can hardly be distinguished individually, one specific mode sometimes dominates locally, revealing itself as a checkerboard pattern like the one pointed by the arrow on the right.

Figure 6. Kinetic energy spectra for simulation P1 in (ℓ, ω) space as defined by equation (24), at different radii, one in the convective region (panel a) and the three others in the stratified layer, with increasing distance from the interface located at $r \approx 1$ (panels b to d). The horizontal dashed lines denote the value of the horizontal mean Brunt-Väisälä frequency at the corresponding radius. The plain lines correspond to iso-values of the attenuation depth λ_{eff} (see equation (31)), $\lambda_{\text{eff}} = 0.02$ and $\lambda_{\text{eff}} = 0.07$. The dashed-dotted line corresponds to the $\lambda_{\text{eff}} = 0.2$ line and approximately separates propagating waves (below the line) and modes (above the line). The colorbars are in logarithmic scale and span several orders of magnitude. The colorscale has been cut at a lower bound to focus on the most energetic signals. The three colorbars in panels (b), (c) and (d) are identical while panel (a) focuses on much larger amplitudes, characteristic of the convective region.

Figure 7. Ratio of the frequency spectra E^r/E^\perp , at $r = 1.318$, averaged between $\ell = 1$ and $\ell = 140$. $\omega^* = \omega/N$ is the frequency normalized by the Brunt-Väisälä frequency. The red curve shows the law (25) (see main text), which is valid only in the GW region. The curve matches the spectrum in the waves region, close to $\omega = N$ and below. The mismatch at lower frequencies indicates that the low-frequency part does not contain only linear GW.

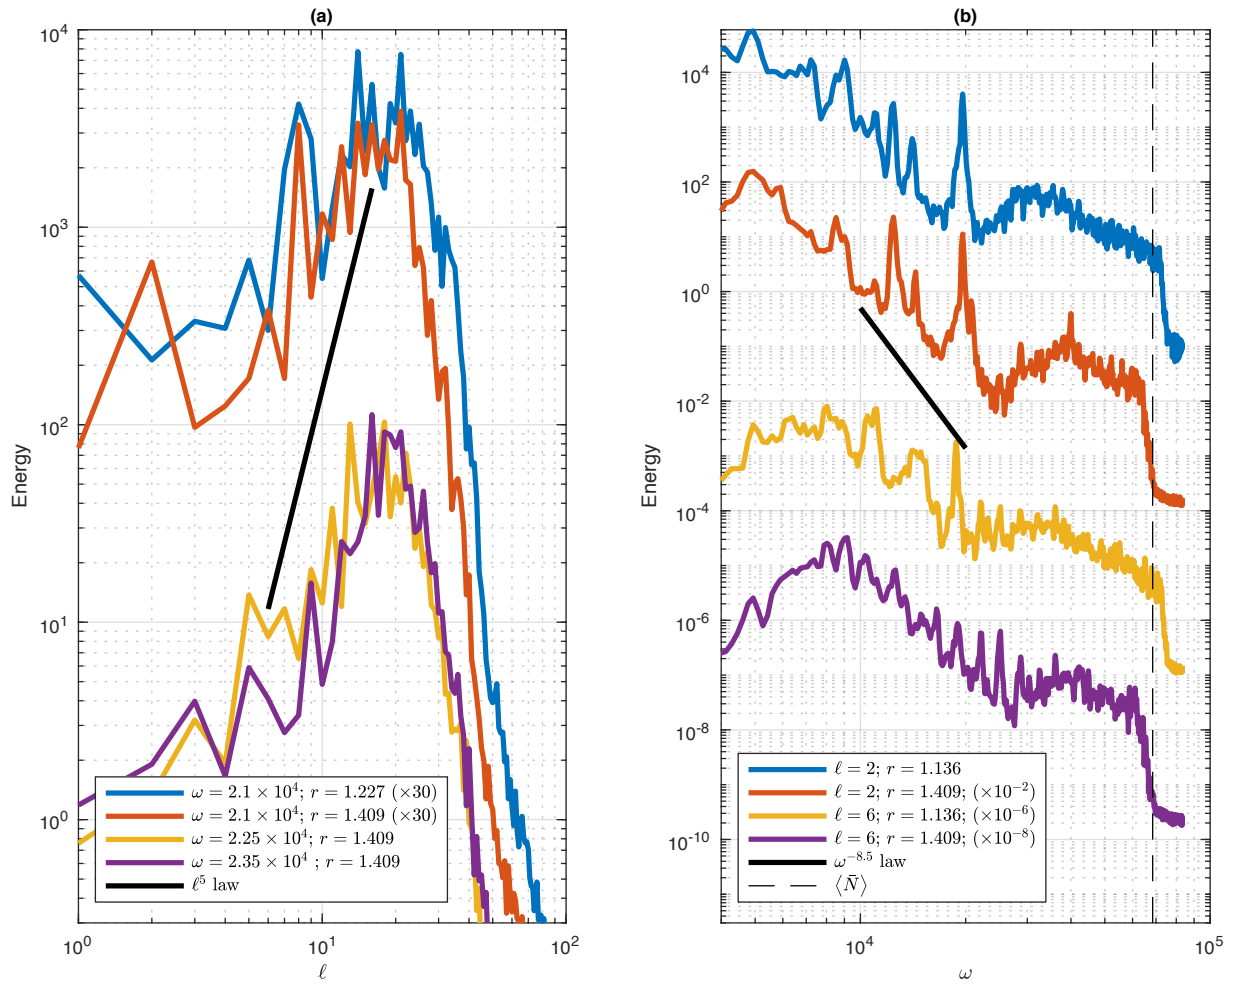

Figure 8. (a): ℓ spectra at two radii and for two fixed frequencies. (b): ω spectra for two radii and two fixed values of ℓ . The vertical dashed line corresponds to $\omega = \bar{N}$. Two of the spectra in (a) and three of the spectra in (b) have been shifted upwards/downwards to better visualize the modes (the spikes that superimpose to the global drop in kinetic energy) and to compare slopes of the different spectra. The black lines indicate the slopes of the power laws predicted by the theory of Lecoanet & Quataert (2013).

Figure 9. (ℓ, ω) spectra at $r = 1.136$ for simulation P1 ($S = 30$, left panel) and simulation P1_S100 ($S = 100$, right panel). Note that the colorbars are the same for both subfigures and span several orders of magnitude.

Figure 10. Kinetic energy spectra in (ℓ, ω) space as defined by equation (24) at $r = 1.136$. a: simulation P1 (without damping term). b: simulation P1d (with damping). Note that the colorbars span several orders of magnitude and are in logarithmic scale.

Figure 11. (ℓ, ω) spectra at $r = 1.318$ for simulations P03 ($Pr = 0.3$), P1 ($Pr = 1$) and P3 ($Pr = 3$). The horizontal dashed lines indicate the Brunt-Väisälä frequency at the radius considered.

Figure 12. (a): radial profile of the kinetic energy. The dashed line shows the law in equation (39) with a prefactor $A = 8 \times 10^{10}$. The inserted subfigure shows the behavior with the distance to the interface radius ($r_{\text{int}} = 0.97$) in log-log scale. (b): ℓ -spectra of the kinetic energy in the convective region ($r \leq r_{\text{int}} - 0.025$) and in the stratified layer ($r \geq r_{\text{int}} + 0.025$), for simulation P1. To allow for a better comparison, the spectrum in the stratified layer has been renormalized by a factor $E_{\text{conv}}(\ell = 1)/E(\ell = 1) = 89.3$.

Figure 13. Kinetic energy transmission factor between the convective region at $r = 0.863$ and the stratified layer at different radii.

Figure 14. Order of magnitude of the change in the Stokes coefficients for the first spherical harmonics degrees and for two different values of N spanning the range proposed in the literature. The dashed line indicates approximately the sensitivity limit of present-day gravimeters, about 1 nGal (Rosat & Hinderer, 2018).
